ABSTRACT

CTD data obtained during the period 28 December 1992 to 08 January 1993 are used to examine the hydrography and water mass distributions at the entrance to the Gulf of California. Data were collected for one across- and one along-gulf transection that intersected near the Gulf's mouth. The circulation at the Gulf's entrance was generally cyclonic. In the upper 200 m, a narrow, high-salinity core of strong baroclinic outflow (max speed 72 cm/sec) traversed the western sector of the region. The high-salinity ($S \geq 34.9$ psu) component of the core correlates to Gulf Water that originates in the inner-Gulf. Partitioned at the mid-basin Alarcon Seamount, the mouth's eastern sector was characterized by numerous bands of reversed flow, including inflowing cores of fresher ($S \leq 34.6$ psu) water from the Pacific. The estimated net transport across this

section was a 1.9 Sv inflow, with the majority of the flow occurring below 500 m. Comparison with data from an April 1992 cruise along the same across-gulf transection revealed greater transport and the notable absence of Gulf Water. The April circulation may represent simple recirculation of waters resident across the region.

ACKNOWLEDGMENT

I would like to express my gratitude to my thesis advisor, Dr. Curtis A. Collins, and to my co-advisors, Dr. Antonio Sanchez-Devora and Dr. Newell Garfield, for their support and guidance. I also thank Paul Jessen, and extend a special thanks to Tarry Rago for his help and patience.

I. INTRODUCTION

At the mouth of the Gulf of California, two prominent flows of water are observed. Nearshore, off the eastern banks of Baja California, is warm, highly saline ($S \geq 34.90\%$), equatorward flowing "Gulf Water" (Roden, 1964) that formed from a water mass originating in the northern Gulf. Converging at the southern tip of the Baja California peninsula, offshore from Cabo San Lucas, are Eastern Tropical Pacific Water of intermediate salinity ($34.65 \leq S \leq 34.85\%$) and cool, fresh California Current Water from the North Pacific ($S \leq 34.60\%$) (Roden and Groves, 1959). These two elemental water masses combine to supply a poleward flow of cooler, fresher water into the Gulf (Wyrcki, 1967; Griffiths, 1968), and are generally found along the central and easternmost sections of the Gulf's entrance.

This region is regarded as a transition zone in which the three aforementioned water masses interact to produce a complex local circulation (Stevenson, 1970). The vertical structure of these flows has been most recently studied by Bray (1988a). She inferred a three-layered thermohaline circulation system, having: 1) a surface layer, which is approximately 50 m thick and reverses transport direction with the seasonally reversing large-scale wind field, flowing north in the summer and south in the winter, 2) baroclinic outflow flowing along the western shores of the Gulf between the surface layer and about 250 m depth, and 3) baroclinic inflow flowing predominantly in the central sector of the Gulf between 250 and 500 m depth.

This paper is an attempt to refine the description of the hydrography and circulation occurring at the Gulf of California's entrance using Conductivity-Temperature-Depth (CTD) soundings collected in late December 1992 and early January 1993. The

December across-gulf structure will also be compared with a similar section obtained in April 1992 aboard the *USNS DeSteiguer* (Rago, et al., 1992).

A. OCEAN CIRCULATION IN THE GULF OF CALIFORNIA

The thermohaline circulation occurring near the mouth of the Gulf of California is the result of a series of complex forcing conditions within the Gulf that make the entire system unique (see Appendix A). Historically, the principal driving mechanism behind the Gulf's thermohaline circulation was thought to be evaporation in the northern Gulf. But Bray (1988a) noted that air-sea heat fluxes and momentum fluxes are likewise important to the Gulf's thermohaline circulation. She stated that, "...it appears that the Gulf gains heat from the atmosphere on an annual average, unlike the Mediterranean and Red seas, which have comparable evaporative forcing." To offset this heat gain and the accompanying moisture loss, Bray (1988b) explained that an advective flux of cold, fresh inflow and warm, salty outflow occurred at the

Gulf's entrance. Bray (1988a) also added that the Mediterranean and Red seas are characterized by a stabilizing vertical salinity gradient (in which salinity increases with depth) and show a two-layer exchange in which the outflowing layer is denser and more saline than the inflowing. The Gulf of California differs in that it consistently has a destabilizing vertical salinity gradient over the upper 700 m of the water column (salinity decreases with depth). This condition is maintained with few exceptions, and indicates that the temperature-salinity relationship follows a like trend, i.e., temperature decreases, salinity decreases. Lastly, temperature dominates the density signal and predictably decreases with depth. It follows that the vertical structure of transport, on average, consists of surface outflow and subsurface inflow. This theory agreed with observed vertical gradients of temperature and salinity and with baroclinically determined circulation patterns.

B. BACKGROUND REVIEW

Using temperature charts constructed from ships' logs, Thorade (1909) first described the circulation of surface waters in the southern regions of the Gulf of California as cyclonic with net surface transport in the direction of seasonal winds (Alvarez-Borrego, 1983; Merrifield and Winant, 1989).

Sverdrup (1941), using hydrographic data from the *E.W. Scripps* cruise of 1939, described the water masses of the Gulf. Analyzing water samples collected from cross-gulf transects along the entire Gulf, he noted that deep water samples collected in the "outer portion of the Gulf" (near the entrance) matched water properties of samples collected from the equatorial regions of the Pacific Ocean (salinity minimum $\approx 34.5\%$; temperature $\approx 5.0^{\circ}\text{C}$). Sverdrup added that surface temperatures in the "outer portion of the Gulf" were higher than those in the northern sections. Below the surface, at depths of 200 or 300 m and below, temperature was very uniform and decreased

regularly towards the bottom. His examination of the distribution of salinity revealed similar features. He noted that the highest salinities were found near the surface; but, maximum values increased going north from the Gulf's entrance. A layer of salinity minimum was observed at depths between 500 and 1100 m in the Gulf's "outer portion." Sverdrup added that the lowest values, corresponding to the salinity minimum of slightly less than 34.55‰, were observed near the Gulf's mouth.

Griffiths (1968) was able to build upon Sverdrup's findings at the Gulf's entrance. Deploying Nansen bottles along similar cross-gulf transections at the entrance, he observed an **Intermediate Water** at about 800 m (marked by a salinity minimum of * 34.5‰) and a **Subtropical Subsurface Water** overlying the Intermediate water, and extending up to about 200 m depth (marked by a salinity maximum of 34.8‰). Griffiths defined two additional layers. He explained that the convergence of southward flowing,

high-salinity **Gulf Surface Water** ($S > 35\%$) with the less saline **California Current Surface Water** at the entrance formed a high-salinity layer atop a salinity minimum. This minimum, found at about 100 m depth and at the western entrance of the Gulf, marks the presence of the California Current Surface Water (marked by a shallow salinity minimum of $\approx 34.1\%$).

