Abstract

This work studies the influence of using hydrodynamic conditions (Reynolds number, $Re = 0$ to $Re = 600$) during Ti anodization and Li^+ intercalation on anatase TiO_2 nanotubes. The synthesized photocatalysts were characterized by using Field Emission Scanning Electron Microscope (FE-SEM), Raman Confocal Laser Microscopy, Electrochemical Impedance Spectroscopy (EIS), Mott-Schottky analysis (M-S), photoelectrochemical hydrogen production and resistance to photocorrosion tests. The obtained results showed that the conductivity of the NTs increases with Li^+ intercalation and Re . The latter is due to the fact that the hydrodynamic conditions eliminate part of the initiation layer formed over the tube-tops, which is related to an increase of the photocurrent in the photoelectrochemical water splitting. Besides, the photogenerated electron-hole pairs are facilitated by Li^+ intercalation. Finally, this work confirms that there is a synergistic effect between Re and Li^+ intercalation.

Keywords: TiO_2 nanotubes; hydrodynamic conditions; water splitting; electrochemical impedance spectroscopy (EIS); Mott-Schottky analysis.

1. Introduction

In recent years, nanotube (NT) arrays based on transition-metal oxides are gaining interest in a wide field of applications, such as in dye-sensitized solar cells [1, 2], photocatalysis [3-7] and biomedicine [8]. Among all transition-metal oxides, TiO₂ is the most extensively studied material due to its unique properties. Especially, in photocatalytic reactions, TiO₂ is used as a photocatalyst due to its high stability and semiconductor abilities capable of generating charge by absorbing energy [9-13]. Besides, its suitable band-edge positions make possible the photoelectrochemical water splitting [14] (using solar energy) into H₂ and O₂ to generate hydrogen, the potential fuel of the future.

In order to achieve a high surface area and consequently, to enhance the photocatalytic activity, TiO₂ is synthesized in the form of nanotube arrays [15]. Nowadays, TiO₂ nanotubes are synthesized by several methods, including sol-gel transcription [16, 17], hydrothermal processes [18, 19] and anodization of titanium in fluoride-based electrolytes [20, 21]. The latter is the most promising because it allows obtaining highly ordered nanotube arrays, and their dimensions (length, diameter, and tube wall) can be precisely controlled [22].

In order to carry out the anodization two types of electrolytes can be used: aqueous-based or organic-based. Organic electrolytes are the most used because these electrolytes result in highly ordered longer tubes [23, 24]. Nevertheless, the nanotubes formed in organic electrolytes show an “initiation layer” over the tube tops, which blocks the nanotube arrays and therefore the solar energy absorption is reduced [22, 25].

Nowadays, several methods are investigated to remove this “initiation layer”, such as mild sonication [23] and hydrodynamic conditions applied during anodization with a rotating electrode configuration [22]. The latter has the advantage of removing the “initiation layer” in the same process of anodization and, therefore, other independent processes in order to remove this layer are not needed. Moreover, the use of hydrodynamic conditions can significantly affect on the final TiO₂ nanotube geometry [22, 26, 27]. After anodization, an amorphous structure is obtained which implies the presence of a high number of defects. These defects act as recombination centers and a thermal treatment is required in order to convert the amorphous structure into a crystalline one [28].

On the other hand, the efficiency of TiO₂ nanotubes is limited by its wide intrinsic band gap of ≈ 3.2 eV for TiO₂ in anatase phase [29, 30]. Thus, the usable fraction of the solar spectrum which can be exploited is only 5% [31]. In this way, the process of inserting impurities in the TiO₂ NTs is widely used for the purpose of modulating their electrical properties (doping), thus, the efficiency of TiO₂ NTs might be increased. Recently, several works [28, 32, 33] studied the Li⁺ cation insertion into TiO₂ lattice and they obtained a drastic change in electronic properties, such as a highly increase in the conductivity of TiO₂ [32, 33]. However, these studies were made in static electrolyte and the influence of hydrodynamic conditions during the anodization process was not evaluated.

In this work, we investigate the synergistic effect between Reynolds number (Re) and Li⁺ cation insertion in the TiO₂ lattice in order to optimize the photoelectrochemical water splitting for hydrogen production. To characterize the nanostructures, different

microscopy techniques have been used: Field Emission Scanning Electron Microscope (FE-SEM) and Raman Confocal Laser Microscopy. Additionally electrochemical techniques: Electrochemical Impedance Spectroscopy (EIS) and Mott-Schottky technique (M-S), as well as photoelectrochemical techniques have been also used.

