13. ABSTRACT *(maximum 200 words)*

In Server and Agent Based Active Network Management (SAAM) architecture, a server will make routing and other important decisions on behalf of the routers in its region. In order to make the right decisions and to support QoS (e.g., IntServ and DiffServ), the SAAM server needs to maintain an accurate region-wide view of network performance. This will be achieved as routers periodically send Link State Advertisement (LSA) messages to the SAAM server. Currently, the LSA messages report two key Link Performance Statistics, the average delay and the loss rate experienced by packets. Moreover, the server needs to perform sanity checks of these statistics by probing specific links. This thesis describes a server probing solution in which the SAAM server probes a router by dynamically injecting customized probing programs into the adjacent routers. In other words, the probing will be done with the active networking approach. An important feature of the server probing solution is that the probing activities cannot be detected by the router being probed.

ACKNOWLEDGEMENTS

I would like to thank Dr. Geoffrey Xie for his assistance in my research. His guidance, support, knowledge and enthusiasm helped me to carry this thesis to completion. His efforts to provide and access resources for my study were invaluable. I would also like to thank my second reader, James Bret Michael, for his support.

I express my deepest gratitude to my family, whose love and patience have been a constant inspiration to me throughout my two years of study at the Naval Postgraduate School.

I. INTRODUCTION

A. THE INTERNET

The Internet dates back to the late 60's, that started as a project named "ARPANET." Mainly experimental, ARPANET was used for academic research purposes, and one of its main goals was to tolerate link failures. The Transmission Control Protocol/Internet Protocol (TCP/IP) suite was developed for this purpose, and was accepted as the standard protocol for the ARPANET.

The network that began as ARPANET has become the global network what we know as the "Internet." Nobody can precisely estimate the number of hosts or users connected to the Internet today, because no central authority exists that controls the entire network. However, there is no doubt that the Internet is growing at an explosive rate. In 1983, approximately 500 hosts were connected to the network. This number expanded to over 300,000 hosts in 1990, and to over 5 million in 1995.

The use of the Internet has also changed since the early days. Five to seven years ago, the Internet was mainly used for file transfer, e-mail, and access to the World Wide Web. Nowadays the transmission of voice and video are prevalent on the Internet. These types of data require certain Quality of Service (QoS) from the network.

The increase in volume and diversity of the network traffic raises new challenges for network management. In order to support applications as diverse as teleconferencing, video-on-demand, e-commerce and distributed computing, the resource management of the Internet needs to be improved.

B. QUALITY OF SERVICE

1. Voice and Video Requirements Over IP

Transmitting audio or video over a network requires more QoS guarantees from the network than just sufficient bandwidth. These types of applications are sensitive to timeliness of data; and hence we call such applications "real-time applications." Real-time applications need a guarantee from the network that their data will arrive on time and smoothly.

For example, to support high quality audio conferencing, the network needs to provide a low-latency and low-jitter service. Latency measures the time for a packet to travel from source to destination, and jitter measures the variation in latency for a set of packets. On the other hand non-real-time applications just need to make sure that their data arrives correctly. In this situation, a "best-effort" type of delivery in which the network just tries its best to deliver the packets but doesn't give any guarantee is sufficient.

One might think that more bandwidth would meet the requirements of voice and video. Improving the infrastructure of the Internet with fiber optic data links is one aspect of providing more bandwidth. However, in the short term, this solution would be neither feasible nor cheap. Applications are becoming more bandwidth-hungry, and that is true now and will remain true for the future. Better network management software for the Internet QoS capabilities, that would not require major change in the infrastructure is

essential. The new system should also be backward compatible, meaning that the system should support the best-effort delivery.

2. IETF Proposals

There is a great deal of on-going research being done to resolve the lack of QoS for the Internet. In particular, the Internet Engineering Task Force (IETF) has proposed some service models and protocols for meeting the demand of QoS. Currently, the main service models and protocols are: Resource ReSerVation Protocol (RSVP), Integrated Services (IS), Differentiated Services (DS) and Multiprotocol Label Switching (MPLS) [Ref.5].

C. SERVER AND AGENT BASED ACTIVE NETWORK MANAGEMENT

Under the DARPA funded Next Generation Internet (NGI) initiative, a research project was initiated at Naval Postgraduate School to develop a Server and Agent Based Active Network Management (SAAM) system that provides an efficient solution for QoS. The SAAM architecture is designed to scale well with integrated services.

1. SAAM Architecture

In the current network architecture each stand-alone router needs to participate in almost all routing and management tasks --an inefficient way to meet the Quality of

Service (QoS) demands of the Next Generation Internet. The SAAM architecture will relieve the individual routers from the majority of routing and network management tasks. The proposed SAAM architecture consists of a SAAM server that controls a SAAM region including a number of routers (see Figure 2). The server will collect the global picture of the region and will make decisions on behalf of the routers. This method will provide a lightweight router that will perform only its primary task of forwarding the packets to their destination addresses. In this manner, SAAM allows the deployment of sophisticated software solutions to servers, the implementation of network QoS, and optimization of resources usage.

In order to illustrate the concept of SAAM, consider road traffic monitoring and control during commute hours in a big city like Istanbul. The radio stations are the management entities for the city's traffic control. In order to collect a global picture of the traffic in the city, radio stations send out helicopters to monitor the traffic on a particular region. The helicopters collect the information and send it back to the radio control station. Information obtained from different sources is aggregated, and the radio stations broadcast advice messages. In this way commuters can get the traffic information in "real-time". This early warning of congestion is the key for effective traffic control.

2. SAAM Server and Router

The SAAM Server will control a set of lightweight routers in terms of functionality, and will perform decision-making tasks for the routers. The SAAM Server will have two major functions.

First, the server will maintain the global view of the SAAM region by building a Path Information Base (PIB) to support QoS. With the PIB the server will be able to assign paths for flows that require QoS. The Server will identify the possible paths to route flows (see Figure 1). The server will also compute path performance parameters by collecting link performance data (Link State Advertisement) sent from the lightweight routers.

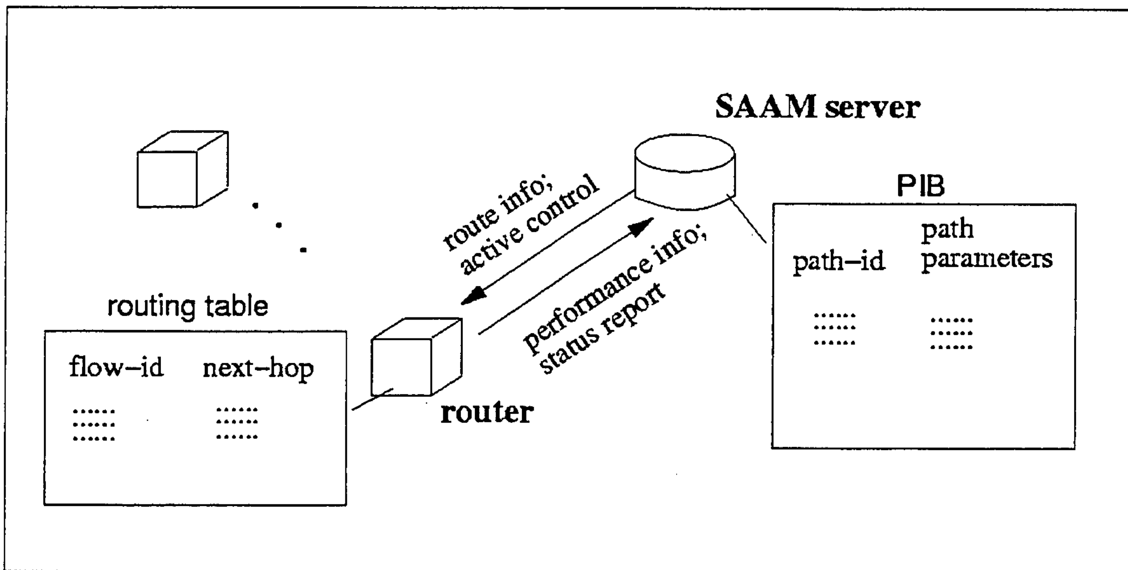

Figure 1. Logical Model of SAAM [From Ref. 1]

Second, the SAAM Server will make decisions on behalf of the routers in the region. Recall that each SAAM region will consist of at least one SAAM Server and a set of lightweight routers. The router will pass flow requests to the server. Once the server receives a flow request, it will compute the best route for that particular request, and pass routing table updates to the routers. The router is only responsible for routing packets.

3. Hierarchical Organization of the SAAM Servers

For scalability purposes, SAAM will organize its servers in a hierarchical model similar to the way in which the Domain Name Service (DNS) is organized. Each server will be responsible for a set of nodes. SAAM partitions the network into autonomous regions and sets up one server for each region. Each server will communicate with its immediate *children*, which might be one of the lightweight routers or a SAAM server. An example of a two-level server hierarchy is illustrated in Figure 2.

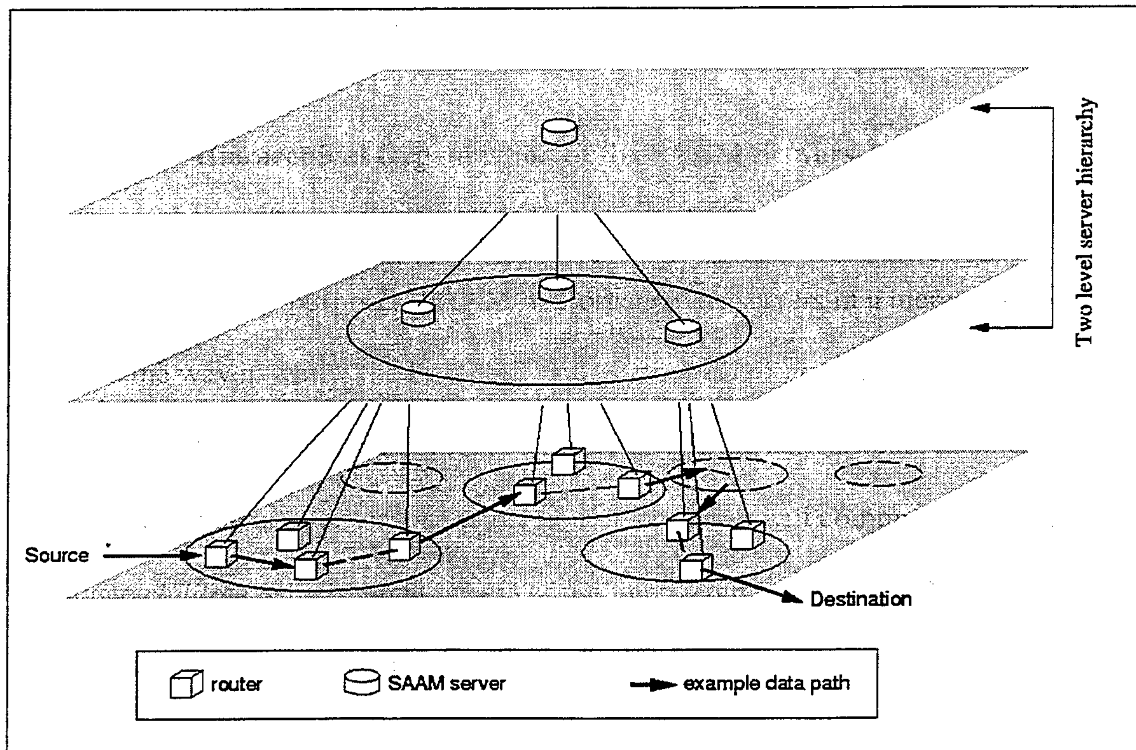

Figure 2. Hierarchical Organization of SAAM Servers [From Ref. 1]

The first level of the hierarchy controls a set of routers in a SAAM region. Each server needs to deal with flows in its region. If a flow needs to go across another region,

then the second level SAAM Server needs manage this request. The first level servers will summarize the QoS parameters of its region for the second level server. Thus the second level server will have the big picture of the three SAAM regions as shown in Figure 2. This summary will allow the server to present itself as a router to the second level server.

In addition to being scalable, another important advantage of the hierarchical organization of the SAAM Servers is that it provides the gradual deployment of SAAM into today's network, and still compatible with the existing networks. As stated previously, the SAAM architecture improves the usage of the network resources without making a major change in the current system, and hence best effort traffic will still be supported by this system.

4. Benefits of SAAM

The Internet consists of many Internet Service Providers (ISP), which are operated independently. The primary concern of the ISPs is how to attract more customers to increase the ISP's total profits. More customers means more traffic. The ability to accommodate more traffic without changing the infrastructure would be very advantageous for the ISPs. SAAM meets such needs by improving the usage of the resources while providing more predictable performance to data flows. With SAAM, an ISP can provide several QoS levels to their customers including guaranteed, premium, assured or best effort. At the same time, a customer can decide what type of QoS level he or she needs, and pay according to that selection. The SAAM architecture will be

backward compatible, meaning that it can be deployed gradually, and will not affect the existing infrastructure.

D. SCOPE OF THIS THESIS

The primary goal of this thesis is to add server performance probing capabilities to the SAAM prototype. This addition to the server will explicitly deploy code (executable modules) to particular links or nodes to measure throughput, loss rate, latency, and utilization. According to the received performance information, the server will verify whether or not the LSA (Link State Advertisement) reports from the routers under probe are acceptable. If the SAAM server detects any major discrepancy between the probe data and the LSA reports, then the server will try to verify the performance parameters with the next LSA reports. If the discrepancy still exists, the SAAM server will use the probing data over the LSA reports and generate an alert for the network administrator.

The probing approach will be first tested using PLAN (Packet Language for Active Networking). One or more PLAN packet(s) will be sent from the server to probe a particular set of links. The active packet(s) will collect performance information on the links and carry the data back to the SAAM server. The second implementation of server probing will be done using Java programming language, which will be integrated into the SAAM server/router prototype. The main reason for using PLAN for test purposes is to ensure that the technique/algorithm of server probing is feasible.

E. ORGANIZATION

In Chapter II, detailed background information is presented to explain the active networking approach and resident agent support for the SAAM prototype. Chapter III is devoted to the SAAM server probing approach and algorithms that perform this task. Chapter IV explains the server probing in Packet Language for Active Networking (PLAN) environment, and also explains the implementation of server probing in PLAN. Chapter V explains the server probing designed specifically for the SAAM prototype. Chapter VI is devoted to the server probing implementation and the observations. Finally, Chapter VII concludes the thesis with lessons learned and future work of this study.

THIS PAGE INTENTIONALLY LEFT BLANK

II. BACKGROUND

A. ACTIVE NETWORKING APPROACH

In the SAAM architecture, a SAAM Server will make routing and other important decisions on behalf of the routers in its region. In order to make the right decisions and support QoS (e.g., IntServ and DiffServ), the SAAM server needs to maintain an accurate region-wide view of network performance. This will be achieved as routers periodically send Link State Advertisement (LSA) messages to the SAAM server (Currently, the LSA messages report two key Link Performance Statistics, the average delay and the loss rate experienced by packets.) Moreover, the server needs to perform sanity checks of these statistics by probing specific links. The SAAM server will probe the links by dynamically injecting customized probing programs. In other words, the probing will be done with the active networking approach.