Roden (1964) made similar conclusions from a series of hydrographic surveys conducted in the Gulf (1956-1961). He too noted the existence of numerous salinity maxima and minima in the water column's upper layers, and added that the region was characterized by a significant thermocline throughout the year. He stated that during February and April the isotherms and isohalines were observed ascending toward the coast of the Mexican mainland, suggesting upwelling by northwesterly winds. Spring and winter months revealed both a 50 m deep high-salinity core off the southern Baja coast and a salinity minimum of less than 34.7% at 100 m depth in the central sector of the Gulf.

Roden contended that the high-salinity core represented southeasterly flow from the interior Gulf, and that the salinity minimum reflected northwesterly flow from more southerly latitudes.

Roden (1972) conducted the most thorough sampling of the thermohaline structure at the Gulf of California's entrance. In late November-early December 1969, a densely spaced (* every 9 km) 34-station salinity-temperature-depth (STD) sensor cross-gulf transection was carried out. Observations were limited to the upper 1500 dbar. Excellent vertical and horizontal resolution of the thermohaline structure and baroclinic flow field at the Gulf's entrance was obtained. Like Griffiths (1968), Roden concluded that four distinct layers comprised the salinity structure at the Gulf's entrance. The layers described by Roden support Griffiths' earlier analysis with the exception of slight variation in depth ranges.

Roden (1972) computed the baroclinic flow across the Gulf of California entrance from the STD

data (see Appendix A). The observed flows were referenced to the 1500 dbar surface (or bottom, if encountered first). Baroclinic outflow from the Gulf was observed as a narrow high-velocity core near the western shore. The width of the core was about 30 km and extended to more than 1000 m in depth. Observed velocity maxima within the core included 55 cm/sec at the surface and just over 40 cm/sec at 600 m depth. Roden stated that this outflowing current had its origin in the northern realm of the Gulf and could be traced there using its salinity maximum, which exceeded 35.2‰ (Roden, 1964).

Roden observed the baroclinic inflow to be broader than the outflow, with the inflow predominantly in the central sector of the Gulf's entrance. Two cores of inflow were delineated. The first was approximately 20 km wide, with a maximum velocity of 26 cm/sec and centered between 50 and 450 m depth. The other core was located more to the east and found to be slightly wider. The corresponding flow

was restricted to the surface and had a maximum velocity of 46 cm/sec.

Roden (1972) determined the baroclinic transport above 1500 dbar to have a net outflow of 2.0 Sv (Sverdrup). This value was computed as the difference between the southward transport (12 Sv) and northward transport (10 Sv).

II. METHODS

As part of a joint study with the Mexican Navy and the Universidad Autonoma de Baja California (UABC), the Naval Postgraduate School (NPS) conducted a two-part study of the currents and hydrographic conditions at the entrance to the Gulf of California. The cruise and hydrographic surveys occurred during two consecutive weeks aboard the R.V. *Pt Sur*. Beginning on 28 December 1992 and ending on 08 January 1993, temperature and salinity data were collected via Conductivity-Temperature-Depth (CTD) soundings. Two transections were occupied and are represented in Figure 1. The first ran across-gulf, with the first CTD cast (CTD cast #20) made off the southeastern tip of Baja California. The transection extended approximately 180 km east-northeast to the continental shelf off El Dorado, Sinaloa, with a total of 19 CTD casts and 12 Pegasus drops.

The second transection ran along-gulf, consisting of 12 CTD casts collected between 03 and 08 January 1993. The transection started at 23° 11'N, 108° 25'W (CTD cast #37) and extended 210 km northwest into the Gulf, ending at 24° 34'N, 109° 50'W (CTD cast #60). The transections intersect at 23° 35'N, 108° 47'W. These two transections allow examination of both along- and across-gulf structure and associated geostrophic circulation at the Gulf's entrance.

Merrifield and Winant (1989) state that the region where the above transections were deployed consists "...of a series of trough-shaped, deep basins (1000-3000 m) and in open communication with the Pacific Ocean to depths of 3000 m..." The bathymetry of the across-gulf transection characteristically deepens offshore from Baja California and is dominated by the Alarcon Seamount located to the east. This narrow pinnacle, centered just north of the position where the along- and across-gulf transections intersect, rises sharply to within 1500 m of the surface

(Figure 1). Along the across-gulf transection, the seamount divides the Pescadero Basin into two bathymetrical regimes. The western basin separates the seamount from Baja and deepens quickly (in excess of 2500 m) in the absence of any significant continental shelf. East of the seamount, the Pescadero Basin initially acquires great depth, but the broad, shallow shelf extending some 80 km from the shores of Sinaloa is more characteristic. North of the Alarcon Seamount the Pescadero Basin narrows and extends for approximately 200 km, with maximum depths exceeding 3000 m. This deep water section (depicted by hatching in Figure 1) runs parallel to, and has its westernmost edge at 1-30 km from, the track marking the along-gulf transection. Centered between the 1000 and 2000 m isobath curves and bordering the narrow banks of southern Baja is the northernmost extension of the along-gulf transection (casts 55-60). West of this line and the 1000 m isobath are the shallows of the Cerralvo Bank. This shallow region, formed along the

outlying Isla Cerralvo (adjacent to cast #58), projects southward along with the southern reaches of Baja's banks. Depth contours along these features uniformly decrease inshore.

A. CTD DATA COLLECTION

The hydrographic data were collected using a Neil Brown MK-IIIB CTD. For each cast the CTD was lowered to near the bottom. CTD data were acquired during the downcast. With retrieval of the CTD, water samples were collected at the deepest depth of the cast, at intermediate depths, and at the surface. The water samples would later be used to calibrate CTD salinity. The CTD is considered accurate to within ± 0.005 psu (salinity), ± 0.005 °C (temperature), and ± 3.2 dbar (pressure) when properly calibrated and operated. Salinity, temperature, and pressure are resolved to 0.001 psu, 0.0005 °C, and 0.05 dbar, respectively. Tables C1 and C2 of Appendix C provide the date/time (GMT), geographic position, and bottom depth (m) for

each cast of the transections examined. Table C3 lists the data of those casts.

The CTD temperature and pressure sensors were calibrated at the Naval Postgraduate School calibration laboratory just prior to departure for the cruise. The pre-cruise calibrations were applied to the data during *in situ* data collection processes. The CTD pressure transducer was calibrated against a known standard, deadweight tester (DWT). Indicated pressures from the DWT and the CTD sensor were recorded across several equally spaced pressure intervals between 0 to 6200 dbar, at room temperature. Regressions fitting the CTD pressures to those of the standard yielded a CTD pressure correction of: $P = 1.00015 * (\text{CTD } P) - 14.25718$. Similarly, indicated temperatures from a known standard and the CTD temperature sensor were recorded over a range of equally spaced temperatures from 0 °C to 25 °C. Subsequent regression analysis yielded a CTD temperature correction of: $T = 0.99989 * (\text{CTD } T) - 0.00031$.