2. Experimental procedure

Anodization was carried out using Teflon coated titanium rod (8 mm in diameter, 99.3 % purity) as the working electrode, i.e. 0.5 cm² were exposed to the electrolyte. On the other hand, a platinum mesh was used as the counter electrode. Prior to anodization, titanium surface was abraded with 220 to 4000 silicon carbide (SiC) papers and degreased by sonication in ethanol for 2 minutes. The samples were then mounted in a rotating electrode to perform the anodization under hydrodynamic conditions using a voltage source. Different Reynolds numbers were used: 0, 200, 400 and 600, which correspond to 0, 1728, 3456 and 5185 rpm. Anodization was performed in ethylene glycol, 1M H₂O and 0.05M NH₄F electrolytes at 55 V during 30 minutes. Current density during anodization was measured versus time. After each test, the titanium rod was sliced to characterize the morphology of the obtained nanostructures by using Field Emission Scanning Electron Microscopy (FE-SEM). In order to transform amorphous TiO₂ to an anatase phase structure, the anodized samples were annealed at 450 °C for 1 hour. The crystalline microstructure of TiO₂ was examined by means of a Raman Confocal Laser microscopy. For these measurements, a 632 nm neon laser with 420 μW was used.

In order to add Li^+ to the obtained nanostructures (doped-nanostructures), samples were immersed in an 1M LiClO_4 solution, applying $-1.5 \text{ V}_{\text{Ag}/\text{AgCl}}$ during 3 seconds. In this way, Ti^{+4} was reduced to Ti^{+3} and, at the same time, Li^+ was intercalated into the TiO_2 lattice. In order to perform the Li^+ intercalation, a three electrode electrochemical cell was used. The TiO_2 NTs after annealing served as the working electrode, while a Ag/AgCl (3 M KCl) electrode was the reference electrode, and a platinum tip was the counter electrode.

For the electrochemical and photoelectrochemical water splitting tests, an electrochemical cell with the same electrodes and electrode configuration than the used for doping the samples, was employed. The area of the TiO_2 nanostructures (working electrode) exposed to the test solution was 0.13 cm^2 . The electrochemical measurements were conducted in a 0.1 M Na_2SO_4 solution using an Autolab PGSTAT302N potentiostat under dark conditions (without irradiation). EIS experiments were conducted at the open circuit potential (OCP) over a frequency range from 100 kHz to 10 mHz with a 10 mV (peak to peak) signal amplitude. Mott–Schottky plots were subsequently obtained by sweeping the potential from the OCP in the negative direction at 10 mV s^{-1} with an amplitude signal of 10 mV at a frequency value of 10 kHz.

The photoelectrochemical experiments were carried out under simulated sunlight condition AM 1.5 (100 mW cm^2) in a 1M KOH solution. Photocurrent vs. voltage characteristics were recorded by scanning the potential from $-0.8 \text{ V}_{\text{Ag}/\text{AgCl}}$ to $+0.55 \text{ V}_{\text{Ag}/\text{AgCl}}$ with a scan rate of 2 mV s^{-1} . Photocurrent transients as a function of the applied potential were recorded by chopped light irradiation (60 s in the dark and 20 s in

1 the light). Samples were left at $+0.55 \text{ V}_{\text{Ag}/\text{AgCl}}$ in the light for one hour, in order to
2 evaluate their stability against photocorrosion.

8 *3.1. Current density transients during anodization*

9
10
11
12
13
14 The growth of the TiO_2 nanotubes was monitored by recording the current density
15 during anodization. **Figure 1** shows that all the samples present three stages. Firstly, in
16 stage I, current density decreases because a compact oxide layer (TiO_2) is formed on
17 titanium [25, 34]. Then, in the second stage (stage II), current density increases due to
18 the fact that fluoride ions present in the electrolyte attack the formed TiO_2 layer, which
19 results in water-soluble $[\text{TiF}_6]^{2-}$ species. Thus, the current density increases as the
20 reactive area also increases [25, 35]. Finally, in the third stage (stage III), current
21 density remains almost constant due to the formation and growth of regular nanotubes
22 [25, 26].