With the active networking approach, the network is no longer viewed as a passive mover of bits or bytes, but rather as a system capable of dynamically loading and executing programs written in a variety of languages. One can inject customized programs into the network, which can collect router state information, or even change some of the router's core modules (e.g., packet scheduler).

A typical active network consists of active nodes that have the ability to process active packets -- packets that carry a self-contained runnable code. The node's operating system is responsible for allocating and scheduling resources such bandwidth and the CPU. Each node also has one or more execution environments, each of which is a virtual

machine that understands active packets written in a particular language. An example of such a virtual machine is the Java Virtual Machine (JVM). Another example is the Ocaml Virtual Machine. Execution environments will be explained in depth later in this chapter.

1. Active Network Encapsulation Protocol (ANEP)

As stated above, within the active networking approach the network is no longer passive; on the contrary, it is capable of dynamically loading and executing programs, written in different languages (e.g., PLAN, ANTS). The programs sent to an active node must be forwarded to their respective Execution Environment (EE). ANEP provides a mechanism for encapsulating active network packets for transmission over different media, and a proper de-multiplexing to the appropriate execution environment. Each Execution Environment has a type identifier number in the ANEP header, which is assigned by the Active Networks Assigned Numbers Authority (ANANA). The format of ANEP is shown in Figure 3.

<table>
<tr><td>0   7</td><td>8   15</td><td>16   31</td></tr>
<tr><td>Version</td><td>Flags</td><td>Type ID</td></tr>
<tr><td colspan="2">ANEP Header Length</td><td>ANEP Packet Length</td></tr>
<tr><td colspan="3">Options</td></tr>
<tr><td colspan="3">Payload</td></tr>
</table>

Figure 3. Format of ANEP Header

The length of the *version* field is 8 bits, and indicates the header format in use. The active node will discard the packet if it does not recognize the packet's version number.

The length of the *flags* field is 8 bits, and indicates what the node should do if it does not recognize the *type ID*.

The length of the *type ID* field is 16 bits, and indicates where the packet will be evaluated. According to this field, the packet will be forwarded to the proper *execution environment*. As stated above, the authority for assigning *type ID* values is the ANANA.

The *ANEP header length* field is 16 bits, and specifies the length of the ANEP header in 32 bit words. The field value must be 2, if no options are included in the packet.

The *ANEP packet length* is 16 bits, and specifies the length of the entire packet including the packet payload. This field will serve to recover the packet if it has been transmitted over a lower layer that does not provide recovery of the packet length.

Options in the form of Type/Length/Value (TLV) can be included in the *options field.*

The active network packet format including the ANEP header is illustrated in Figure 4.

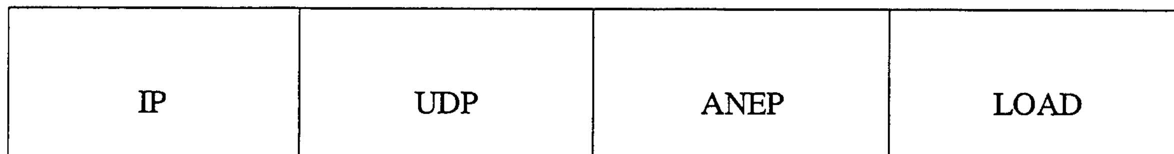

Figure 4. Active Network Packet Format

2. Active Network Daemon (ANETD)

ANETD is an experimental daemon specifically designed to support the deployment, operation and control of active networks [Ref. 7]. It connects the active node to the Active Networking Backbone (ABONE), which is an experimental backbone to support active nodes with active packets.

ANETD performs two major functions.

- It allows the deployment, configuration and control of networking software (including current active networking execution environment prototypes) into the network. [Ref. 8]
- It de-multiplexes active network packets (encapsulated using ANEP) to multiple execution environments on the same network node and sharing the same input port. [Ref. 8]

The daemon listens to a user defined UDP port, and intercepts active packets encapsulated within an ANEP header. The daemon also checks the *type ID* field of the header, and de-multiplexes the active packet to the appropriate execution environment.

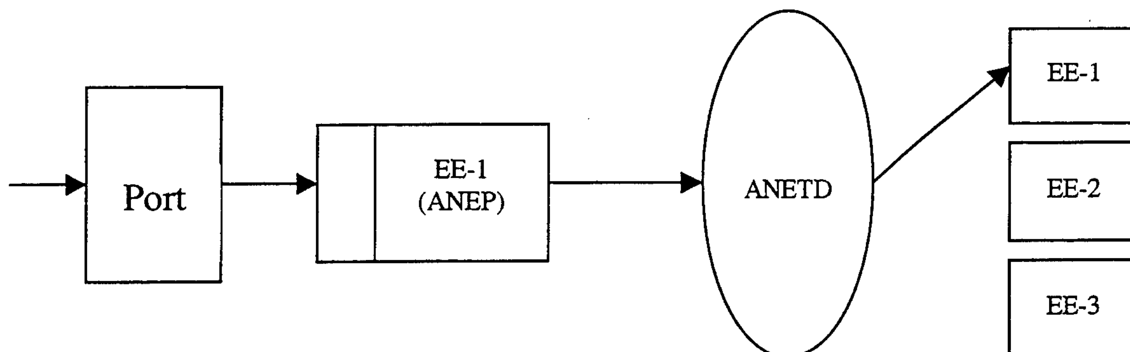

Figure 5. Illustration of De-multiplexing an Active Packet to EE-1

In Figure 5 we can see that an active packet arrives to a UDP port. Since ANETD will listen to that particular port, it will receive the packet, check for the *type ID* in the ANEP header, and will de-multiplex the packet to the appropriate execution environment. In this case it will de-multiplex the packet to EE-1.

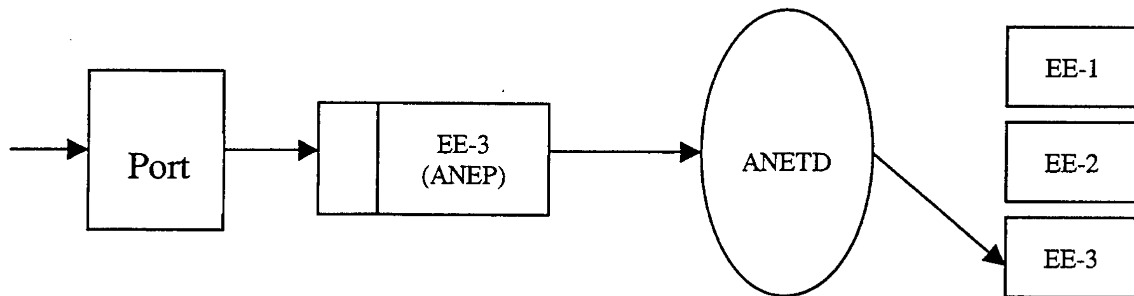

Figure 6. Illustration of De-multiplexing an Active Packet to EE-3

The same concept is shown in Figure 6. In this case the active packet is de-multiplexed to EE-3, because the type ID in the ANEP header shows that its appropriate execution environment is EE-3.

The deployment of networking software is similar to the concept of plug-in requirements enabling browsers to perform certain tasks (e.g., audio stream plug-in, video display plug-in). The network services are specified as Universal Resource Locator (URL). The daemon downloads the service with the Hypertext Transfer Protocol (HTTP) *get* command from the corresponding URL, and then strips off the Hypertext Markup Language (HTML) header from the received code and installs the service. This process is illustrated in Figure 7.

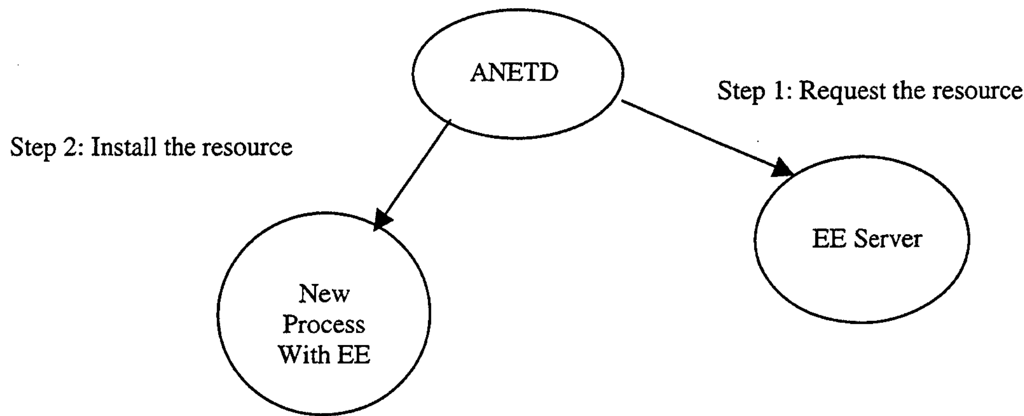

Figure 7. Illustration of the Deployment of an Active Network Resource

Currently, ANETD is available for Solaris on Sparc, Linux on x86 and FreeBsd on x86, and is implemented in C programming language. The daemon can be invoked as a user application and does not need any runtime privileges [Ref. 8]. The daemon will listen to port number 3322 by default, and the following command line on a computer with Linux Operating System (OS) will start the daemon..

ad.<operating system type>[-p <ANEP port>][-u<local port pool start>] [-s]

- *<operating system type>* the available options are
  - *solaris* = SunOS 5.5.x running on Sparc
  - *linux* = Linux running on Intel x86 platform
  - *bsd44* = FreeBsd running on Intel x86 platform
- *<ANEP port>* is the port number which ANETD will be listening to. The default value will be 3322.
- *<local port pool start>* is the starting port number for dynamically allocating local ports. The default value is 8000.

- *-s* authorizes ANETD to send heart-beat packets every 30 seconds to the main ANETD server, *sequoia.csl.sri.com.*

In order to illustrate the invocation of the ANETD, let's examine the following command line:

ad.linux –p 3326 –u 8800 –s

When this command line is executed, the ANETD will listen to UDP port 3326 for active packets. It will also use port 8800 for dynamically allocating local ports. At the same time, the daemon will send heart-beat packets every 30 seconds to the main ANETD server. From this command line, we can determine that the daemon is running on an Intel x86 processor based computer with Linux OS.

3. Execution Environments (EE)

As mentioned earlier in this chapter, an execution environment is used for evaluating the active packets. The daemon will de-multiplex the active packets according to the *type ID* field in the ANEP header, to its relevant EE. The *type ID* number that is associated with a particular EE is assigned by ANANA. Currently the ANANA is Bob Braden (braden@isi.edu) as of July, 1997.

There are couple execution environments available for download (e.g. ANTS, PLAN, Smart Packets). These execution environments are implemented by different institutions, and each claim advantages over the others. For research purposes, we have chosen Packet Language for Active Networking (PLAN) as the execution environment.

PLAN is implemented in both Java and Ocaml programming languages. To avoid confusion, the details of PLAN will be discussed in Chapter 4.

4. Active Networking Backbone (ABONE)

ABONE is an experimental backbone for active networking purposes. An interested party who wants connect to the backbone has to fill out the registration information available at http://www.csl.sri.com/ancors/abone/. This information will be available for other institutions experimenting with active networking. During the registration process, one will need to provide a public key. The key generation program is available from the same URL described above. Once you get the key generation program for your experimental platform, you can register and connect to ABONE. There are two important requirements once the node is connected to ABONE. First, the experimental node needs to be up and running. Second, the experimental node must be reachable through a non-standard UDP port, implying that one might need to apply to the network administrator for firewall configuration. After installing and invoking the ANETD, the node will be part of ABONE.

In order to implement SAAM server probing with the active networking approach, melon.cs.nps.navy.mil is registered and connected to ABONE. The ANETD version 1.0 runs under Linux OS. Recall that ANETD can run with Linux on Intel x86, FreeBsd on Intel x86 and Solaris on Sparc. The graphical status of ABONE is shown in Figure 8.

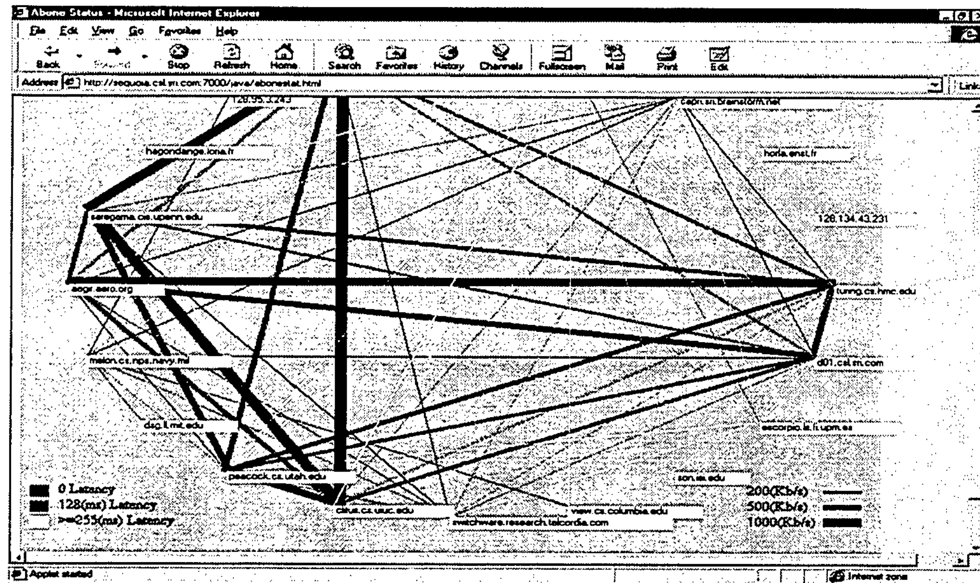

Figure 8. Graphical Status of ABONE

B. RESIDENT AGENT SUPPORT OF THE SAAM PROTOTYPE

A working prototype of the proposed SAAM architecture has been developed in the Java programming language. The main reasons for using Java as the programming language are its portability and support of resident agents, together which allow us to use the active network approach. It is desirable for the server to dynamically send some components, instead of leaving them to reside permanently on every router. This is a suitable approach to the lightweight router concept. The SAAM server simply sends the resident agents to the routers, which will be installed as a module and will perform its tasks. Once the task is completed the resident agent can be uninstalled, thus relieving the router from performing extra tasks or having extra components. The resident agent support also allows us to update some modules on the router.

The following quote from *Programming and Deploying Java Mobile Agents with Aglets™*, Danny B. Lance/Mitsuru Oshima, page 35, summarizes the concept of resident agents:

"A key feature of mobile agents is that they can be serialized and deserialized. Java conveniently provides a built-in serialization mechanism that can represent the state of an object in a serialized form sufficiently detailed for the object to be reconstructed later. The serialized form of the object must be able to identify the Java class from which the object's state was saved and to restore the state in a new instance. Objects often refer to other objects. To maintain the object structure, these other objects must be stored and retrieved at the same time. When an object is stored, all the objects in the graph that are reachable from the object are also stored."