Post-cruise calibration was performed on the CTD sensors upon return to the Naval Postgraduate School. Post-calibration checks instrument performance while assuring the accuracy of the data collected. Post-cruise calibration methods were similar to those of the pre-cruise. For this cruise, differences between the results of the two calibration sets were negligible.

B. CTD DATA PROCESSING

CTD data were recorded at a rate of 32 Hz. These data were first processed using standard software that allows the user to scan the raw data and then to eliminate and interpolate across obviously bad data points (EG & G Marine Instruments). The program is dynamic and allows for the application of the time response constants for the conductivity, temperature and pressure sensors. The data were then bin averaged over 2 dbar intervals. Conductivity derived salinities were calibrated against salinity values determined from salinometer analyses of upcast bottle samples

(Table C4 of Appendix C). Following the procedure described in Rago et al. (1992), data points greater than two standard deviations from the mean of the differences between the compared salinity sets were discarded. A regression analysis on the remaining data points provided final correction to the CTD salinity data. Final correction to salinity yielded a CTD salinity of: $S = 0.99691 * (\text{CTD } S) - 0.05745$, with a standard deviation of ± 0.0047 .

Hydrographic data are presented in the form of vertical sections, scatter plots (e.g., T-S diagram) and data listings. The bulk of the illustrations within this paper were obtained by gridding and plotting the corrected CTD data using the **SURFER** contouring program by Golden Software, Inc (1989). All grids were constructed using the kriging method with a quadrant search of three points per quadrant. Shallow-layered profiles (surface-500 m depth) employed a grid spacing of 5 km horizontally and 20 m vertically. Deep-layered profiles (surface-3000 m depth) were made

with a grid spacing of 8 km horizontally and 20 m vertically, with the exception of geostrophic velocity, where the grid spacing was 5 km and 30 m, respectively. All corresponding plots were smoothed using the smooth option offered in the TOPO section in **SURFER**.

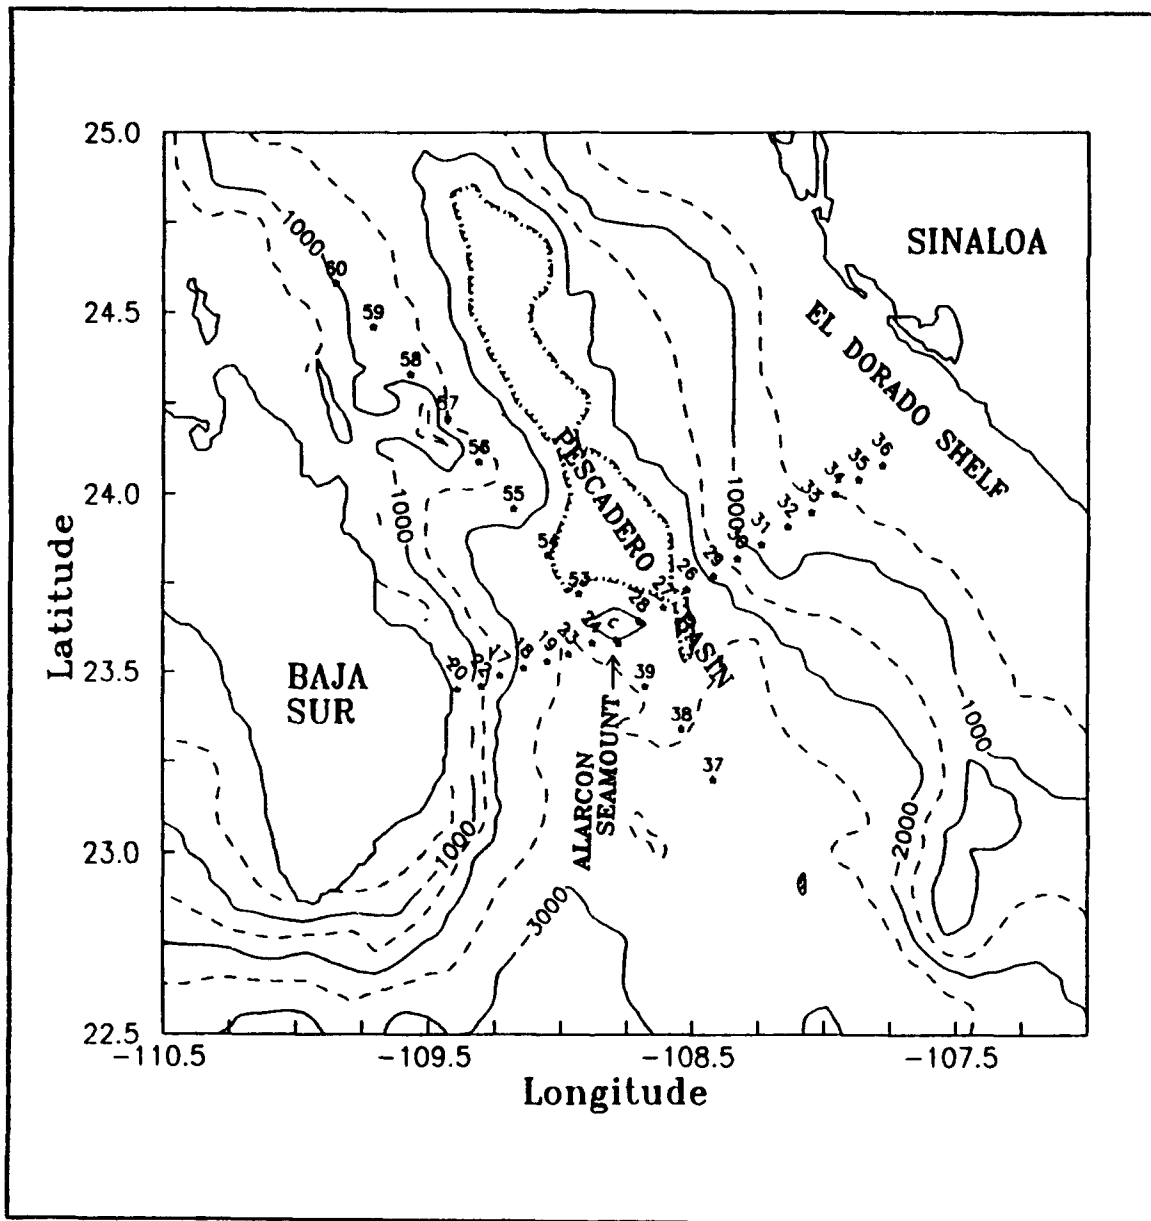

Figure 1. Location of CTD casts on the PESCAR 02 cruise at the entrance to the Gulf of California, December 28, 1992 - January 08, 1993. Labeling of casts 25 and 52 has been omitted to more clearly display Alarcon Seamount. Isobath spacing is 500 m.