36
37
38

39 The slope corresponding to stage II is different depending on the Reynolds number.
40 **Figure 1** shows that the curves of anodization under hydrodynamic conditions show a
41 higher positive slope in stage II compared to the one obtained at $\text{Re} = 0$. This confirms
42 that diffusion process is favoured due to hydrodynamic conditions. Moreover, since the
43 slope corresponding to stage II increases until $\text{Re} 400$ and it remains almost constant for
44 $\text{Re} 600$, it can be said that hydrodynamic conditions favour the fluoride ions diffusion
45 until $\text{Re} 400$ (the highest increase being obtained between $\text{Re} 0$ and $\text{Re} 200$).

3.2. Field Emission Scanning Electron Microscopy (FE-SEM)

Figures 2, 3 and 4 show the morphology of the samples obtained by electrochemical anodization of TiO₂ under static and hydrodynamic conditions by using a FE-SEM microscope. A porous TiO₂ layer can be observed over the nanotubes, i.e. an initiation layer (**Figures 2a and 2b**). This initiation layer blocks the nanotubes preventing part of the solar radiation from being absorbed at the photoelectrode. **Figure 2b** clearly shows the top of the tubes in delimited areas since parts of the initiation layer was removed. Besides, hydrodynamic conditions applied during anodization mainly affect on three parameters related to the morphology of the nanostructures: the length of the nanotubes, the initiation layer and the thickness of the nanotubes. **Figure 2c** shows that self-organized TiO₂ nanotubes were formed. On the other hand, variations on the morphology after Li⁺ intercalation were not observed (not shown in **Figure 2**).

Figure 2d shows the influence of Reynolds number on the length of the nanotubes. The length is higher as the Reynolds number increases. This effect involves an increase of the surface area available for the photocatalytic reactions.

Figure 3 shows the top view of the nanostructures using FE-SEM. It is important to point out that in **Figure 3a** (Re=0) there is a continuous initiation layer, however, this layer begins to detach in certain delimited areas as hydrodynamic conditions increase (**Figure 3b, 3c and 3d**, corresponding to Re from 200 to 600).

On the other hand, **Figure 4** shows that in those areas where the initiation layer is still attached, an increase in the average diameter of the porous presented in the initiation layer is observed when hydrodynamic conditions are applied in relation to static

1 conditions (**Figure 4a, 4b and 4c**). Therefore, the entrances of the real tubes become
2 more accessible. Finally, **Figure 4d** shows a decrease of the thickness of TiO₂
3
4 nanotubes as hydrodynamic conditions increase, which might reduce the electron-hole
5
6 recombination process.
7
8
9

10 11 *3.3. Raman Confocal Laser Microscopy*

12
13
14
15
16 Evaluation of the crystallinity of the as-prepared and annealed (doped and undoped)
17
18 TiO₂ nanotubes was carried out by means of Raman Confocal Laser Microscopy.
19
20 **Figure 5** shows, as an example, the Raman Spectra of the as prepared, undoped and
21
22 doped nanotubes anodized at Re 600, since no differences were found in the Raman
23
24 Spectra regardless of the Re used during anodization.
25
26
27
28
29
30

31
32 The crystallinity of the TiO₂ nanotubes is evaluated according to the peaks presented in
33
34 the Raman spectra. Anatase phase shows four peaks in the spectra at roughly 141.7,
35
36 396.2, 515.1 and 639.3 cm⁻¹ [36-38]. In **Figure 5** it can be observed that the as-prepared
37
38 TiO₂ nanotubes are characterized by a spectra without peaks, which is in agreement
39
40 with an amorphous phase. However, annealed (doped and undoped) TiO₂ nanotubes
41
42 present four characteristics peaks, which correspond to the peaks of the anatase phase.
43
44 This confirms that annealing at 450 °C for 1 hour, generates TiO₂ nanotubes with
45
46 anatase phase. Moreover, the peaks obtained for the annealed, both undoped and doped
47
48 NTs, are almost the same. Therefore, it can be concluded that there are no significant
49
50 variations on the crystalline structure after Li⁺ intercalation.

3.4. EIS measurements

EIS measurements were performed at open circuit potential (OCP) in order to study the changes caused by the hydrodynamic conditions applied during anodization and the Li⁺ cation intercalation. **Figure 6** shows the Nyquist (**Figure 6a**), Bode-phase (**Figure 6b**) and Bode-modulus (**Figure 6c**) plots.