III. SAAM SERVER PROBING APPROACH AND ALGORITHMS

A. LINK STATE ADVERTISMENT (LSA) MESSAGES

In the SAAM architecture, a SAAM server will make routing and other important decisions on behalf of the routers in its region. In order to make the right decisions, the SAAM server always needs to maintain an accurate region-wide view of network performance. This accurate view will be achieved as routers periodically send LSA messages to the server.

Currently, the LSA messages report two key Link Performance Statistics (LPS), the average delay and the loss rate experienced by packets. These LPSs are calculated for every service level pipe of each router's interface. The LSA messages will serve as a base for the server to develop an accurate picture of regional paths crossing multiple service level pipes for QoS. The concept of service level pipes is illustrated in Figure 9.

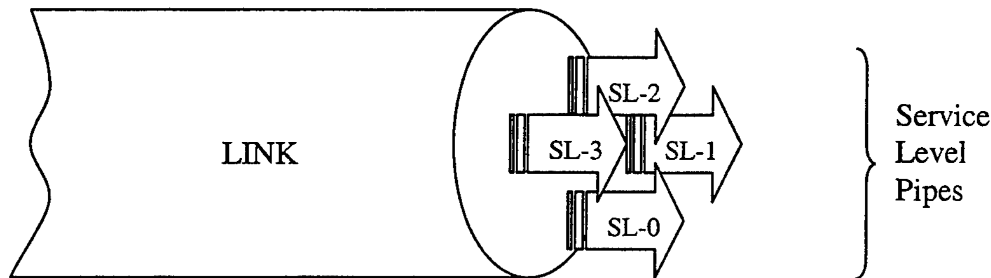

Figure 9. Service Level Pipes in a Link

Each service level pipe may have multiple input queues. Four separate service levels are assigned respectively to *control traffic*, *guaranteed service traffic*, *differentiated service traffic*, and *best effort traffic*.

B. SERVER PROBING FOR SANITY CHECK

The SAAM server will build the region-wide picture of network performance according to the LSA messages. For verification purposes, the server needs to perform a sanity check of these statistics by probing specific links.

Another important reason for verifying the accuracy of the statistics sent with the LSA messages is related to SAAM security. A compromised node can feign a good performance, and might mislead the SAAM server in making decision. This will certainly affect the QoS of many flows using that link.

There are two potential explanations as to why a node feigns good performance parameters. The first is that the router might be misconfigured and does not perform its tasks correctly. The second is that destructive individuals tamper with the traffic flow of a SAAM region, and degrade the overall network performance.

Since the SAAM server will make decisions according to LSA statistics, it is important that the server has an independent method to verify the validity of LSA data.

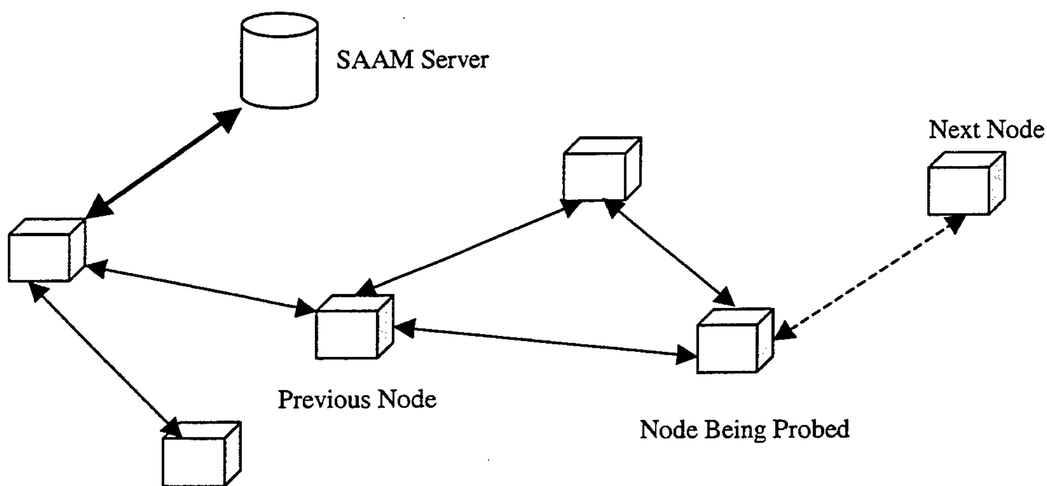

Figure 10. SAAM Server Probing

Let's first explain the terminology used in Figure 10. The node we wish to probe will be referred to as, *node being probed.* The previous neighbor of the probed node will be referred to as, *previous node.* The next neighbor of the probed node will be referred to as, n*ext node*.

The *previous node* will receive a command from the server to generate probing packets for the particular flow of a service level. The *next node* will also receive a command from the server to collect the probing results of a particular flow. After the *next node* collects the probing parameters, it will send the results back to the server. Then, the server will compare the parameters with those sent with the LSA messages. If the difference between the LSA result and the probe result is not within acceptable limits, the server will try to verify the information. If the discrepancy still exists after the first attempt to verify, the SAAM server will use the probing data over the LSA reports and generate an alert for the network administrator.

C. BANDWIDTH MEASUREMENT TECHNIQUES

Current bandwidth measurement techniques have many problems [Ref. 9]:

- Poor accuracy;
- Poor scalability;
- Lack of statistical robustness;
- Poor agility in adapting to bandwidth changes;
- Lack of flexibility in deployment;
- Inaccuracy when used on a variety of traffic types.

Developed by Stanford University, the Packet Pair Algorithm is one of the techniques used to measure the bottleneck bandwidth of a route with reasonable accuracy.

The bottleneck bandwidth of a route is the ideal bandwidth of the lowest bandwidth link (the bottleneck link) on that route between two hosts. In most networks, as long as the route between two hosts remains the same, the bottleneck bandwidth remains the same.

The bottleneck bandwidth is not affected by other network traffic. The available bandwidth of a route is the maximum bandwidth at which a host can transmit at a given point in time along that route. Available bandwidth is limited by other traffic along that route. [Ref. 9]

One of the most popular and simple techniques is to use throughput as an approximation of bandwidth. Throughput is the amount of data transported per unit of time. One drawback to this approach is that packet drop rate may have a significant effect on throughput, although not affecting bandwidth.

TCP uses a technique where it sends more and more packets until one is dropped. TCP estimates the bandwidth to be somewhere between the sending rate when the packet was dropped and half that rate. This approach has several flaws: [Ref. 9]

- TCP is measuring the bottleneck router's buffer size in addition to the bottleneck bandwidth;
- TCP wastes network resources by forcing a dropped packet and filling the router's buffers;

- TCP has to increase its sending rate slowly, or else it will over-shoot the real bandwidth and cause massive packet loss.

There are two algorithms to measure the bottleneck bandwidth. The first is the *Pathchar Algorithm,* and the second is the *Packet Pair Algorithm.* We will not discuss the Pathchar Algorithm in further detail, as one of its drawbacks is that its heavy consumption of network bandwidth resources. If this algorithm were used for a large number of hosts, it would consume too much bandwidth to be used regularly. As an approximation, for a 1-hop Ethernet network with a latency of 1ms, the average bandwidth consumed would be around 6 Mb/s.

D. PACKET PAIR ALGORITHM

For SAAM server probing, the performance parameters sent with the LSA messages should be verified. In order to measure the throughput of a particular link, we want the server sending a notification message or a resident agent to the *previous node*, so the *previous node* can initiate the probing process. The throughput measurement will be done using the *Packet Pair Algorithm.*

The principle of *Packet Pair Algorithm* is quite simple but very practical. Once the *Previous Node* receives a command or a resident agent, it will generate two packets for a particular flow of a service level with a signature to identify that the incoming packet is a probing packet. When the two packets are queued next to each other at the link, then they will exit the link t seconds apart. Since we know the packet size, we can simply calculate the throughput of the link with the following equation:

$$bandwidth(bnl) = \frac{size}{time(t)}$$

Equation 1. Mathematical Equation of Packet Pair Algorithm

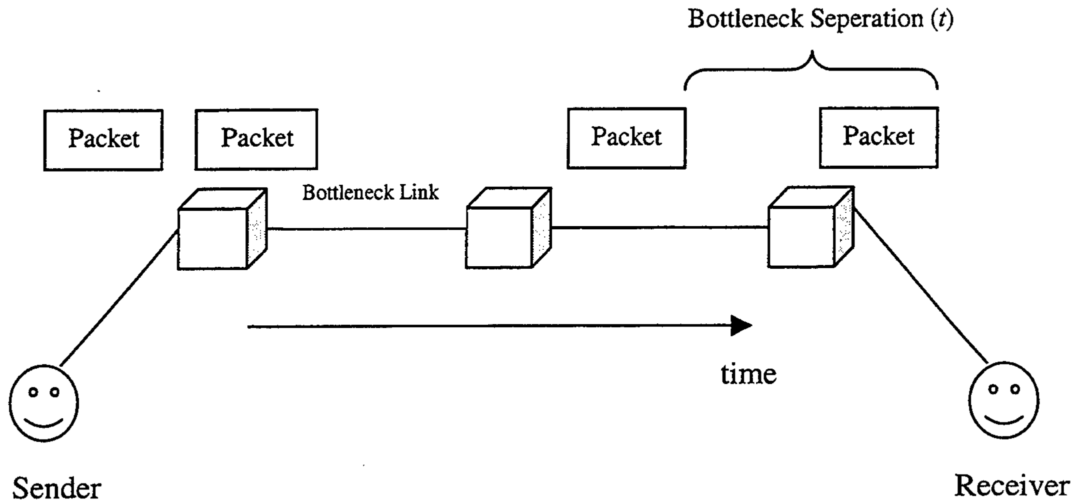

Figure 11. Packet Pair Algorithm

The variable *size* in the equation indicates the second packet's size. However, in our approach, the *size* variable is irrelevant, as the *previous node* will always send two completely identical packets. There will a separation between the two packets after they will leave the bottleneck link, which is the *bottleneck separation*. Since there are no links with lower bandwidth than the bottleneck link downstream from that link. Assuming the packets are the same size, the second packet will never catch up to the first packet. Within our approach the *next node*, which is the neighbor node of the n*ode being probed* will record the time of the bottleneck separation with the packet size, and calculate the bandwidth for the link. The *Next Node* will distinguish the probing packets from the regular data packets with the signature placed in the payload.

The two packets must be the same size, because different size packets have different velocities. If the second packet were smaller than the first, then its transmission delay would always be less than the first packet's. Consequently, it would pass through links faster than the first packet, that of quickly eliminating the *bottleneck separation.* Similarly, if the first packet is smaller, then it will be faster than the second packet, and continuously lengthen the bottleneck separation [Ref. 9].

THIS PAGE INTENTIONALLY LEFT BLANK

IV. IMPLEMENTATION OF SERVER PROBING IN PLAN

PLAN is an active network programming language developed by the SwitchWare project at University of Pennsylvania [Ref 10]. Based on calls to node-resident service routines, PLAN provides a restricted set of primitives and data types. PLAN programs are meant to execute remotely, a feature that makes it difficult to determine the cause of an unexpected PLAN program behavior. Therefore, it is important to provide apriori assurances about a program's behavior. The strong type check feature of PLAN makes debugging easier. Another PLAN property aimed at protecting network availability is the guarantee that PLAN programs use a bounded amount of network resources.

A. PLAN DISTRIBUTION

Currently, there are two implementations of the PLAN programming environment. The first implementation is written in Java programming language, and the version is 2.21 at the time of the publication of this thesis. The second implementation is written in the Ocaml programming language, and its current version is 3.2. The following subsections will explain both implementations.

1. Java 2.21 Distribution of PLAN

Java is a programming language developed by Sun Microsystems. The main advantage of Java is its portability, a characteristic that enables users to run Java

programs on a great variety of operating systems. The compilation of the Java source code generates byte codes, which will be interpreted by the Java Virtual Machine (JVM).

The distribution of the Java version of PLAN includes class files, source code, documentation and sample programs. You can get the Java class files and execute them directly or you can get the source code and build it yourself. The file can be downloaded from **http://www.cis.upenn.edu/~swithware/PLAN/download.html**. Since we were using RedHat Linux 5.1 for our active networking test bed, we downloaded the file for the Unix OS.

Three packages are needed to install the Java distribution of PLAN.

(1) Java Development Kit (JDK) 1.1.x. The download and installation procedures are explained in APPENDIX A.

(2) Pizza version 0.39. This package is a substantial companion to JDK. The download and installation procedures are explained in APPENDIX B.

(3) The Java Compiler Compiler (JavaCC) version 0.6.1. The download and installation procedures are explained in APPENDIX C.

After these three packages are installed, one can unpack the source code of PLAN under a directory of his desire. One needs to compile the source code to generate the class files, or one can simply download the class files and install them.

2. Ocaml 3.2 Distribution of PLAN

Caml is a programming language developed by INRIA (French Research Institute for Computer Science) and is freely available. Ocaml (Objective Caml) is a version of the

Caml programming language. Ocaml is a modular system with support to the object-oriented paradigm, and includes an optimizing compiler.

One of the main objectives of the language is safe programming. That's why the compiler performs many sanity checks on source code before compilation. Ocaml programs are statically type-checked, a process that reduces programming errors. In addition to these features, Ocaml is a functional programming language.

The most recent version of the PLAN distribution written in Ocaml is 3.2 . The PLAN implementation is changed from Java to Ocaml programming language to improve the overall performance and safety of PLAN programs. The Ocaml version 3.2 is built with the following available packages:

- Ocaml version 2.02
- CamlP4 version 2.02, which is a preprocessor of Caml.
- Ocaml patch to enable Ethernet access on computers running Linux OS.

Download and installation procedures are explained in APPENDIX D.

B. PLAN ENVIRONMENT AND PROGRAMMING

1. PLAN Packets

In the active networking approach, the network is no longer viewed as a passive mover of packets, but rather as a capable of dynamically loading and executing programs. PLAN programs are bundled into packets, injected into a network, and then evaluated.

After the evaluation, the packet might create other packets, which may then be evaluated at other nodes in the network.

A PLAN program consists of two components, the *code* and the *bindings*. The bindings serve as resource constraints, so all PLAN programs are guaranteed to terminate and consume limited amount network resources [Ref.10].

2. Model of PLAN Evaluation

In this section, the PLAN evaluation environment is explained to promote a better understanding of how PLAN programs are evaluated in an active networking environment.