III. RESULTS

Analyses of the data will be discussed in two parts. An interpretation of the study area's hydrography will precede discussion of the thermohaline circulation and water exchange balances.

A. HYDROGRAPHIC CONDITIONS

Hydrographic conditions in the region are defined by examining the across- and along-gulf transections of temperature, salinity and density anomaly. Water mass analyses are included to supplement these results. The structural definition gained from the examination of hydrographic properties should help understand the dynamics of the flow.

1. Temperature

Inspection of Figure 2a shows strong stratification in the upper 125 m of the across-gulf section. Surface temperatures across the Gulf's entrance are still warm (exceeding 22 °C) from the

preceding summer's intense insolation. Interesting features of the near-surface temperature structure include the upward bending of the 22 °C isotherm, breaking the surface on the western side of the Gulf between CTD casts #17 and #18. West of this position, surface temperatures are from 2 to 3 °C cooler than observed farther offshore. Depressed isotherms, centered in approximately 50 m of water below casts #17 and #18, indicate the presence of a warm-water core. On the eastern side of the Gulf, 140-160 km offshore from the Baja peninsula, elevated isotherms above 50 m depth mark the presence of a cooler core of water. Also, in the upper structure, between 100 and 200 m, warmer waters are found closest to Baja. Below 200 m, warmest waters are found next to shore, while it is cooler offshore in the open Gulf. A final point about the upper 500 m water column regards the wavy character of the isotherms as they stretch across the Gulf's mouth. Because of limited data, it's difficult to prove what exactly the wavy isotherms imply, but

they may be indicative of internal waves. The deep layers, depicted in Figure 3a, reveal no unusual details. Below 200 m, the temperature is uniform and decreases monotonically towards the bottom. At about 750 m the isotherms appear level. At 2250 m depth, water temperatures have cooled to 2 °C.

Examination of Figures 4a and 5a, the along-gulf temperature data sets (PESCAR 02, Leg III), reveal that the near-surface structure just described stretched some 40 km north into the Gulf's interior. North of cast #54, the isotherms slope down to the north, breaking the continuity of the upper ocean structure observed over the southernmost stations. This introduces an extensive surface core structure of 50 km length and 100 m depth between casts #55 and #60. These core waters are about 2 °C warmer than corresponding waters south of cast #54. In the subsurface waters below this section, the isotherms gently rise to the south and begin to level. The deep-layer structure again shows monotonic decreasing of

the isotherms and leveling below 1500 m. Observed as a whole, the along-gulf isotherms are sloped negatively across the transection, indicating slightly cooler subsurface waters to the south.

2. Salinity

The vertical salinity structure across the Gulf's entrance is shown in Figures 2b and 3b. The profile is characterized by salinity maxima and minima layers in the upper water column. The contouring illustrates that these layers are not uniform horizontally. The observed cores are distinct and prominent in the strongly temperature / density stratified upper 100 m layer. The best defined high-salinity core is centered near-surface in the westernmost realm of the transection (casts #20 to #18), reaching from the surface to about 75 m depth. Salinities within the core are in excess of 34.9 psu, with maximum values reaching 35.1 psu. Temperatures corresponding to this saline core exceed 20 °C. Owing to its high salinity, this core of water is easily

traceable to water of Gulf origin, and will often be referred to as Gulf Water. Examination of the central and eastern regions of the transection reveal intermittent surfacing of both saline and fresher water. Between casts #24 and #28, a relatively fresh pool of 34.6 psu salinity breaks the surface from 25 m depth. Farther east, originating at cast #27 and extending 60 km east, saline water of 34.8 psu pools at the surface from 75 km depth. The diversity of surface water salinity across the study area reflects mixing of the water masses comprising the near-surface layer (Stevenson, 1970). Across the central sector of the transection, several cores of low-salinity water embody the lower half of the upper 125 m layer. Indicated by hatching, the cores are observed 40-150 km offshore from the Baja peninsula in waters from 50 to 125 m deep. Salinities decrease from 34.6 to 34.3 psu within the cores. Associated temperatures range from 14 to 18 °C, and the isotherms show doming where the cores exist. The cores appear highly structured

and seem not to mix significantly with the surrounding water.

Plotting salinity on density anomaly surfaces offers another perspective of the salinity structure (Figure 2d). It delineates the location of the isohaline curves with respect to the density surfaces at each cast. This structure removes the presence and associated influences of internal waves, which in turn, allows closer inspection of the salinity cores. Also, spreading the density surfaces uniformly expands the upper layer, thus helping to distinguish the independent identifiable salinity cores there. Waters below this layer reveal less variability of salinity on a given density surface. The shallow salinity minimum (shaded triangles in Figure 2b) identified by Griffiths (1968) and Roden (1972) crosses through the heart of the cores. The nodes of low-salinity water ($S \leq 34.6\%$) have clear origins from the California Current Water (Griffiths); and the matrix of higher salinity water ($34.65 \leq S \leq 34.85\%$) is representative

of subsurface components of the Eastern Tropical Pacific Water (Stevenson, 1970). The latter extends to more than 350 m, forming parcels of higher salinity water that occupy the entire cross section. The deep salinity minimum is observed in the next underlying layer, stretching across the Gulf in waters ranging between 500 and 650 m deep (Figure 3b). Characterized by a salinity minimum of 34.5 psu and temperatures varying between 5 and 7 °C, this water mass is Pacific Intermediate Water (Reid, 1965). Beyond the deep salinity minimum, the Pacific Deep Water is distinguished by increasing salinity with depth, that reaches a maximum value of 34.65 psu near the bottom (Robles and Marinone, 1987). The deep layer T-S signature resembles that found in the Eastern Pacific, suggesting that there are no processes occurring in the Gulf to modify the deep waters. The waters that are modified in the Gulf are only apparent above the 11 °C mark, or approximately 250 m.

The along-gulf salinity structure is seen in Figures 4b and 5b. The most striking feature observed in the upper 500 m layer is the sudden and sharp descension of the isohalines north of station #54. This, in effect, outlines a large body of high-salinity water to the north that reaches from the surface to 175 m depth. The plot of salinity on density anomaly surfaces, Figure 4d, shows high-salinity Gulf Water ($S \geq 34.9$ psu) settled between the 24.25 and 25.25 kg/m^3 density surfaces. This observation appears to coincide with the same Gulf Water signature found on similar density surfaces in the western section of the across-gulf transection (Figure 2d). Such would imply that the origin of the high-salinity water isolated at the across-gulf transection is the inner-Gulf. Also, in the shallow subsurface waters below cast #53 (Figure 4b), a prominent vertical salinity boundary is disclosed. Reaching to 200 m depth, the boundary marks the dividing line between the higher salinity northern

waters and the less saline southern waters. Below the 200 m layer, the isohalines steadily decrease towards the deep salinity minimum at 650 m depth. The deep layer structure closely resembles that observed with the across-gulf transection. Below the deep salinity minimum, at a given depth, salinity to the north of Alarcon Seamount is less than that to the south.