From **Figure 6a**, it is possible to discern that undoped TiO₂ NTs have higher impedance values than the doped TiO₂ NTs. Besides, among the undoped samples, TiO₂ NTs synthesized at Re 0 possess the highest impedance. Bode-phase plots, (**Figure 6b**), show two unfinished semicircles for the samples anodized at Re 0, Re 200 and Re 400 without Li⁺ intercalation, which correspond to the presence of two time constants. However, for the nanotubes synthesized at Re 600 without Li⁺ and for all the doped samples, the Bode-phase plots show only one semicircle due to the superposition of the two time constants. The two time constants can be attributed to the formation of the nanotubular layer on top of the compact TiO₂ layer [39, 40]. On the other hand, Bode-modulus plots in **Figure 6c** show a decrease of impedance modulus as hydrodynamic conditions increase at low and intermediate frequencies. Moreover, Li⁺ insertion also involves a decrease in the impedance modulus for the same frequency range. Additionally, the impedance at high frequencies in Bode plots corresponds to the resistance of the electrolyte which possesses similar values regardless the Reynolds number and the doping conditions.

EIS experimental data were fitted to an electrical equivalent circuit. The electrical equivalent circuit proposed is shown in **Figure 6d** and it is formed by a resistive

1 element (R_s), corresponding to the electrolyte resistance, and two groups of resistances
 2 and constant phase elements (R-CPE), corresponding to the nanotubular layer (R_1 -
 3 CPE₁) and the compact TiO₂ layer (R_2 -CPE₂) [15, 40]. This electrical equivalent circuit
 4 has been already used by other authors. Constant phase elements (CPEs) have been used
 5 instead of pure capacitors to account for frequency dispersion and non-ideality. Then,
 6 CPEs have been converted into pure capacitances (C) by using the following equation
 7 [41, 42]:

$$16 \quad C = \frac{(Q \cdot R)^{1/\alpha}}{R} \quad (1)$$

17 where Q is the impedance of the CPE and R corresponds to R_2 when **eq 1** is used to
 18 calculate C_2 . However, in order to determine C_1 , R is calculated according to **eq 2**.

$$19 \quad \frac{1}{R} = \frac{1}{R_s} + \frac{1}{R_1} \quad (2)$$

20 **Table 1** shows the values of the different parameters which characterize the electrical
 21 equivalent circuit. R_s has similar values for all the studied conditions (between 32-42
 22 Ω), since the resistance of the electrolyte remains almost constant. Besides, R_2 is higher
 23 than R_1 regardless of the hydrodynamic and doping conditions because the nanotubular
 24 layer has higher surface area than the compact TiO₂ layer, i.e., the nanotubes possess a
 25 higher conductivity. On the other hand, the CPE constant, α , lies between -1 (pure
 26 inductance) and +1 (pure capacitor) [43]. In this work the α values are between 0.5 and
 27 1 which are in agreement with a non-ideal capacitive behavior. **Table 1** shows that α_1
 28 takes values lower than α_2 for all the nanostructures. This confirms that the TiO₂
 29 nanotubes layer is more heterogeneous in comparison to the compact TiO₂ layer, the
 30 latter having a behavior similar to an ideal capacitor.

Table 1 also shows that R_1 decreases as Reynolds number increases for the undoped and doped nanotubes, indicating that TiO_2 NTs formed at higher hydrodynamic conditions possess higher conductivities than nanotubes formed at $\text{Re} = 0$. Moreover, C_2 values increase as the Reynolds number increases (regardless the doping conditions), indicating that the thickness of the compact TiO_2 layer decreases, which can be interpreted as a transition from a mostly compact layer to a nanotubular one [40]. Concerning the influence of Li^+ insertion, it can be observed that R_1 decreases significantly when the TiO_2 nanotubes are doped. This fact can be explained by a higher number of controlled defects due to Li^+ intercalation and, therefore, the conductivity is favored.