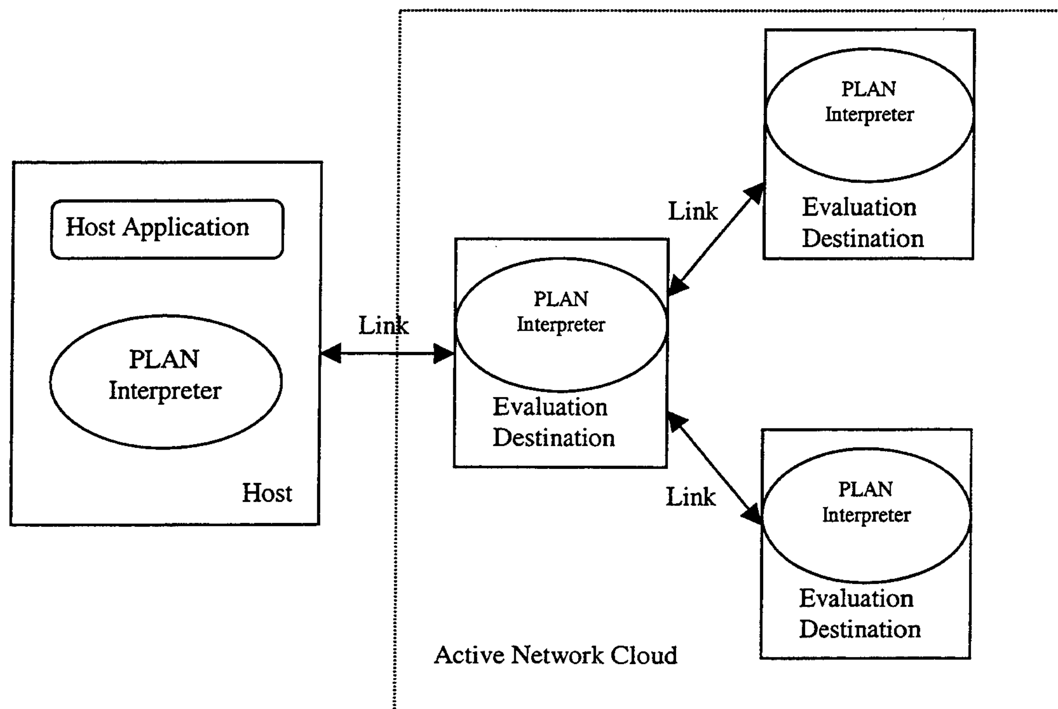

Figure 12. The PLAN Evaluation Environment

Consider Figure 12. A PLAN network consists of hosts, which form the end-points of the environment, and routers, which form the cloud. We will refer hosts and routers as *nodes* throughout the rest of this chapter. Hosts are distinguished from routers in that they may serve host applications, forming part of a PLAN application [Ref.11]. All the nodes in the PLAN evaluation environment are capable of evaluating PLAN programs.

When sending a PLAN packet to the active network cloud, one must send it from the host node, where a PLAN packet begins its life cycle. The packet will be injected into the active cloud after being passed to the PLAN interpreter through a port. (The results from the active nodes executing the PLAN packet will be received through this same port to be displayed as standard output.) The local interpreter then proceeds to route the packet to its evaluation destination, which is one of the nodes in the active cloud. At each "hop" on the way to its evaluation destination, the resource bound of the packet is decremented to limit the use of network resources. In case packet's resource bound is exhausted, the packet is terminated, and a message is sent back to the source for potential recovery of the data [Ref. 11].

The PLAN packet is evaluated when the packet has reached its evaluation destination. First, the code is parsed top-down to register the top-level bindings. All function bindings respect static scooping; that is, the set of bindings (available to a function when it is evaluated) are those that were available when the function was defined. Evaluation then begins with the function call defined by the invocation. Any value that would have been returned by the function is discarded. [Ref. 11]

3. Starting PLAN Aware Routers

One can set up more than one PLAN-aware routers on a computer. These routers will have the ability to process and forward PLAN packets. ANETD is not essential for the PLAN environment for de-multiplexing PLAN packets. PLAND (PLAN Daemon) is a replacement for ANETD, and performs the same function. It de-multiplexes PLAN packets to the PLAN execution environment, and serves as the entry point of the active node for a PLAN packet. The PLAN distribution has the following executable files [Ref. 12].

- *pland*: The PLAN daemon implementing an Active Router.
- *inject*: Sends a PLAN program to the local *pland* to be interpreted.
- *plan*: A non-network PLAN interpreter in *read-eval-print* mode used to test out basic programs.

In order to set up an active router on a computer, one needs to invoke the PLAN daemon by typing the following command. (The *-help* switch will give information about the usage of this command.)

% bin/pland –help

The following help message will be displayed as the output of this command:

usage: bin/pland [-router] [-firewall d1, d2, ...dn] [-l log] [-ip port] [-rf rout_tab_files]

[-policy policy_file] [-authlist h1, h2, ...hn] ifc_spec_file

-router : Turn on router mode.

-firewall: Specify devices to firewall (default is none)

-ip: Specify static route table file.

-hf: Specify host name file (default=*./key.<local portnum>*).

-policy: Specify policy specification file (depends on policy engine in use).

-authlist: Specify nodes to authenticate with (default is none).

Let's build an active cloud with two active routers to illustrate a step by step procedure. First of all we have to define the interface files. Let's call them respectively m1, m2, and the contents of those files will be as follows:

File m1 contains:

1 ip0 ip melon.cs.nps.navy.mil:3324 melon.cs.nps.navy.mil:3325

File m2 contains:

1 ip0 ip melon.cs.nps.navy.mil:3325 melon.cs.nps.navy.mil:3324

Remember, we are creating those active nodes on the same computer, so it is a virtual active network cloud with two nodes. The first file indicates that the node *m1* has one IP interface named *ip0* with the address, "melon.cs.nps.navy.mil:3324", and its neighbor has the interface address, "melon.cs.nps.navy.mil:3325". The file *m2* has also one IP interface named *ip0.*

Before we can start running our active nodes, we must add the IP number and the identification name of our local computer to the *EXP_IP_ADDRS* file. Once accomplished, we can run the active routers on our local computer by invoking the PLAN daemon with the appropriate flags:

% bin/pland –l log3324 –ip 3324 m1

% bin/pland –l log3325 –ip 3325 m2

This command sequence will call the *m1* and *m2* files and create the active routers. If we don't specify any port number, the default number for the PLAN daemon is 3324.

4. Injecting PLAN Packets To Active Cloud

Thus far, we have built an active cloud, which is ready to receive PLAN packets. Let's create a simple PLAN program called HelloWorld.plan, and then inject it to the active network to illustrate a step by step procedure. The program contains the following code:

```
svc print : 'a -> unit
fun start() =
        ( print( "This is a hello message for first programming experience \n") )
```

This program has just one function named *start()* with no parameters, and will simply display the message string as output. In order to inject this packet we need to use the command below. The *–help* flag shows us its usage.

% bin/inject –help

usage: bin/inject [-v] [-val] [-p port] [-ed evalDest] [-rf routFun] [-hf host_file]

[-o outfile] <codefile> <Resource Bound>

-v: Turn on verbose mode

-val: Unmarshall and print responses as values (rather than strings).

-p: Set initial evaluation destination.

-rf: Specify routing function.

-fid: Specify flow ID (default is 0).

-hf: Specify file for hostname resolution (default is the *EXP_IP_ADDRS* file).

-o: Specify file to output marshalled packet (default is none).

A sample of a command to inject the "HelloWorld.plan" program would be as follows:

% bin/inject HelloWold.plan 10

Since we didn't specify the port in which to inject the packet, the default port number will be used by the daemon. We also specified the resource bound *take 10.* After injecting the program, the PLAN code will wait to receive the next input, which is the *initial invocation.* Recall that a PLAN program is a list of definitions, and when the program arrives at an active host, one must specify which function to start executing, and with what arguments [Ref.11]. In the "HelloWorld.plan" case, the function *start( )* is not expecting any parameters, so we simply type at the command line:

start();

After the invocation of the function, we will receive the output message string of the program.

% This is a hello message for first programming experience

This sample program illustrates the simple procedures to build an active network cloud, consisting of active nodes, and injecting active PLAN packets to this network. The following section will explain the implementation of the *Packet Pair Algorithm* in PLAN.

C. IMPLEMENTATION OF PACKET PAIR ALGORITHM IN PLAN

It is important for the SAAM server to have the most accurate performance parameters of the links, to build the maintain an accurate region-wide view of network performance. These performance parameters will be sent by the nodes using LSA messages. Moreover, the server needs to perform sanity checks on these statistics by probing specific links. The probing should not be detected by the *node being probed* at the same time for security considerations mentioned in Chapter III. For throughput probing of a specific link, the server will use the Packet Pair Algorithm. The implementation of this algorithm in PLAN is presented in APPENDIX E.

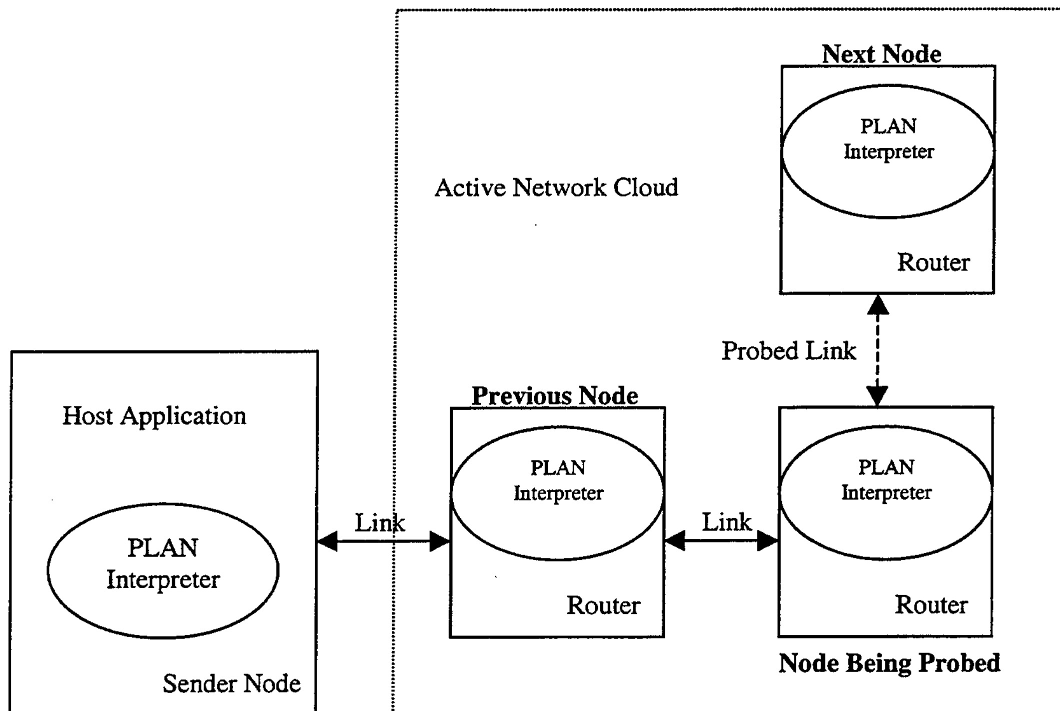

Figure 13. Packet Pair Probing with PLAN

In Figure 13, a topology with three active nodes is shown, which allows injecting the *packet pair* program. First, the *packet pair* PLAN packet is injected into the *previous node*. When the packet reaches its evaluation destination, or the *previous node*, the PLAN packet will generate two other packets with the address information of the host node, providing a return of the acknowledgment packets, generated by the *OnRemote()* service call. The two packets are generated with the following code snipped.

```
if(thisHost() = previousNode ) then
        OnRemote(|sendpacket|( senderNode), nextNode, 50, defaultRoute)
else();
if(thisHost() = previousNode ) then
        OnRemote(|sendpacket|( senderNode), nextNode, 50, defaultRoute)
else()
```

The syntax for *OnRemote()* is as follows:

OnRemote(E, H, Rb, Routing)

The meaning of *OnRemote()* service call is, "evaluate E on node H, and use the routing function to determine how to get to node H." The resource bound restriction is passed with the variable *Rb*.

The sendpacket( ) method that creates two acknowledgement packets including the time stamp values is as follows:

```
fun sendpacket( senderNode:host )=
```

```
(
        let val record_time1:int*int = gettimeofday( ) in
        OnRemote( |ack|(thisHost(), record_time1), senderNode, 30,
                defaultRoute)
        end
)
```

When the two created packets arrive at the *next node*, each of them will send one acknowledgment packet back to the *sender node,* including a time stamp showing its arrival at the *next node*. When the acknowledgment arrives at the *sender node,* (this is the equivalent of the SAAM server node) the *sender node* will simply display the identification of the *next node* with the time stamp.

```
fun ack( where:host, time:int*int) =
( print( "Host is :"); print( where );print( "Time stamp is ");print(time) )
```

With the time stamp information, the *sender node* can calculate the packet separation of the two acknowledgment packets. Dividing the packet size of the acknowledgements by the time separation will give us the throughput metric of the probed link, which is the dotted link in Figure 13. The test results for getting the time stamps of the acknowledgement packets are shown in Table 1, and a snapshot of the command window displaying the time stamp values are shown in Figure 14.

Packet	Timestamp (sec)	Throughput (Kbps)

V. SERVER PROBING DESIGN FOR THE SAAM PROTOTYPE

A. SAAM PROTOTYPE

1. Overview

A working prototype of the proposed SAAM architecture was developed by two former Naval Postgraduate School students, Dean Vrable, and John Yarger, using the Java programming language. The main reason for using Java as the programming language is its portability. Java programs can run on any platform without changing the precompiled byte code.

IPv6 supports flow routing. In order to take advantage of this support, an emulated environment was built to route IPv6 packets at the application layer over an IPv4 network.

The prototype consists of a router module and a server module. The router is designed to maintain a flow routing table as well as an Address Resolution Protocol (ARP) cache table. The router manages its functionality by using the standard concept of transport layer ports.

The server has two primary tasks. The first task is to maintain an accurate status of its region. This task is accomplished through the building of a Path Information Base (PIB) from auto configuration messages and Link State Advertisement (LSA) messages. The second task is to respond to flow requests. This task is accomplished by accessing the PIB in order to identify the optimal path for a requested flow from the set of paths

that can support the request. If this optimal path can be found, then the routers in the path are sent appropriate update for their flow routing tables. Finally, the requesting application is notified of the assigned *flow ID*, if the flow can be supported. [Ref. 3]

2. Resident Agent Support

The probing component should be sent dynamically by the server, instead of residing permanently on every router. Java is perfectly suited for this approach. The SAAM prototype is designed to support resident agents, allowing the components of a router to be upgraded and installed dynamically during runtime. The precompiled byte code of a resident agent is registered as a new module of the receiving node. The module may run itself by creating a thread, or it may be called by an existing thread. For instance, after a node in the prototype receives a server resident agent it becomes a SAAM server, otherwise it stands up as a router.

The following quote from *Programming and Deploying Java Mobile Agents with Aglets™*, Danny B. Lance/Mitsuru Oshima, page 35, summarizes the concept of resident agents:

"A key feature of mobile agents is that they can be serialized and deserialized. Java conveniently provides a built-in serialization mechanism that can represent the state of an object in a serialized form sufficiently detailed for the object to be reconstructed later. The serialized form of the object must be able to identify the Java class from which the object's state was saved and to restore the state in a new instance. Objects often refer to other objects. To maintain the object structure, these other objects must be stored and

retrieved at the same time. When an object is stored, all the objects in the graph that are reachable from the object are also stored."

B. SERVER PROBING APPROACH AND ANALYSIS

The server needs to install the probing components dynamically to the routers during runtime. In order to probe a link we have the concept of a *previous node*, and a *next node*.