3. DENSITY ANOMALY (γ_0)

The density anomaly discussed in this section was calculated from algorithms in Volume 4 of the International Oceanographic Tables (UNESCO, 1987). Commonly referred to as the potential density anomaly, with units of kg/m^3 , it is the density of water (ρ) calculated as a function of potential temperature (θ) referenced to the ocean surface, pressure (p), and *in situ* salinity (s) minus 1000 kg/m^3 . In equation form: $\gamma_0 = \rho(\theta, s, p) - 1000 \text{ kg/m}^3$ (UNESCO, 1991).

The density field, shown in Figure 2c, closely resembles that of the temperature

distribution. Isopycnal curves in the upper 150 m layer have the same character as the isotherms. The tight packing of the isopycnals indicates the strong stratification existent in the upper layers. Of particular interest is the abrupt shoaling of the 24.0 kg/m³ isopycnal curve, observed breaking the surface near cast #23. This feature marks a near-surface frontal boundary dividing denser water west of the curve from less dense surface water to the east. East of the Baja peninsula, between 75 to 175 m depth, are two sections of depressed isopycnals divided by an upward bulge or ridge centered 50-70 km offshore. The ridge approximately overlies the Alarcon Seamount located a few hundred meters below. The presence of the ridge implies water of lesser density along its flanks; and consequently, opposing geostrophic flows. Waters east of the ridge would flow north and into the Gulf, while waters west of the ridge flow in a southerly direction. Seasonal upwelling may be occurring on the eastern side of the Gulf as indicated

by the general upslope pattern of the near-surface isopycnals (Warsh and Warsh, 1973). Between 200 to 500 m depth, the isopycnal surfaces become less stratified and assume a bowed shape, bending downward towards the coasts. This feature supports the assumption that cyclonic subsurface exchanges occur as water flows into the Gulf along eastern boundaries and flows out along western shores. Predictably, the flow pattern would appear to circumscribe the mid-basin Alarcon Seamount. As with the temperature distribution, the density structure levels with depth, implying little or no motion at depths below 1500 m (Figure 3c).

The along-gulf density anomaly structure (Figures 4c and 5c) parallels that of the temperature, indicating a continuous upper layer structure stretching some 40 km into the Gulf. North of cast #54, the isopycnal surfaces tilt sharply down towards the north, before bending upward at about cast #58. The tilting isopycnals persist down through the upper subsurface layers, resulting in broadening with depth

of the area bounding their slope endpoints. The area defined by the sloped isopycnals represents a frontal boundary that consequently widens and protrudes south with depth. This boundary represents a transition zone separating less dense waters to the north from slightly denser waters south. Examination of the deep layer section (Figure 5c) shows that the isopycnals level at about 1250 m. This suggests a depth of no horizontal pressure gradient; and, may in turn suggest a good depth for establishing the level of no motion (LNM) when determining geostrophy. Approaching the bottom, the isopycnals show slight downward tilting towards the north. Such reflects that benthic waters north of the seamount are less dense than deep waters to the south. These features, when considered collectively, are indicative of westward flow onto the Baja banks, and further suggest the existence of a cyclonic horizontal circulation pattern.

4. Water Mass Analyses

Stevenson (1970) wrote that at the entrance to the Gulf of California Eastern Tropical Pacific Water, California Current Water and Gulf of California Water converge and interact. Isolating these water masses discloses to what extent they interact and how each influences the structure. Identifying them is achieved via the hydrographic relationships specific to each.

In the following sections, temperature - salinity (T-S) and density anomaly - salinity (σ_{θ} -S) diagrams are examined in order to resolve the water masses comprising the area of study. The T-S diagram, plotting temperature ($^{\circ}\text{C}$) versus salinity (psu), is first addressed. A succeeding discussion of the σ_{θ} -S relationship should offer an additional perspective on the water structure. Spiciness (π) analysis is

consistent with previous discussion and is included as an appendix (Appendix B).

a. T-S Diagram

The T-S diagram (Figure 6a) reveals three regimes of water. The regimes are: the surface layer (0-50 m); mid-layer (50-250 m); and, deep layer (250 m-bottom). Waters of the upper 50 m regime are clearly warm and high in salinity ($T \geq 22$ °C; $S \geq 34.7$ psu). Examination of the CTD data (Table C3 of Appendix C) shows that along the across-gulf transection there exists a varying surface mixed layer of 10 to 30 m within the surface layer. There is some resolution in the regime via a small break where salinity is about 34.9 psu. The break divides the well-mixed, warmer and less saline Tropical Surface Water from slightly cooler higher salinity water. The latter is conceivably Gulf of California Water (Gulf Water), high-salinity water from the inner-Gulf, and cooled by the seasonal southward winds as it moves south along the Baja banks.

The second regime of water extends from the bottom of the upper layer down to the 11 °C temperature break, which corresponds to a depth of 250 m. In this subsurface section, salinities range from the low extreme ($S \leq 34.4$ psu) to maximum salinity values ($S \geq 34.9$ psu). The section is a region of strong vertical stratification with minimal vertical mixing occurring. Citing Stevenson's classifications, the 34.6 psu salinity mark distinguishes California Current Water (where $S \leq 34.6\%$) from the more saline subsurface composites of the Eastern Tropical Pacific Water, or Subtropical Subsurface Water ($34.65 \leq S \leq 34.85\%$). Both masses were observed previously as independent cores in the salinity distribution diagrams. To a lesser degree, Gulf Water (where $S \geq 34.9\%$) is observed at the top of the section.

Proceeding deeper, the third and final regime is characterized by uniformity. A deep salinity minimum is reached at about 6 °C, corresponding to 700 m depth. This water corresponds

to the oceanwide Pacific Intermediate Water (Reid, 1965). Below the minimum, salinities increase slightly with depth, marking Pacific Deep Water (Robles and Marinone, 1987).

b. γ_θ -S Diagram

The γ_θ -S diagram (Figure 6b) is similar to the T-S plot. The diagram is also characterized by a three regime structure: extensive mixing is observed near the surface of the uppermost regime (where $\gamma_\theta \leq 24.75$ kg/m³); uniformity occurs at depth (where $\gamma_\theta \geq 26.50$ kg/m³); and, considerable variability occurs in between. The upper layer regime offers the same conclusions derived from the T-S diagram. Regarding the identification of Gulf of California Water, the 34.9 psu salinity break separates a pocket of more saline, slightly denser water from lighter, less saline water. The former likely corresponds to the dense Gulf Water from the inner-Gulf. The remainder of the layer appears well-mixed when compared to the

underlying stratified layers of the middle regime ($24.75 \leq \gamma_0 \leq 26.50 \text{ kg/m}^3$), where greater variability in salinity is observed.