3.5 Mott-Schottky analysis

The Mott-Schottky analysis is a common tool used for the characterization of the electrochemical capacitance of the semiconductor/electrolyte interface as a function of the applied potential [44]. The Mott-Scottky equation predicts a linear relationship of C_{SC}^{-2} with the applied potential (U), as described by the following equation for an n-type semiconductor [40, 45-47]:

$$\frac{1}{C_{SC}^2} = \left(\frac{2}{e \cdot \varepsilon_0 \cdot \varepsilon_r \cdot N_D} \right) \cdot \left(U - U_{FB} - \frac{k \cdot T}{e} \right) \quad (3)$$

where N_D is the donor density, ε_0 ($8.85 \cdot 10^{-14}$ F/cm) the vacuum permittivity, ε_r the dielectric constant, e the electron charge ($1.60 \cdot 10^{-19}$ C), U_{FB} the flatband potential, k the Boltzmann constant ($1.38 \cdot 10^{-23}$ J/K) and T is the absolute temperature. The dielectric constant varies depending on the Li^+ intercalation, this parameter takes values of 100 for the undoped TiO_2 NTs [48, 49] and a value of 500 is assumed for doped TiO_2

NTs [31]. In fact, Van de Krol claimed that the increase in the dielectric constant may be originated by an increase in the polarizability of the TiO_2 from the intercalated Li^+ cations [45].

Figure 7 shows the Mott-Schottky plots for the undoped and doped TiO_2 nanotubes anodized from Re 0 to Re 600. The results given in **Figure 7** were obtained at the frequency of 10 kHz in dark conditions, since at this high frequency value the capacitances do not depend on the frequency [50, 51]. **Figure 7** shows that the capacitance values are higher for the doped TiO_2 NTs (lower values of C_{SC}^{-2}). In this way, a magnification of the Mott-shottky doped plots have been performed as an inset in **Figure 7**, in order to show the straight lines presented in the doped samples.

Table 2 shows the donor densities determined from the positive slopes of the straight lines in the Mott-Schottky plots using **eq 3**. It can be observed that the donor density notably increases for the doped samples (two orders of magnitude) compared to the undoped ones. The increase in the donor density might be associated with an increase in the number of defects present in the TiO_2 nanotubes due to the Li^+ intercalation. Thus, these defects improve the charge transfer along **the** nanotubes (this is in agreement with the results obtained by means of EIS, **Table 1**). Concerning to the influence of hydrodynamic conditions, it is possible to observe that the donor density increases, to some extent, as Reynolds number also increases for the undoped samples. This fact indicates that, although the morphology of the TiO_2 nanostructures did not change with Re (i.e, nanotubes were formed in all cases), a higher number of oxygen vacancies and/or Ti^{3+} interstitials were introduced within the TiO_2 NTs structure when anodizing under hydrodynamic conditions. On the other hand, the influence of hydrodynamic

1 conditions in the donor density for the doped samples is not clear (N_D varies between 1
2 and $4 \times 10^{21} \cdot \text{cm}^{-3}$). This might be due to the high influence of the Li^+ insertion that
3 hinders the influence of hydrodynamic conditions.
4
5
6

7
8
9 On the other hand, **Table 2** also shows the U_{FB} values obtained from the intercept of
10 the straight line with the potential axis. The flatband potential is the potential that needs
11 to be applied to the semiconductor to reduce the band bending to zero. Additionally, this
12 electrochemical parameter is related to the potential drop at the depletion space charge
13 layer (U_{SC}) and the applied external potential (U) [15], according to **eq 4**.
14
15
16
17
18
19
20
21

$$22 \quad U_{SC} = U - U_{FB} \quad (4)$$

23
24 where U_{SC} is the driving force to separate the photogenerated electron-hole pairs
25 (charge separation). Thus, according to **eq 4**, in order to favor the charge separation, the
26 flatband potential should be high and negative. **Table 2** shows that flatband potential is
27 more negative for the doped TiO_2 NTs than for the undoped ones, which indicates that
28 the charge separation is favored by Li^+ intercalation.

40 *3.6. Photocurrent measurements*

41
42
43
44 **Figure 8a** shows the photoelectrochemical water splitting tests carried out under
45 simulated sunlight AM 1.5 conditions for the different samples. Regardless of the
46 doping condition, photocurrent densities increase with Reynolds number. This is in
47 agreement with the EIS and M-S measurements (lower R_1 values and higher N_D for
48 higher R_e) and FE-SEM images. The high photocurrent densities obtained for the
49 nanostructures anodized at higher Reynolds numbers are related to an increase in the
50 conductivity of the NTs, due to a higher density of defects within their structure, which
51
52
53
54
55
56
57