The server sends a resident agent to the *previous node* to initiate the probing process. Before the probing starts, the resident agent needs to obtain certain parameters from the server to create the appropriate probing packets. This will be achieved as the server sends a *probing activation message* to the *previous node*. The server sends another resident agent to the *next node* to intercept the probing packets and compute the throughput metric. The server will also send the required parameters to the *next node probing resident agent* with an activation message. Sending activation messages allows a generic resident agent which is capable of performing various server probing (i.e. throughput, loss rate, latency, utilization). The activation message determines what kind of task to perform. (The format and parameters of the activation messages will be explained later in this chapter.)

After the *next node resident agent* receives the *activation message* the resident agent will monitor the packets and will look for the probing packets to compute the performance metrics by identifying an embedded signature in the last four bytes of the payload.

In the activation message, the server sends a four byte *probe ID,* which is an arbitrary number to keep track of probing results for various links. This *probe ID* is also used as the signature in the payload. The ordinary and the probing packet formats are shown in Figures 15 and 16 respectively.

40 bytes	Variable
IPv6 Header	Payload

Figure 15. Data Packet Format

40 bytes	Variable	
IPv6 Header	Payload	
		4 bytes
		Probe ID

Figure 16. Probing Packet Format

1. Previous Node Activation Message Format

After the server sends the resident agent to the *previous node*, the server needs to send to the agent certain parameters to customize the probing process (e.g., IPv6 header to use for probe packets, probe ID, etc.).

The server first determines a particular flow to mask probe packets, and then sends a copy of IPv6 header for that particular flow to the probe agent. Recall that the

server is the central authority, and has information about flows in its region. The *previous node activation message* has four parameter fields, shown in Figure 17.

The *type of probing* field will identify the kind of probing the *previous node resident agent* will initiate. For instance, if we want to measure the throughput metric, the resident agent will use the Packet Pair Algorithm as the probing process. Or, if we want to measure the loss rate metric, then the resident agent will initiate a different probing process (i.e., sending a set of packets).

The probe identification will be used as the signature for the probing packets, to differentiate probe packets from the ordinary data packets.

Once the probing process is completed and the agent instantiates the probe result message, the resident agent uses this probe identification with the associated probe result. This system provides a way of keeping track of probe results on the server side.

The *payload length* will determine the size of the Ipv6 probing packets.

1 byte	1 byte	4 bytes	40 bytes	2 bytes
Type ID	Type of Probing	Probe ID	IPv6 Header	Payload Length

Figure 17. Previous Node Activation Message Format

Type ID: Is 1 byte in length and is a predefined identification number. All Previous Node Activation (PNA) messages will have a *type ID* of 13.

Type of Probing:

0	Delay (ms)
1	Loss Rate (0.01%)
2	Throughput (Kbps)
3	Utilization(0.01%)

Probe ID: This probe identification number will be used as the signature in the payload of the probing packets.

IPv6 Header: This header information is a copy of the IPv6 header of a particular flow the server wants to probe.

Payload Length: Will determine the size of the probing packets.

2. Next Node Activation Message

After the *next node resident agent* is installed, it requires certain parameters to initiate the measurement process (e.g., probe ID, source address).

The format of the *next node activation message* is shown in Figure 18.

The *type ID* will identify that this message is a next node activation message. This is a predefined identifier, and it has a value of 14.

As it was for the previous node activation message, the *type of probing* field will determine what kind of probing is in progress, and what metric the next node resident agent shall compute.

The *probe ID* will be used to check for the signature in the data packets. The probing packets are the same as the ordinary data packets, except for the signature in the end of its payload.

With the *IPv6 header* information, the resident agent will determine what kind of packets to monitor, and the *measurement interval* field will determine how long the resident agent will remain active for packet monitoring. After the *measurement interval* expires, either the resident agent will be uninstalled, or will remain passive waiting for another activation message to perform another measurement.

The *NIC to be monitored* field will tell the resident agent which network interface to monitor for probe packets.

1 byte	1 byte	4 bytes	40 bytes	2 bytes	1 byte
Type ID	Type of Probing	Probe ID	IPv6 Header	Measurement Interval (ms)	NIC to be Monitored

Figure 18. Next Node Activation Message Format

Type ID: Is 1 byte in length and is a predefined identification number. All Next Node Activation (NNA) messages will have a *type ID* of 14.

Type of Probing:

0	Delay (ms)
1	Loss Rate (0.01%)
2	Throughput (Kbps)
3	Utilization(0.01%)

Probe ID: This probe identification will be used to detect the signature in the last four bytes of the payload in the probing packets.

IPv6 Header: This is a copy of the IPv6 header of a particular flow the server wants to probe. The resident agent will determine what type of traffic it should monitor.

Measurement Interval: This value will determine for how long the resident agent will monitor probing packets.

NIC to be Monitored: This value will identify the network interface card to be monitored for incoming probing packets.

3. Probe Result Message

Once the probing process has ended and the *next node probing agent* has performed the metric performance computation, the agent sends back the results to the server. The results will be encapsulated in a message format shown in Figure 19.

1 byte	4 bytes	1 byte	3 bytes * Number of Results	
Type ID	Probe ID	Number of Results	Type of Result (1byte)	Measurement Result (2bytes)

Figure 19. Probe Result Message Format

Type ID: It is 1 byte in length and is a predefined identification number. All Probe Result (PR) messages will have a *type ID* of 15.

Probe ID: The server will identify for which link this probing result is for, and will keep track of all the ongoing probes. It will assign a unique *probe ID* for each probing process.

Number of Results: The message format may contain more than one probing result. The next node resident agent may send all four types probing results in a single message.

Type of Result:

0	Delay (ms)
1	Loss Rate (0.01%)
2	Throughput (Kbps)
3	Utilization(0.01%)

Measurement Result: The probing result for the particular *type of probing*, and *probe ID*.

4. Flow Chart And Timing Diagram of Server Probing Process

The server initiates a probing process by sending a resident agent to the *next node*, which is capable of collecting and computing probing statistics. This resident agent will wait for an activation message, that will tell the resident agent which network interface to monitor, how long the monitoring task must be performed, and most importantly, the signature *(probe ID)* of the probing packets.

The server then sends another resident agent to the previous node, which is capable of constructing probing packets and passing them to an output interface as regular packets. This resident agent will also wait for an activation message, which contains all the information for creating the appropriate probing process.

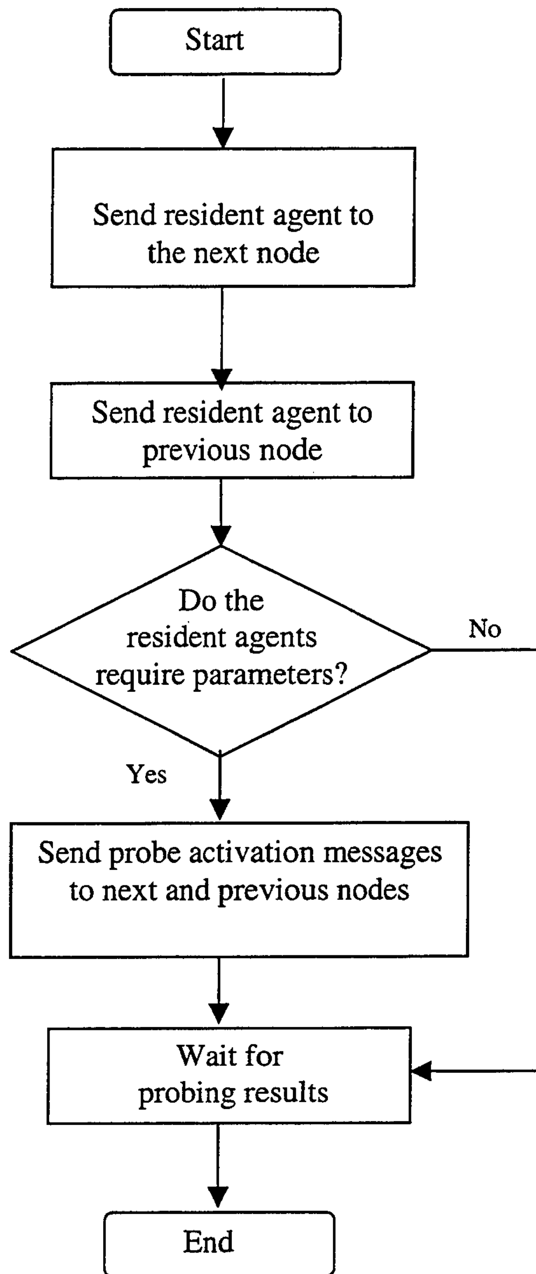

Figure 20. Flow Chart of Probing Process on the Server Side

The *previous node* receives the resident agent, and waits for the *activation message*, that will initiate the probing process. The flow chart reflects the overall process on the *previous node* side.

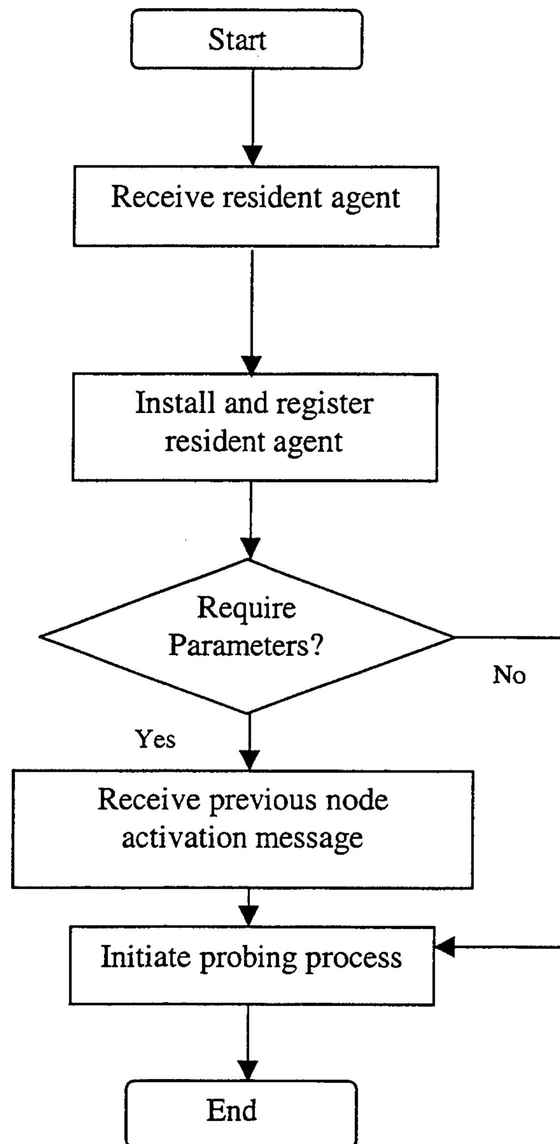

Figure 21. Flow Chart of Probing on the Previous Node Side

The *next node* receives the resident agent and waits for the activation message that will initiate the probe monitoring and computation process. The flow chart reflects the entire process on the *next node* side.

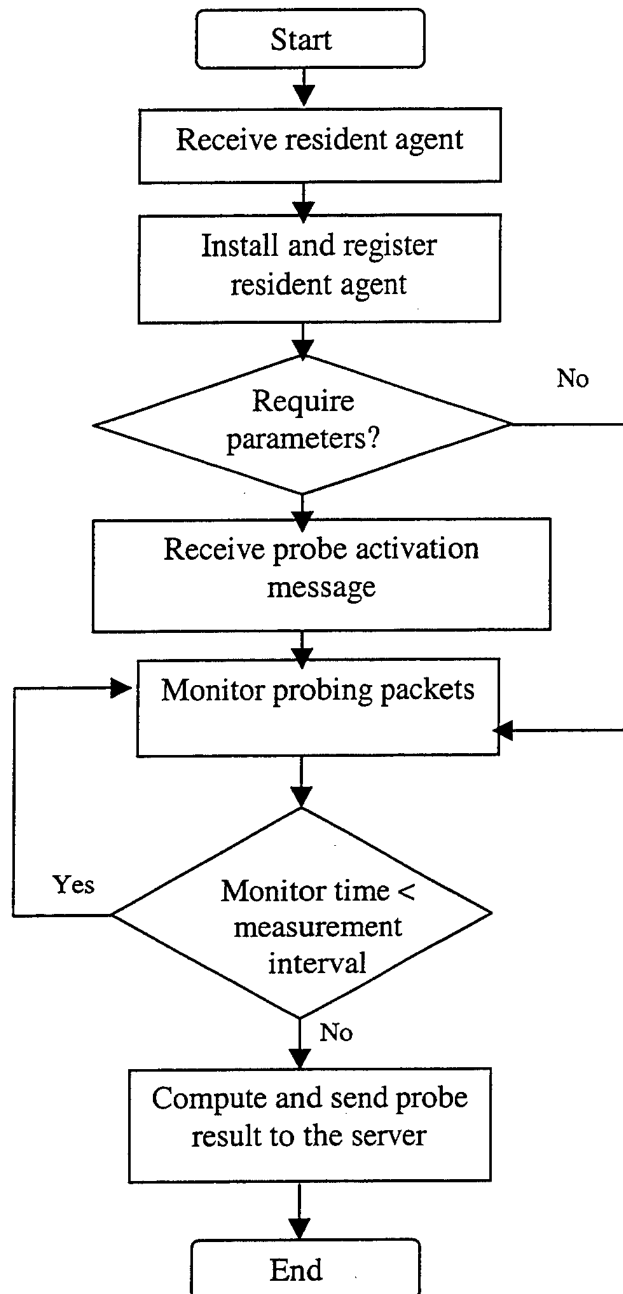

Figure 22. Flow Chart of Probing on the Next Node Side

The timing diagram of the overall SAAM server probing is shown in Figure 23. The resident agent needs to be sent first to the *next node* and then to the *previous node* to make sure that the *next node resident agent* is ready to monitor probing packets. Then the activation messages can be sent respectively.