The middle regime extends to more than 250 m from the surface, embodying separate cores of high-salinity water and water of lesser salinity. Classification by salinity is used to determine along which isopycnal surfaces the elemental water masses are dispersed. Subsurface California Current Water has densities ranging from 24.75 - 25.50 kg/m^3 . Densities representing the subsurface regime of the Eastern Tropical Pacific Water (Subsurface Subtropical Water) range between 24.75 - 26.50 kg/m^3 . The increased variability observed in the subsurface layer is consistent with the strong stratification there. The stability of the layer diminishes vertical mixing between the water masses, giving the banded structure observed.

The third regime, corresponding to a depth below 250 m, indicates the water structure

assuming uniformity and stability with depth. The density of the deep salinity minimum of the Pacific Intermediate Water is approximately 27.15 kg/m^3 . Densities increase to 27.75 kg/m^3 approaching the bottom.

5. Summary

The study area's hydrography supports the concept of a two-tiered water exchange process existing at the Gulf of California's entrance. The near-surface vertical structure is interlaced cores of both warm, saline water and cooler, less saline water. The former is believed to represent equatorward flow exiting the Gulf, while the latter is generally associated with poleward flow into the Gulf. A warm (but cool at the surface) saline layer, penetrating down to 75 m depth and centered 25 km offshore from the Baja peninsula, is suggestive of equatorward flow believed to have originated within the Gulf's interior. Fresher salinity cores were observed east of a ridged transition zone centered approximately 45 km

from Baja. These cores, with salinities less than 34.7 psu, are thought to be northward intrusions of admixtures of California Current Water with the surrounding subsurface Eastern Tropical Pacific Water (Subtropical Subsurface Water). Combined with the influx of an unchanging deep layer Pacific Intermediate Water ($S \leq 34.6$ psu, $T \leq 10$ °C), these cool and fresher waters account for nearly all of the inflow into the Gulf. An along-gulf transection indicates a large frontal boundary stationed near the across- and along-gulf intersection. The front, besides marking a transition of saltier near-surface, but less dense, northern waters from southern waters, also lends credence to the existence of a large cyclonic horizontal circulation encompassing the entire field of study.

B. BAROCLINIC FLOW

CTD station data were used to compute dynamic height, which was in turn used to examine the geostrophic flow field. Three techniques, each distinguished on the basis of where the level of no motion (LNM) was assumed, were employed and compared.

1. Geostrophy Using Deepest Common Depth

The first technique established the LNM at the deepest common depth (DCD) between stations. The resulting geostrophic velocity transection in Figure 3d shows four distinct currents. Baroclinic outflow, observed as negative (southward) flow, is predominant in the western part of the Gulf as a narrow high-speed core. The flow width stretches eastward from cast #18 some 25 km and extends down to 1250 m deep. Current velocities within the core reach a maximum of 58 cm/sec at the surface, while a subsurface maximum of 72 cm/sec was recorded at 60 m depth. Less prominent incidences of southward flow are observed in the eastern part of the transection at cast #27 and as a

wedge along the Sinaloa coast shoreward of cast #32. These flows are less intensive and only penetrate the upper layer of the water column, producing minimal outflow. According to Roden (1972), the intense and deep running outflow hugging the Baja banks should be high-salinity water of northern Gulf of California origin. The observations made previously regarding the salinity distribution give support to this.

Baroclinic inflow into the Gulf is observed as cores of positive (northward) flow. The first of two of these northward flows is centered 70 km east of the Baja peninsula. The core of this northward flow is confined to the upper 100 m layer of the water column and is approximately 20 km wide. Currents near the surface reach a maximum speed of 56 cm/sec, while weaker currents are observed with depth. The location of the velocity core coincides with the position of the cool, low-salinity cores examined previously in the temperature and salinity distribution diagrams, suggesting intrusion of California Current Water into

the Gulf. The second incidence of northward flow is observed between casts #26 and #29. This core has a maximum width of about 15 km and extends to nearly 500 m depth. Highest speeds (approaching 35 cm/sec) are observed near the center of the upper 100 m layer.

Isotachs of .0 cm/sec separate regions of northward and southward flow. In Figure 3d, three 0 cm/sec isotachs are observed extending vertically from the surface, then almost merging as they level between 1250 and 1500 m. This infers that geostrophic velocities in the vicinity of 1500 m approximate zero. Below 1500 m, weak currents are observed. The currents in this deep layer vary in direction and have speeds seldom exceeding 5 cm/sec.

2. Geostrophy Using 1500 m Reference Level

From the preceding observance of near zero velocities at 1500 m, the second technique for determining the geostrophic velocities was applied. In this procedure, while it was still necessary to use the DCD method for shallow water casts, deep casts of

the transection were referenced to a 1500 m LNM (Figure 3e). This technique provided no significant change over using the DCD technique independently. Minor differences in the results include expected leveling of the 0 cm/sec isotachs at the 1500 dbar level. The 0 cm/sec isotachs below the 1500 dbar level appear to have greater distortion. This feature results from velocity changes below the LNM associated with the weak horizontal and vertical gradients which occur there.

3. Geostrophy Using Reid and Mantyla

The third and final technique used in determining the geostrophic velocities was derived from Reid and Mantyla (1976). In its simplicity, the gradient of the offshore dynamic height field (with respect to the 1500 dbar level in this application) is repeatedly extrapolated shoreward along the deepest common standard pressure surface between station pairs. The technique was derived in order to explain variations of coastal sea level and, hence, achieve a

better representation of the geostrophic flows occurring in the shallower water. The Reid and Mantyla method, depicted in Figure 3f, did accelerate the geostrophic velocities in the eastern half of the Gulf. East of station #26, several small-scale cores of both inflowing and outflowing water are revealed in the upper 100 m layer. The other distinctive contrast is the descension of the 15 cm/sec isotach from the surface (cast #26) to 750 m depth. Such implies substantial deep-layer current activity occurring in the eastern section of the Gulf.

Of the three techniques used, it is of the writer's opinion that the first method provided the most realistic representation of the baroclinic velocity. Establishing the LNM at the DCD between stations offers a procedure that is consistent over an entire deep/shallow water transection. Adjustments to the LNM are simply made at the individual station pairs, allowing a fuller and more customized representation of the vertical structure. The computed

velocity distribution in turn more accurately portrays the entire current field.