59
60
61
62
63
64
65

1 favors the current flow [15, 52]. These high photocurrent densities obtained for samples
2 anodized under hydrodynamic conditions are also directly related to an increase in the
3 active area of the nanotubes exposed to the electrolyte with increasing Re . As shown in
4 the FESEM images (**Figures 2, 3 and 4**), hydrodynamic conditions during anodization
5 resulted in longer nanotubes lengths and larger diameters of the nanoporous initiation
6 layer, as well as in a partial removal of the nanoporous initiation layer. **It is important to**
7 **point out that the partial removal of the initiation layer at higher Re contributes to an**
8 **increase in the photocurrent densities in the water splitting tests. This fact is observed in**
9 **Figure 8b, where the photoresponse of TiO_2 NTs of the same length ($\sim 6.2 \mu m$), but**
10 **anodized at different Re , are compared. The only difference between both samples is**
11 **that the initiation layer of the sample synthesized at $Re = 600$ was partially removed**
12 **during the anodization process.** Therefore, photocurrent densities increased with
13 increasing Re due to the higher active area of the nanotubes in contact with the
14 electrolyte and due to a slightly increase in the number of defects (**Table 2**). On the
15 other hand, photocurrent densities for Li^+ doped nanotubes are significantly higher than
16 the values obtained for the undoped samples, which can be ascribed to their higher
17 number of defects and flatband potentials (in absolute value) (**Table 2**). Therefore, there
18 is a better charge transfer and transport in the doped nanotubes.

19 Additionally, **Figure 8a** shows that the photocurrents under illumination increase with
20 the applied potential. According to **eq 4**, the potential drop at the depletion space charge
21 layer increases when the potential applied is higher, thus, the charge separation is
22 favored. Moreover, the photocurrent density increases with the applied potential until a
23 potential value of $-0.3 V$ for the undoped TiO_2 NTs, whereas the photocurrent increases
24 in the entire range of potential, for the doped TiO_2 NTs. This means that the undoped

TiO₂ NTs are saturated more easily by means of the potential applied in comparison to the doped TiO₂ NTs.

On the other hand, in order to evaluate the stability of the NTs against photocorrosion they were tested under AM 1.5 illumination at 0.55 V_{Ag/AgCl} during 1 hour. **Figure 8c** shows that the formed NTs were stable since the photocurrents generated in the process of water splitting were constant during the tests.

The synergistic effect between hydrodynamic conditions and Li⁺ intercalation was studied using the photocurrent densities. **Figure 8d** shows that the combined effect (Re + Doping) is higher than the sum of the individual effects obtained at 0.55 V_{Ag/AgCl}. This synergistic effect between the hydrodynamic conditions and the Li⁺ doping arises from the higher active areas of the samples anodized at Re > 0 (as shown in **Figures 2, 3 and 4**), thus enhancing the intercalation of Li⁺ into the TiO₂ nanotubes structure.

4. Conclusions

This work studied the influence of hydrodynamic conditions applied during anodization, as well as the Li⁺ intercalation into TiO₂ lattice in order to increase the photocurrent response in the photoelectrochemical water splitting.

The FE-SEM images show that the influence of hydrodynamic conditions results in an elimination of part of the initiation layer and in an increase of the length of the NTs. These facts involve a higher photocurrent density as Reynolds number increases.

1 On the other hand, Raman Confocal Laser Microscopy revealed that TiO₂ nanotubes in
2 anatase phase were obtained after annealing at 450°C during 1 hour. Besides, the Li⁺
3
4 intercalation does not lead to significant variations on the crystalline structure.
5
6
7

8
9 EIS measurements showed that the resistance of the undoped NTs decreases with Re.
10
11 On the other hand, concerning the Li⁺ insertion, the resistance of the doped TiO₂
12
13 nanotubes decreases due to a higher number of defects, which was confirmed in the M-
14
15 S analysis. Besides, M-S analysis showed an increase in the flatband potential (in
16
17 absolute value) for the doped samples, therefore the photogenerated electron-hole pairs
18
19 are favored. These results explain the higher photocurrent obtained for the doped
20
21 samples in the photoelectrochemical water splitting.
22
23
24
25
26
27

28
29 The synthesized TiO₂ nanotubes were stable in the test electrolyte under illumination.
30
31
32

33
34 A synergistic effect between the hydrodynamic conditions and Li⁺ was found to arise
35
36 from the higher active areas of the samples anodized at Re > 0, thus enhancing the
37
38 intercalation of Li⁺ into the TiO₂ nanotubes structure.