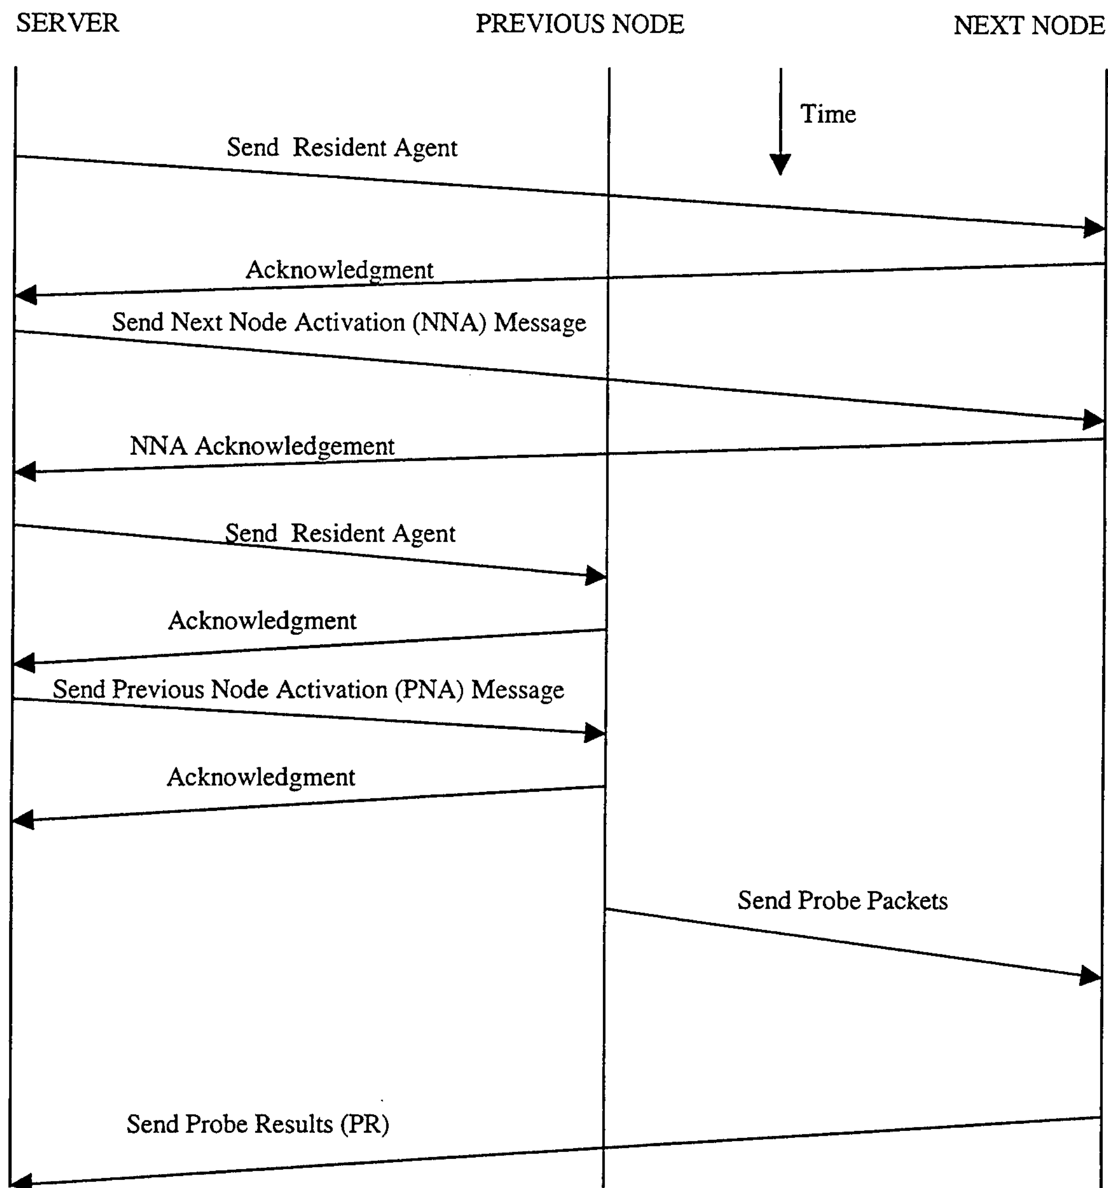

Figure 23. Timing Diagram of the Server Probing

VI. IMPLEMENTATION OF SERVER PROBING

A working prototype of the proposed SAAM architecture was developed by two former Naval Postgraduate School students. The prototype emulates the routing of IPv6 packets within a SAAM network, and operates within the existing IPv4 network environment. Figure 24 illustrates the SAAM model with protocol layers.

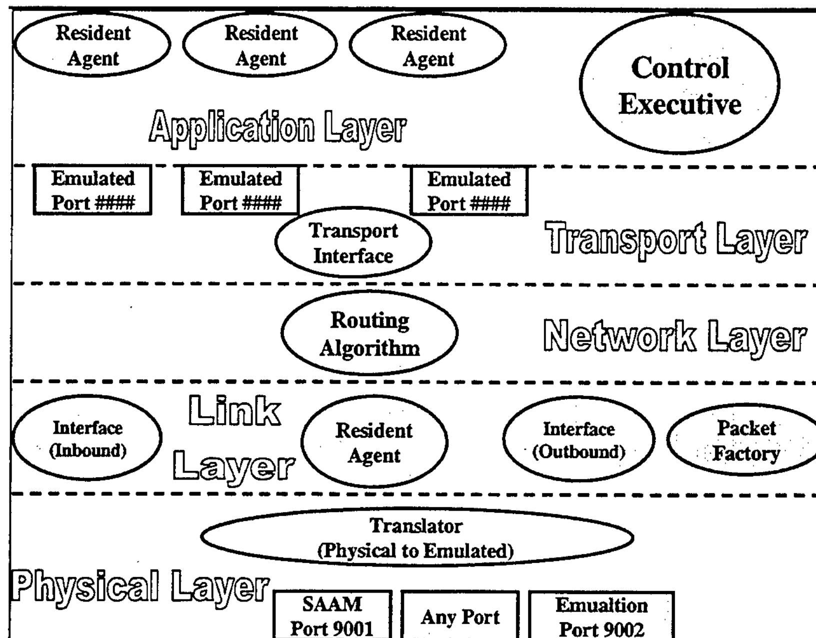

Figure 24. SAAM Prototype with Protocol Layers [From Ref.5]

In order to add server probing functionality to the SAAM prototype, some modifications to the existing code, including some additions to the class files, are proposed. These additions and modifications are based on the research findings of our studies. This chapter explains the added and modified class files, and the tests performed for this study.

A. GENERATION OF PROBE RELATED MESSAGES

1. PreviousNodeAct Class

The *PreviousNodeAct* class is an extension of the abstract *Message* class of the *saam.message* package. This class is used by the server to instantiate a *PreviousNodeAct* message. This message is sent to the *previous node* router to activate the probing agent installed on that router, and to provide the agent with a set of parameters specific to the current probe.

2. NextNodeAct Class

The *NextNodeAct* class is an extension of he abstract *Message* class of the *saam.message* package. The *saam.message* package is used by the server to instantiate a *NextNodeAct* message which is sent to the *next node* router to activate *the next node probing agent*. The *next node* router monitors the probing packets, calculates the probe results, and sends the results back to the server by instantiating a *ProbeResult* message

3. ProbeResult Class

The *ProbeResult* class is an extension of the abstract *Message* class of the *saam.message* package. This class is used by the *next node resident agent* to instantiate a probe result packet that will be sent to the server.

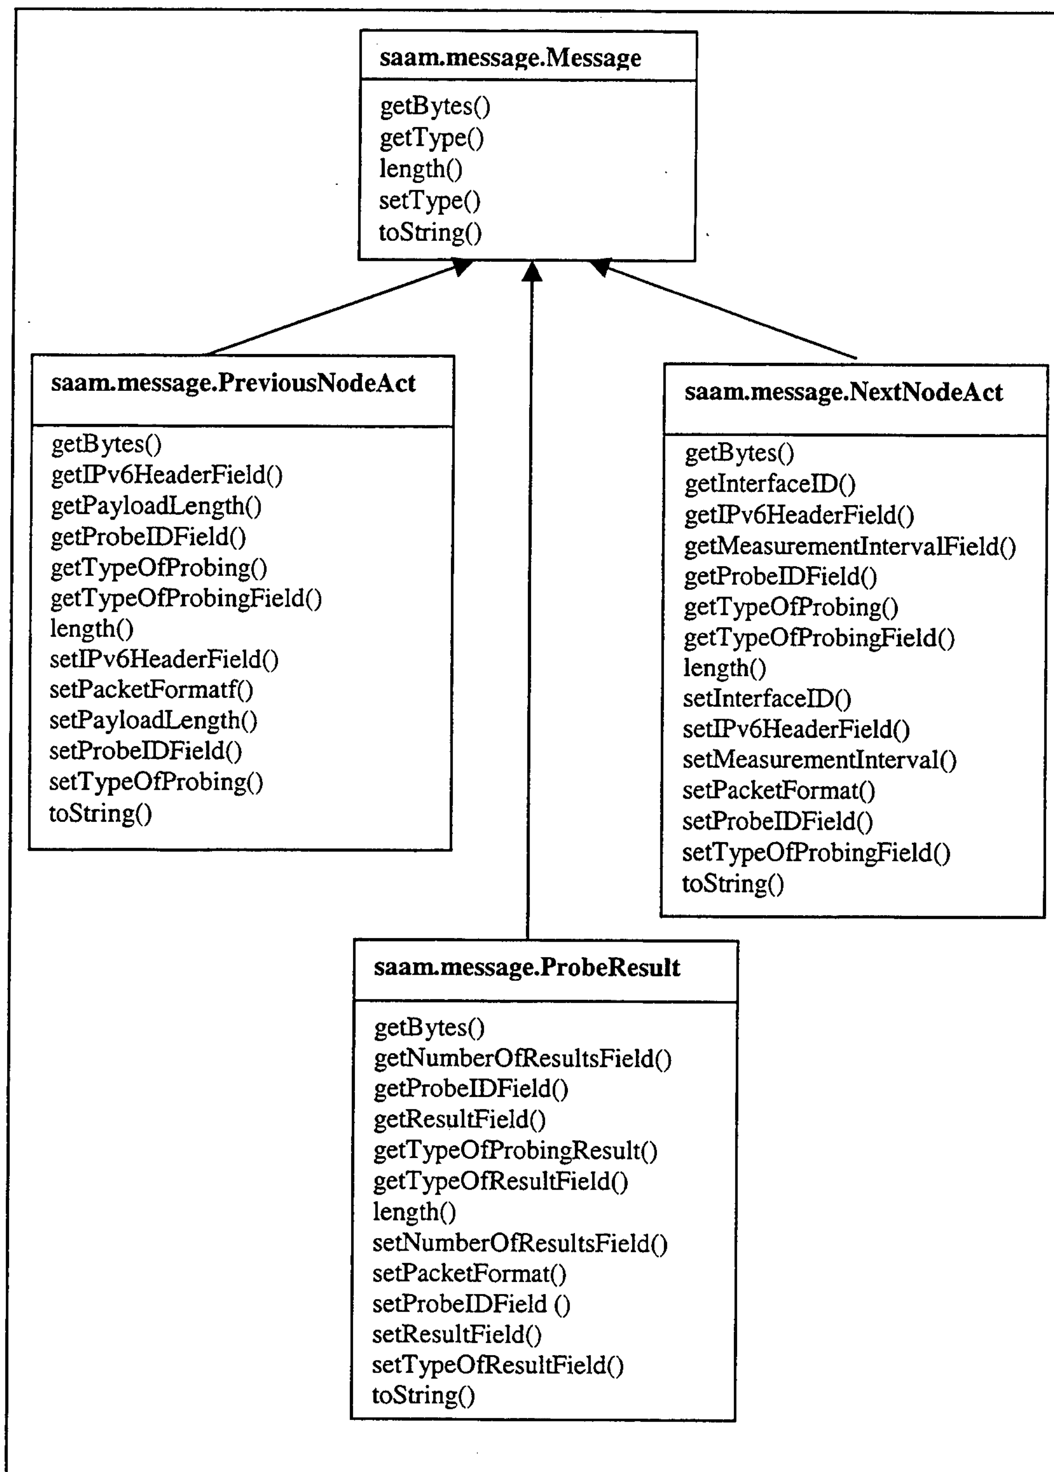

Figure 25. Message Class Structure

B. IMPLEMENTATION OF PROBING RESIDENT AGENTS

1. PreviousNodeProbe Resident Agent

A Java source file named "*PreviousNodeProbe.java*" is added to the *saam.residentagent.router* package, which includes all the resident agents that can be deployed to a router. The new file contains the code for the *PreviousNodeProbe class,* which is an extension of the Java *Thread* class. It implements the *ResidentAgentCustomer, ResidentAgent* and *MessageProcessor* classes of the *saam* package.

Implementing *ResidentAgentCustomer* allows the probing agent to register with the *ControlExecutive* as a dynamic router component. When a replacement of the probing agent arrives, the *ControlExecutive* calls the *replaceAgent()* method on all *customers* of the current *PreviousNodeProbe* agent. "

Implementing *ResidentAgent* provides the necessary calls for the *ControlExecutive (e.g., install, uninstall)*

Implementing *MessageProcessor* allows a probing resident agent to receive probe activation messages. (Recall that the server also sends a *PreviousNodeAct* message to the *previous node* to start the probing process.) Once a *PreviousNodeAct* message is received, the *ControlExecutive* will pass the message to the probing resident agent by calling the *processMessage()* method of that agent. The resident agent will parse the activation message and obtain the necessary parameters to start the probing process.