4. Along-gulf Geostrophy

Examination of Figure 5d, the along-gulf transection using the DCD method, reveals a number of weak upper layer and mid layer velocity cores within the water column. North of cast #54 and flowing in the upper 250 m is a broad negative (westward) flow with maximum velocities of 47 cm/sec occurring near the surface. North of this flow is a similarly broad positive (eastward) flowing current characterized by maximum velocities of 39 cm/sec at the surface. These adjacent, but opposing, current bands may mark the presence of an anticyclonic eddy in the region. The enclosed 0 cm/sec isotachs north of cast #52 disclose additional but slower (velocity \leq 15 cm/sec) flowing eastward currents. South of cast #52, at the position marking the intersection of the across- and along-gulf transections and Alarcon Seamount, westward flowing currents (15 cm/sec isotach) are observed extending

from the surface to about 500 m depth. Below 1500 m, regimes of westward flow to the north of the Alarcon Seamount and eastward flow to the south predominate. Observed together, these velocity cells are indicative of a circulation system scattered with eddylike features in the upper layer structure overlying a larger cyclonic system organized at depth.

5. Volume Transport

The baroclinic volume transports occurring over the entire across-gulf transection were calculated using the cut-and-fill option of **SURFER**. The program calculated positive/negative volumes in units of km^3/sec . The volume calculations were then divided by 10^5 to give volume transports in Sverdrups (Sv). The volume transports are listed in Table 1. Transports were calculated for the full section water column, and then subdivided horizontally into the following three sections: 1) 0-50 m surface layer, 2) 50-250 m mid-layer, and 3) 250-3000 m deep layer. The DCD method yielded a net inflow of

1.9 Sv, the difference between a northward transport of 8.4 Sv and a southward transport of 6.5 Sv. These values are larger than expected, and also indicate a 23 % imbalance between outflow and inflow.

When the water column is divided into subsections, the resulting values would appear to suggest that the greatest source of transport in or out of the Gulf originates in the deepest section (@ 250 - 3000 m). The upper two sections show significantly less transport activity than the deep section. The upper two sections combined yielded a net outflow of -0.7 Sv, the difference between a total northward transport of 2.5 Sv and a total southward transport of 3.2 Sv. These values appear reasonable, and the -0.7 Sv net outflow is in generally good agreement with the ± 0.9 Sv total suggested by Bray (1988a).

The deep layer section yields a net inflow of +2.7 Sv, the difference between an inflow of 6.0 Sv and 3.3 Sv. The uncertainty over the large magnitude

of the full section transport values and exchange imbalance appears to be related to the deep layer analyses. It is conceived that any inaccuracy in estimating the sluggish speeds occupying the voluminous deep layer would translate into considerably larger error in the associated transports.

For the 1500 m LNM calculation, transport results were nearly opposite of those observed using the DCD method. The full section analyses yielded a net outflow from the Gulf of -1.7 Sv, the difference between an inflow of 6.5 Sv and outflow of 8.2 Sv.

The final results are from application of the Reid & Mantyla technique. This resulted in a significantly higher inflow (12.0), and hence a positive net transport value (+3.7).

The transport balance is defined by the following equation: $V_i + R + P = V_o + E$ (Pickard and Emery, 1990). The inflow and outflow transports are given by V_i and V_o , respectively, with runoff (R),

precipitation (P) and evaporation (E) being the other variables. Experimentally, inflows and outflows have not always balanced (Roden and Groves, 1959 and Roden, 1972). Anticipating that evaporation in the Gulf (≈ 0.95 m/yr by Bray (1988a)) to be considerably greater than runoff and precipitation, would suggest an expected small net inflow to balance Gulf processes. The +1.9 Sv full section net inflow is again larger than was expected, and is credited to having included the deep layer section in the results. Still, the weaker currents of the voluminous deep layer do appear to be organized into regions of inflow and outflow. Taken collectively, they are responsible for an appreciable amount of the transport activity occurring at the Gulf's entrance, and should thus be considered.

6. Salt Budget

A salt budget analysis was performed as a tool to help interpret transport values, and also confirm the most suitable geostrophy technique. The salt budget for the study region can be estimated by simply multiplying the volume transports into (V_i) and out of (V_o) the Gulf by their corresponding salinities, S_i and S_o . A reasonable balance of salt should exist, as defined by the following conservation principle: $V_i\rho_iS_i=V_o\rho_oS_o$ (Pickard and Emery, 1990). The densities of the above relation, ρ_i and ρ_o , can be ignored since their variation is not appreciable (less than 3 %).

The cut-and-fill option of **SURFER** performed the necessary operations, producing the salinity transports (or salt fluxes) presented in Table 2. Units of $\text{psu}\cdot\text{Sv}$ were obtained by dividing computed results by 10^5 . The $\text{psu}\cdot\text{Sv}$ were subsequently converted to more conventional units of metric tons salt per

second (tonne/sec), approximating the seawater density as 10^3 kg/m³ and using g salt per kg water for psu.

Review of the full section results in Table 2 reveals that the DCD method provided the best results for this experiment. The Reid and Mantyla method gave the greatest imbalance of the three techniques, over twice that observed with the other techniques. And the negative-valued net salt balance (-5.0×10^4 tonne/sec) obtained using the 1500 m LNM, questions its use as the best option. Given the exchange processes governing the Gulf, where inflow replenishes evaporative loss with water and accompanying salt, a net loss of mass, as calculated above, would seem highly improbable. The salinity transports derived using the DCD method are higher than anticipated (with a net imbalance of $+6.0 \times 10^4$ tonne/sec), but are the most reasonable results from the techniques tried. Predictably, as with the volume transports, the most significant figures were obtained from the deep, 250-300 m layer. Again, the deep layer processes are no

doubt real; however, the lack of balance in the salt transports calculated there seem too high, and should be considered as the most likely source of the wide, full section imbalance.

7. Summary

Three geostrophic velocity regimes comprise the circulation occurring at the entrance to the Gulf of California. A large flux of deeply-penetrating southward flow was prevalent in the western Gulf along the slopes of the Baja shelf. This current exhibited maximum speeds of about 70 cm/sec in the near-surface layer, and was correlated with high-salinity water from the northern Gulf. In the central and eastern sections of the Gulf, a combination of both northward (inflow) and southward (outflow) currents were observed in the upper 500 m layer. Two prominent inflow currents were isolated. One, centered just 20 km east of the large outflowing core, was constrained to the upper 100 m layer and had maximum velocities near the surface, approaching 56 cm/sec. The other, a less intense but larger core, had maximum current speeds of about 35 cm/sec flowing within the core. Centered approximately 75 km off the Mexican mainland, the core extended 400 m deeper into the water column

than the other inflow core. Both inflowing cores entrained cool, low-salinity water, likely originating from California Current Water. Although not as evident as the high-intensity cores found in the upper layers, deep water currents in both directions were prevalent in the voluminous abyssal layer. Rarely exceeding speeds of 5 cm/sec, these currents, when considered as a whole, move immense volumes of water; and therefore, should be recognized as having an integral role in the advective processes occurring in the Gulf. However, the low current speeds prevent an accurate computation of the baroclinic flow. Deep waters to the north of the Alarcon Seamount moved westward towards the Baja shores, while corresponding waters south of the seamount flowed east towards the Sinaloa coast. This implies a cyclonic circulation pattern.