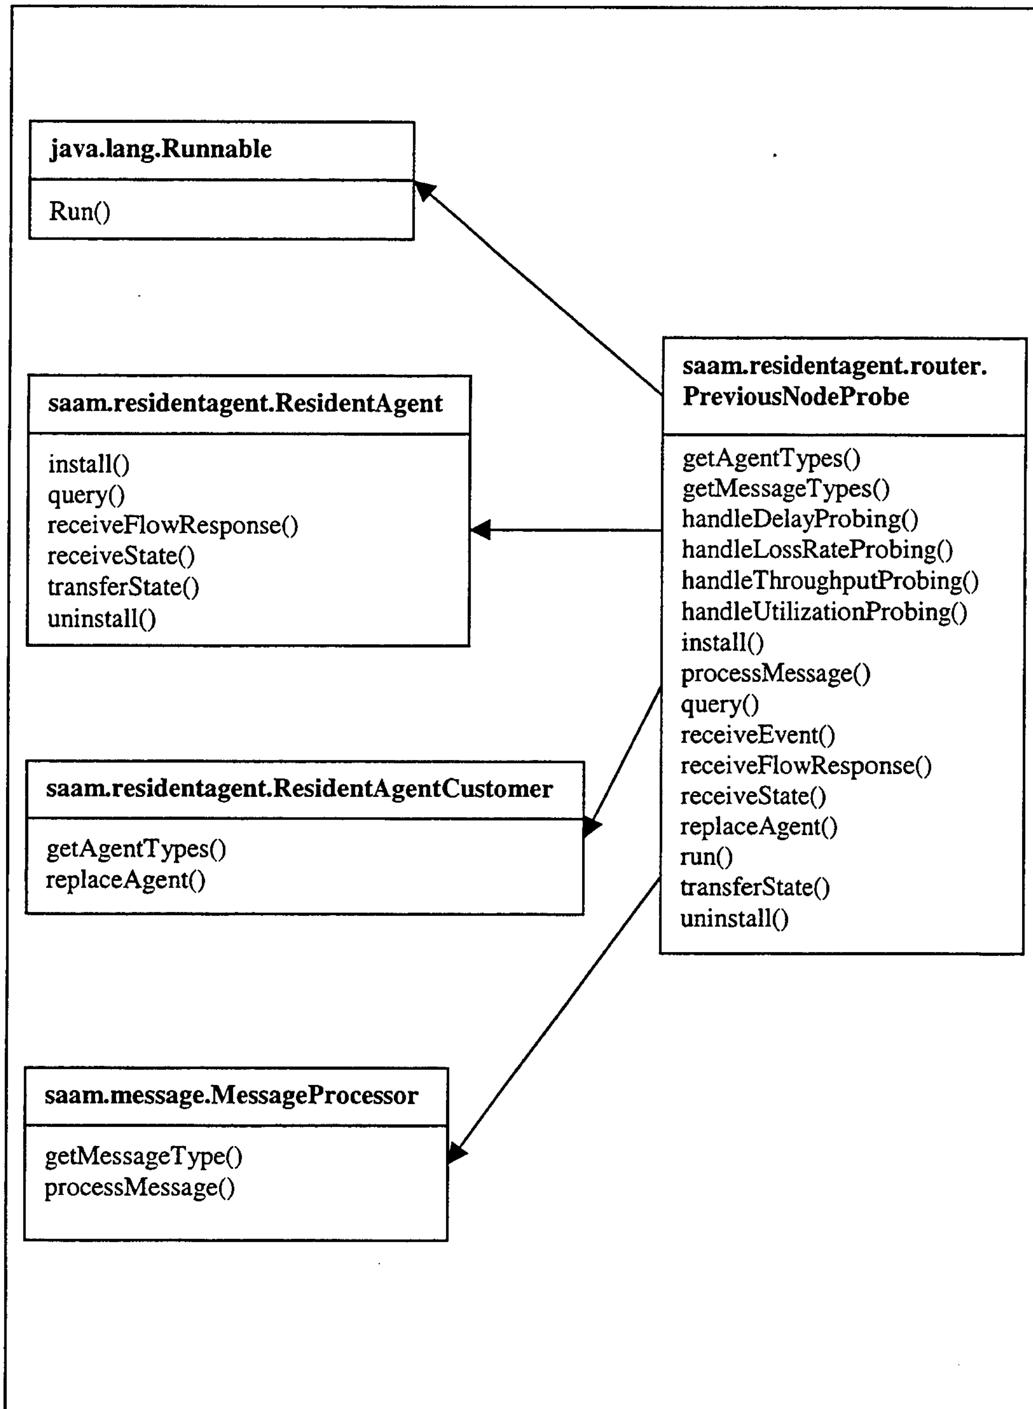

Figure26. PreviousNodeProbe Class Structure

2. NextNodeProbe Resident Agent

A Java source file named *"NextNodeProbe.java"* is added to the *saam.residentagent.router* package. The *NextNodeProbe* resident agent implements the *ResidentAgentCustomer*, *ResidentAgent*, *MessageProcessor*, and *SaamListener* class files.

One difference between the *NextNodeProbe* resident agent and the P*reviousNodeProbe* resident agent is the implementation of the *SaamListener* class. Components in the SAAM emulator can listen to particular *channels* to receive event notification by implementing the *SaamListener* class.

Channels are objects receiving events. Components registered to listen to a *channel* will receive an instance of each event sent to the *channel*. When a module wants to listen to a particular *channel*, the module has to register by using the *addListenerToChannel()* method in the *ControlExecutive* class.

Implementing *SaamListener* is required for the *NextNodeProbe* resident agent to monitor a particular network interface. The *interface ID* is specified in the *NextNodeAct* message, and the associated *channel ID* with the *interface ID* is provided by the *ControlExecutive*. The resident agent will receive a copy of every packet coming through this interface.

The implementation of the *ResidentAgentCustomer*, *ResidentAgent*, and *MessageProcessor* classes are the same as the *PreviousNodeProbe* resident agent. The *ResidentAgentCustomer* is required to receive agent updates. The *ResidentAgent* provides necessary calls for the *ControlExecutive* to perform install, uninstall, and state transfer of

the resident agent. The implementation of the *MessageProcessor* is required for the resident agent to receive the *NextNodeAct* activation message from the *ControlExecutive*.

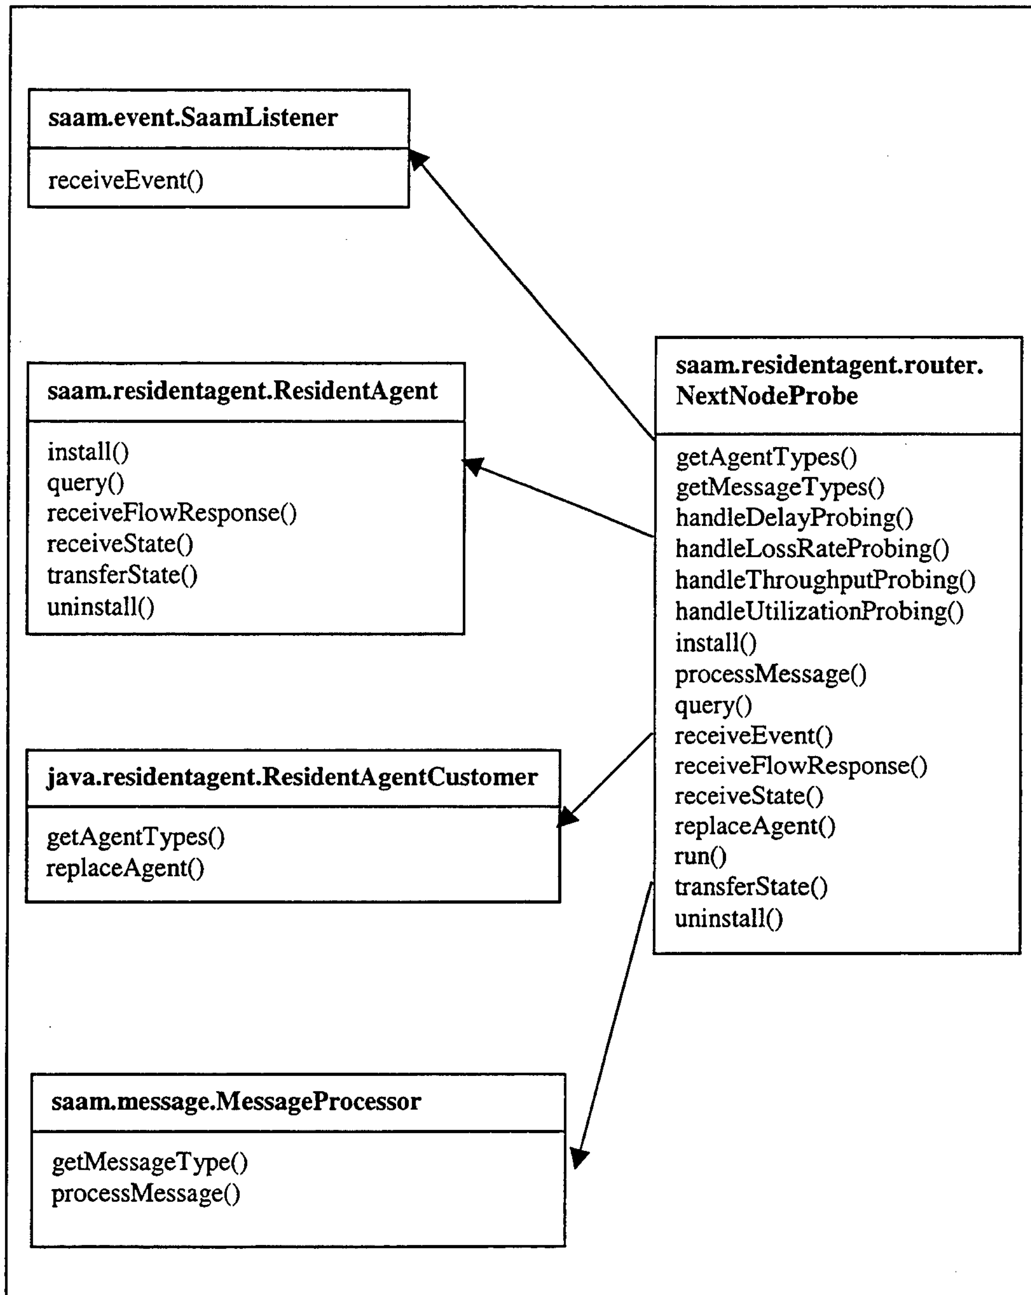

Figure27. NextNodeProbe Class Structure

C. MODIFICATIONS OF EXISTING CLASS FILES

1. PacketFactory Class File

The *PacketFactory* class is used by the *ControlExecutive* to send and receive SAAM control packets. The *PacketFactory* parses the content of each incoming packet to extract individual SAAM control messages. It then passes these messages to their corresponding message processors. For this task, several blocks of code have been added to the *processPacket()* method for handling of the probe activation and *ProbeResult* messages. The *append()* method has also been updated to include code for sending probe activation *ProbeResult* messages.

2. ServerAgent Class File

The *ServerAgent* class is a resident agent in the *saam.residentagent.server* package. A block of code has been added to its *processMessage()* method for handling of the *ProbeResult* messages. When *ServerAgent* receives a *ProbeResult* message, the *Server Agent* will pass the message to the *processProbeResult()* method of the *Server* class.

3. Server Class File

The *Server* class file is in the *saam.server* package. A method named *processProbeResult()* has been added to this class for processing of the *ProbeResult*

messages. This method displays the probe result information sent by the *next node* resident agent.

In order to initiate the probing process from the server side, an *initiateProbing()* method is also added to the *Server* class file.

D. TEST RESULTS

The server probing code has been integrated into the SAAM prototype and tested with the network topology shown in Figure 26. In the test topology, two routers are set up as *previous node* and the *next node*. Although the test topology is simple, it provides a generic test topology. The described probing process is exactly the same for one or more routers between the *previous node* and the *next node*.

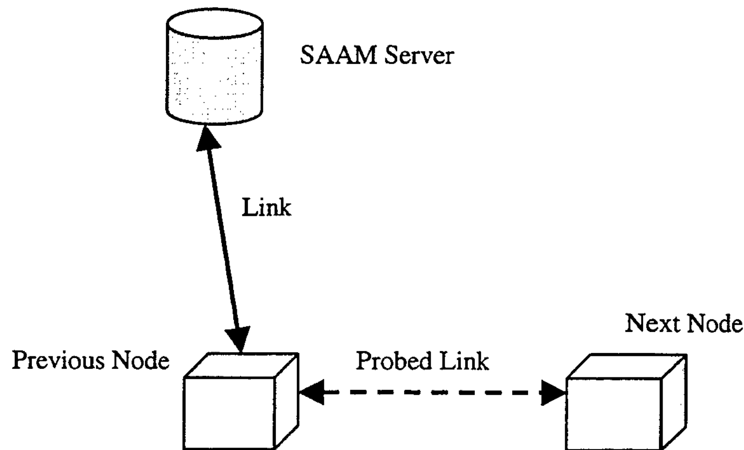

Figure 28. Server Probing Test Topology

The following figures are snapshots of the test results. Figure 29 is a snapshot of the *PreviousNodeProbe* resident agent, and Figure 30 is a snapshot of the *NextNodeProbe* resident agent. Finally, Figure 31 is a snapshot of the graphical user interface of the server displaying the *ProbeResult* message content.

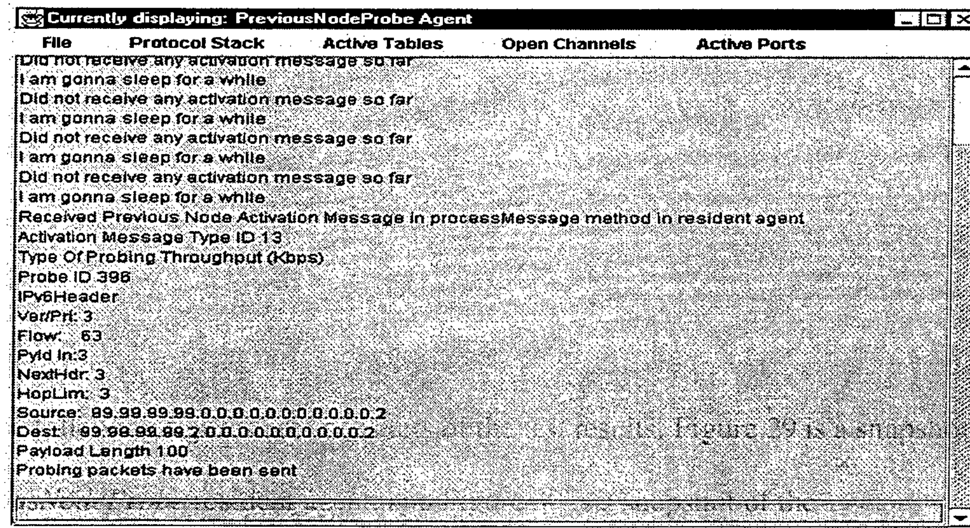

Figure 29. Snapshot of PreviousNodeProbe Resident Agent

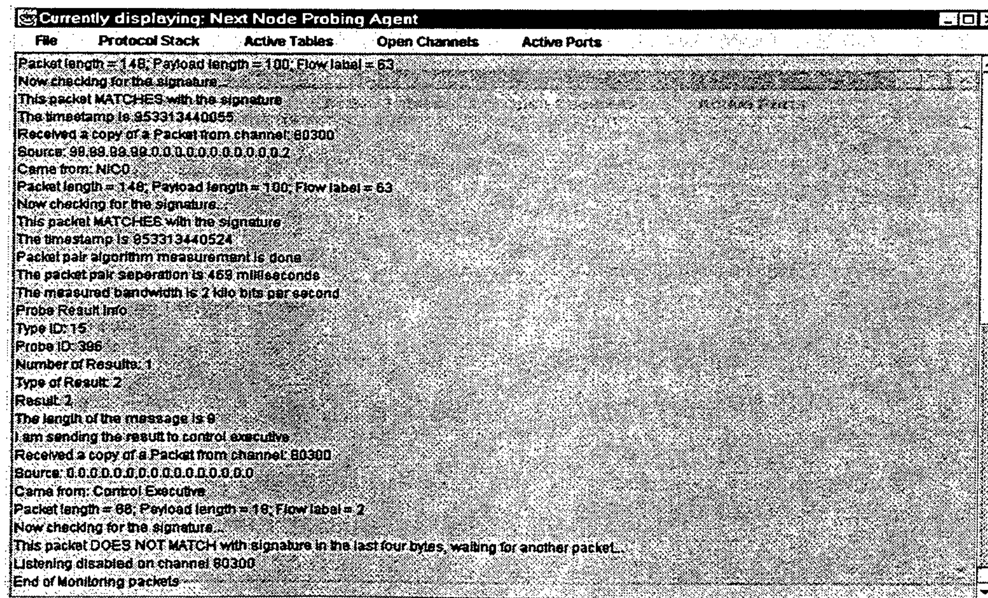

Figure 30. Snapshot of NextNodeProbe Resident Agent

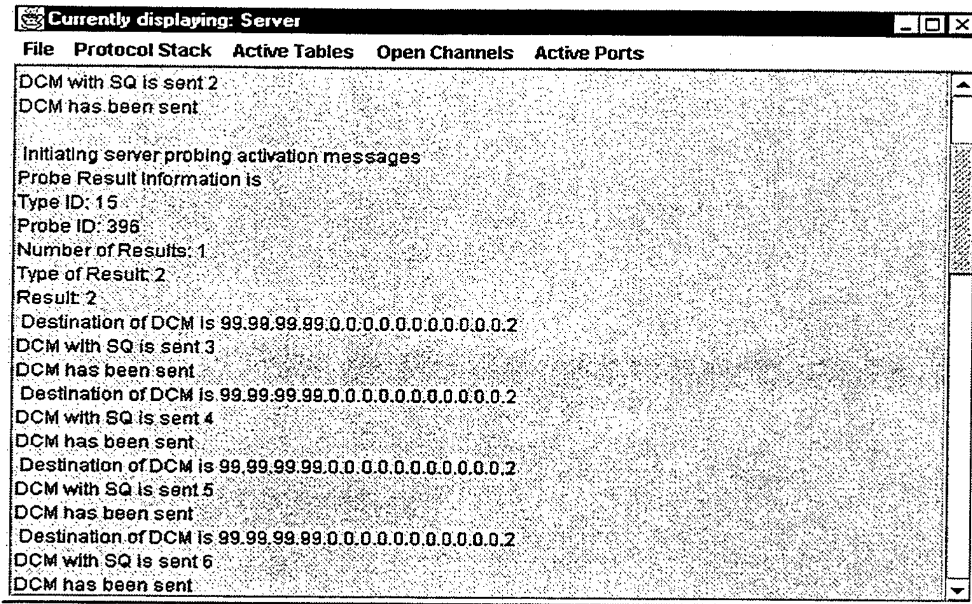

Figure 31. Snapshot of the Server

A series of tests were performed to measure the throughput of the dotted link on Figure 26. Table 2 shows the measured time separations of the probing packets and the computed throughput of the dotted link on Figure 26.

Test Number	Time Separation Of The Two Probing Packets (ms)	Measured Throughput (Kbps)
1	16	74
2	485	2
3	63	18
4	15	78
5	437	2

Table 2. Test Results

The measured throughput values have a wide range, from 2 Kbps to 78 Kbps. The first reason for the unstable results is the operation of the SAAM prototype at the application layer. The prototype runs on a regular PC with many other processes running at the same time. The resource utilization of these processes fluctuates over time. The second reason is the lack of guaranteed CPU time for SAAM related Java threads.

VII. CONCLUSION

A. LESSONS LEARNED

A server probing model has been designed and developed for the SAAM architecture. The implementation has been tested after its integration into the current SAAM prototype. The developed server probing model provides a secure (in terms of not being detected by the *node being probed*) and practical measurement technique for the SAAM server.

1. Integration

The SAAM prototype implementation is getting bigger and bigger, and one of the most difficult part of this thesis was the integration process of the server probing code into the current SAAM prototype. Some unexpected code errors occurred, which were very difficult to debug without first acquiring a thorough knowledge of the existing system.

2. Coordination

Coordination of the SAAM developers is another important issue of this study. Since, every developer's work was inter-related with each other, this study required good coordination and frequent group meetings.

B. FUTURE WORK

1. Extending And Improving Server Probing

The current server probing implementation only allows the server to check the throughput metric of a particular service class for a particular link. It needs to be extended to include support for measurements of other metrics such as *packet loss rate* and *latency*. The framework for such extensions has been put in place and the probing resident agents are designed to be extensible. The most important part is to select an appropriate algorithm for each metric.

In the current implementation, the agents perform just one measurement. This needs to be improved so that the agents could perform a sequence of measurements and collect multiple samples for one probe. The average result could then be computed and sent to the server.

2. Adding Server Probing Intelligence to the SAAM Server

There are two important questions that need to be answered:

- In what circumstance will the SAAM server initiate the probing process?
- How will the server use the results?

The probed link is predetermined and is specified in the current server probing implementation. Instead of this predetermination, heuristics should be built into the server to determine when and which link to probe.

In the current implementation the server just displays the content of a received probe result message on the graphical user interface, without performing any comparison between the probe results and the LSA data from the same link. The server should perform the comparison and take appropriate measures when there is a significant discrepancy between the two data. What kind of measures to take is a future research topic.

3. Security and Policy Management

The Control Executive receives the probing resident agents. Before instantiating these agents, the Control Executive should perform policy and security check. A policy check would prevent agents from accessing the *Channel* class directly and circumventing the Channel registration process. A security check would provide an authentication of the resident agents.

4. Rerouting of The Flows Under Interface Failures

The SAAM server needs to reroute the flows that are affected when an interface fails. The server should also update the PIB by deactivating the paths that include a SLP of the failed interface.

APPENDIX A. JDK INSTALLATION

JDK 1.1.*, is available from http://www.blackdown.org/java–linux /mirrors.html

For Java Development Kit installation, go to the URL above, and find the nearest mirror location. Find the package for i*86 platform, and download the file directly to the desired directory or move the file later to any other location. Once this is completed, follow the installation guideline provided for you. General guideline is provided in this section. Unpack the package using the Linux OS command:

$ tar zxvf filename.tr.gz

Point the PATH variable to the Java executables (e.g., java, javac, jar), which is under the */bin* directory. Here is an example of this process:

PATH=/your-directory/your-directory/jdk1.1.7/bin:$PATH

Also point your CLASSPATH variable to the file *classes.zip*, which is under the */lib* directory in the unpacked Java package. Don't forget to define the full path for the CLASSPATH environment, such as:

CLASSPATH.:/your-directory/your-directory/jdk1.1.7/lib/classes

Make sure, when typing *javac* or one of the Java executables in the command line, the system will recognize it. If not, reboot the system or re-do the instructions provided in the guideline. Another way to check if the system has set the CLASSPATH environment correctly, is by using the command:

printenv CLASSPATH

After running this command, one should be able to see the CLASSPATH variable pointing to the *classes.zip* file as an output in the command shell.

THIS PAGE INTENTIONALLY LEFT BLANK

APPENDIX B. PIZZA INSTALLATION

Pizza v. 0.39, is available at http://www.cis.unisa.edu.au/~pizza/Dist/

Since our test bed has Linux Operating System, we will pick the compressed Pizza distribution for the Unix platform. Download that version to the desired directory or move the compressed file (pizzadist.tar.gz) later on.

Once the downloaded file is unpacked, that file will create a pizza directory with two subdirectories, which are *classes* and *src*. The next step to follow is including the *pizza/classes* subdirectory in the CLASSPATH as shown below.

CLASSPATH.:/your-directory/your-directory/pizza/compiler/Main.class

If you have a CLASSPATH variable defined, then one should simply append the directory structure shown above:

CLASSPATH.:/your-directory-path/pizza/compiler/Main.class

We also need a script file *pc* including the following line.

java –ms8m pizza.compiler.Main

This file can be saved in any directory, where CLASSPATH variable points. Or one can add the full directory path onto the CLASSPATH variable. For the sake of clarity, simply pick the first choice.

If something does not work properly, most likely it might be a problem related to the CLASSPATH variables. Make sure they are set.

THIS PAGE INTENTIONALLY LEFT BLANK

APPENDIX C. JAVACC INSTALLATION

JavaCC 0.6.1, is available at:

http://www.cis.upenn.edu/~switchware/PLAN/software.html

It is a fairly simple installation. Begin downloading the class file from the URL given above, which is approximately 550 Kb. After this is accomplished, run the class file by simply typing:

java JavaCC0_6_1

in a command shell. This process will extract the files, and will create four sub-directories, which are:

- *bin*
- *doc*
- *examples*
- *src*

The *bin* directory includes the *javacc*, *jjdoc*, and the *jjtree* executable files, which are relevant to our PLAN package. The *doc* directory has the installation and information files. The *examples* directory has some sample codes related with different topics. The source code of the *JavaCC* can be found in the *src* directory.

As stated previously, we are primarily interested in the executables in the *bin* directory. Before installing the PLAN package, include the *bin* sub-directory in your PATH as follows:

PATH".:/your-directory/JavaCC/ bin"

THIS PAGE INTENTIONALLY LEFT BLANK

APPENDIX D. OCAML INSTALLATION

Ocaml distribution is available at http://paullac.inria.fr/caml/ocaml/distrib.html. Since we were using Linux OS as the test bed of our research, we downloaded the version for the Linux platform. This is a compressed file, which has to be decompressed with the following syntax.

- *tar zxvf <filename>*

After decompressing the file, it is ready for the installation process. The sequence of installation is as follows:

- *./configure*
- *make world*
- *make bootstrap*
- *make opt*
- *make ocamlc.opt*
- *make ocamlopt.opt*
- *umask 022*
- *make install*
- *make clean*

Ocamlp4 is decompressed the same way. The installation process of it as follows:

- *./configure*
- *make world*
- *make bootstrap*
- *make opt*

- *make install*

One must apply patches, which are available at the PLAN home page. The first patch is needed for proper compilation. The syntax of the patch is as follows:

- *Patch –p1 < ocaml-2.02-patch1.diffs*

There is also another patch for Ethernet card access, and the syntax is as follows:

- *Patch –p1 < ocaml-patch-2.0*

After all these packages are installed, it is time for the installation of the PLAN distribution. First *PLAN-ocaml-3.2-src.tar.z* must be downloaded from the PLAN home page (http://www.cis.upenn.edu/~switchware/PLAN/). This file needs to be decompressed with the following syntax.:

- *uncompress PLAN-ocaml-3.2-src.tar.z*

After the decompressing process, go under the plan directory and type the following syntax:

- *make all*

This process will complete the installation procedure of PLAN 3.2 distribution written in Ocaml programming language.

APPENDIX E. PLAN SERVER PROBING SOURCE CODE

```
(*
This program will create two packets at the destination node. This implements the Packet
Pair algorithm. The basic Packet Pair algorithm relies on the fact if two packets are
queued next to each other at the bottleneck link, they will exit the link t seconds apart:
t= packet size of ack / bandwidth
*)
(* the definitions for the service calls *)

svc print : 'a -> unit
svc getRB : void -> int
svc defaultRoute : host -> host * dev
svc thisHost: void -> host
svc gettimeofday: void -> int*int

APPENDIX F. PREVIOUS NODE ACTIVATION MESSAGE SOURCE CODE

```
/**
 * File: PreviousNodeAct.java
 * Author: Mustafa Altinkaya
 *         Naval Postgraduate School
 * Contact: altinkaya@yahoo.com
 * Date: March 2000
 * Compiler: JDK 1.2.1
 */

package saam.message;

import saam.util.*;
import saam.net.*;

import java.net.UnknownHostException;

/**
 * After the server sends the probe initiating resident agent to the Previous
 * Node, the resident agent needs to know certain parameters to start the
 * probing process. This Previous Node Activation Message contains the necessary
 * parameters to activate the probing process. The message will contain the following
 * fields as the payload.
 *
 * Type ID (byte): The type ID for Previous Node Activation Message is 13.
 * Type Of Probing (byte): There are four probing types, DELAY=0, LOSS_RATE=1,
 *                 THROUGHPUT=2, UTILIZATION=3
 * Probe ID (int): The server will keep track of the probing ID, so it can determine
 *          what link/node is associated with which result.
 * IPv6Header (40 bytes): Since the server wants to probe a particular flow, it simply
 *                 sends a copy of the IPv6Header for that particular flow,
 *                 so the Previous Node can generate packets with this header
 *                 information.
 * Payload Length (short): This will determine the payload length of the probing packets.
 *                 Sending this information will prevent of generating fixed sized
 *                 probing packets. The Node Under Probe will not be able to
 *                 differentiate probing packets from the ordinary data packets.

 * After the server sends the Next Node Probing Agent to the Next Node, this
 * message will serve as an activation message, which also contains the parameters
 * the agent needs.The message will contain the following information as the
 * payload.
 * Type ID (byte): The type ID for this message type is 14.
 * Type of Probing (byte): This will determine what kind of probing will be initiated
 *                  by the Previous Node, so the Next Node Probing Agent can
 *                  do the computation according this information
 * Probe ID (int): This information will serve to set the Probe ID field when constructing
 *              the Probe Result Message. It will also serve as providing information
 *              to intercept probing packets. Because, the signature at the tail of
 *              the probing packets is the same with the probe ID.
 * IPv6 Header (40 bytes): The IPv6 header information of the probing packets
 * Measurement Interval (short): This will determine for how long the resident agent
 *                       should monitor for probing packets.
 * NIC to be Monitored (byte): This will determine what NIC to monitor.
 *

/**
 * A ResidentAgent is an Object that can be delivered across a SAAM
 * network to a router, perform some type of processing or monitoring
 * on that router, and then be replaced, forward its state to another
 * router, or uninstall itself. In this case the NextNodeProbe resident
 * agent is in charge of monitoring the probing packets and compute the
 * probing parameters. There are four probing parameters, this resident
 * agent can compute the statistics of it. These are DELAY, LOSS RATE,
 * THROUGHPUT and UTILIZATION. The resident agent will wait for the
 * activation message which will include the parameters, type of probing
 * probe ID, IPv6Header information, measurement interval, and the NIC
 * identification to be monitored for probing packets. It will monitor
 * the NIC, looking for the packets that match the signature which is
 * at the tail of the payload. For throughput measurement it will
 * intercept the two probing packets recording the time of arrival.
 * The throughput will be computed according the packet pair algorithm
 * with the following formula
 *
 *    throughput = (packet length)/(time separation of the two packets)
 */

/**
* A PacketFactory can be used to build SaamPackets for sending or
* to receive SaamPackets and extract their atomic elements.  These
* atomic elements are currently one of two types:  A subclass of
* saam.residentagent.ResidentAgent or a subclass of
* saam.message.Message.<p>
* A sender would instantiate a PacketFactory to build
* Saam Packets.  The PacketFactory's append methods receive
* Message Objects, ResidentAgent Objects, or a String that represents
* the class name of a ResidentAgent as parameters and then dynamically
* construct the appropriate header based on the number of elements
* received and the current time.  The getBytes method is used to
* retrieve the byte array that represents the SAAMPacket that has been
* constructed by this PacketFactory.<p>
* The ControlExecutive uses the PacketFactory to receive and parse
* SaamPackets.

/**
 * Receives Hello messages from routers and then processes them. It starts
 * building a vector of IPv6Addresses from the interfaces included in the
 * Hello message. This vector is passed to the PIB's doesRouterExist() which
 * determines if a router with any of these interfaces have been identified
 * before. If this is a new router, a new unique node id is assigned.<p>
 * For each of the interfaces identified in the Hello message, if this
 * interface was is not known to the PIB, check to see if the corresponding
 * link is known to the PIB. If this link is not known to the PIB, add it.
 * Next, add the new interface between the node and link. Also, add each
 * service level pipe that is assigned within this SAAM region.<p>
```

```
* The next step is to rebuild the paths that are possible across the network
* now considering this new hello message. The frequency of these rebuilds is
* not a major concern in a controlled environment, but will need to be
* addressed later. Finally, a flow request is create and received for
* communicating back to this node. This is only possible if the PIB's
* determineAllPossiblePaths() has been executed after the processing of this
* particular hello message, if this a new router. After all paths to each
* known router are found, we finish this method with a call to
* determineEffectiveQoSForPaths(). The call to
* determineEffectiveQoSForPaths() ensures that even if no QoS parameters are
* known about these new parts of the network, that at least some initial
* values will be assigned. This initialization allows the new paths to be
* assigned if needed.
* @param hello An initialization message from a router.