Of three geostrophic techniques tried, the DCD method proved to be the most suitable for the area of study. It minimized the net salt transport and provided a reasonable volume transport in the

upper 250 m. Applying the DCD method produced a volume inflow of 8.4 Sv and outflow of 6.5 Sv, corresponding to a net volume transport of +1.9 Sv. Salinity transports using DCD method resulted in an overall salt imbalance of $+6.0 \times 10^4$ tonne/sec. This value, as well as the residual volume transport, are too high. The obvious source of errors coincide with the included integration of the deep layer (@ 250-3000 m) section. This implies that either I failed to resolve the mass field or there are higher order dynamics. Waves trapped by the deep bathymetry along both coasts and Alarcon Seamount could induce noise in geostrophic estimates, inhibiting efforts to accurately balance mass and salt. From these results, it would appear using geostrophy can provide useful estimates in the upper layers, but has limitations at depth.

C. SATELLITE IMAGERY

The satellite image shown in Figure 7 was taken by the NOAA-11 satellite's Advanced Very High Resolution Radiometer (AVHRR) sensor on 15 December 1992. The image exemplifies the SST structure prevalent at the entrance to the Gulf of California two weeks prior to the PESCAR 02 survey. It shows SSTs ranging between 21-25 °C dominating the region, with the highest temperatures offshore and equatorward. But it's the anomalous features in the image that offer the most insight on the circulation processes occurring in the region.

In the western Gulf, along the southern shores of the Baja peninsula, surface waters of 19-20 °C are apparent. A narrow band of slightly cooler water, traced back to the inner-Gulf, is seen hugging the contours of the southern Baja banks (below 24 °N latitude) before meandering into the Pacific. South of Cabo San Lucas, the cooler surface signature gradually fades in the surrounding warmer waters. This

observation lends support to a previous assumption made from the across-gulf temperature structure (Figure 2a). That is, the low temperature cores located just offshore from the Baja peninsula represent equatorward flow of high-salinity Gulf of California Water.

Similarly, across the Gulf and alongshore the Sinaloa coast, another cool tongue of surface water is isolated. Starting at about the 24 degree parallel, the tongue's signature widens and becomes more enhanced as it's traced northward into the Gulf. Coastal SSTs north of 25 °N decrease to approximately 17 °C. According to Roden and Groves (1959), the observance of this cold water tongue may be attributed to localized upwelling brought on by seasonal northwesterly winds.

Figure 2. 500 dbar across-gulf transections for PESCAR 02 (28 December 1992 - 02 January 1993). Cast location and number are given at the top of the figure. Vertical line at cast #25 marks the position of intersection with along-gulf transection. It also denotes the location of the Alarcon Seamount. **(a).** Temperature. Isotherm spacing is 1 °C or as labeled.

IV. CTD DATA FROM APRIL 1992

A. APRIL-MAY 1992 RESULTS

The PESCAR 01 data set was collected from 21 April-08 May 1992 aboard the *USNS DeSteiguer*. The ship performed a total of 17 CTD casts along the same across-gulf transection that was later examined during the December 1992 cruise. A Neil Brown MK-IIIB CTD was employed to collect the data. Data collection and processing procedures were similar to the PESCAR 02 cruise, with the exception that a different software package was used to process the raw data. This difference in the processing of the data had no effect in the comparison of the two cruises' data results. However, the contrasting seasonal conditions associated with the two cruises did result in appreciable differences between the data. Unlike the December cruise, which had cool, blustery winds and confused seas, the April cruise was conducted during a period of warming and was characterized by calm with

flat seas. The following paragraphs describe the observations from that survey.

The PESCAR 01 temperature structure is shown in Figures 8a and 9a. Sea surface temperatures (SSTs) were in excess of 25 °C across the entire region, with those in the eastern one-third of the Gulf measuring 1-2 °C warmer than those in the west. The isotherms reveal strong stratification of the upper layer, persisting down to about 150 m. Perhaps the most dominant feature of the shallow subsurface layer is the sudden shoaling of the 8-12 °C isotherms occurring approximately 65 Km off the Baja peninsula. The detail that makes this observation especially interesting is the fact that the doming occurs in waters overlying the mid-basin Alarcon Seamount. Whether the seamount entirely forces or even contributes to the doming is subject to conjecture. Below 500 m, the isotherms leveled and decreased uniformly with depth.

The vertical salinity structure during this period is depicted in Figures 8b and 9b. Two striking

features are seen in the upper 100 m layer. One is the broad 110 km long, shallow core of relatively low salinity (defined by hatching where $S \leq 34.5$ psu) that stretches across the entire central section of the Gulf. The other is a significantly smaller low-salinity core (defined by hatching where $S \leq 34.5$ psu) centered 25 km offshore from Baja. Defining a gradient between these two cores is a narrow higher salinity 34.6 psu region. The shallow layer salinity minimum (symbolized by shaded triangles) cuts through the center of both cores. What makes the latter core particularly interesting is that it is a core of low-salinity water situated in a region generally associated with high-salinity Gulf of California Water (Gulf Water). The presence of a salinity front may be suggested, judging from the abrupt shoaling of the 34.6 and 34.7 psu isohalines below cast #5. The low-salinity waters observed in the eastern Gulf interleaving the slightly deeper, higher salinity waters to the west (identified by the 34.8 psu

isohaline) could produce such a front. The plotting of salinity on density anomaly surfaces (Figure 8d) also depicts this boundary, existing between the 24 and 25.5 kg/m³ density surfaces. Also of interest is that the shallow salinity maximum (symbolized by squares) is found at the surface. Below 200 m, the isohalines dome sharply near the center of the transection. This feature persists down to the bottom and may be associated with flow around the Alarcon Seamount.

Strong stratification reaching to the surface characterizes the upper 150 m layer of the density anomaly structure (Figures 8c and 9c). The isopycnals remain tightly packed throughout this entire upper layer. Surface layer densities across the Gulf exceed 23.0 kg/m³. Just below the surface and penetrating to about 125 m, a broad section of depressed isopycnals in the western half of the Gulf (between casts 6-10) separate two domed regions of isopycnals. East of cast #14 the isopycnals slope downward towards the Mexican mainland, indicating generally less dense waters in

the eastern region of the Gulf. These observations may suggest a two-celled cyclonic gyre system within the near-surface structure, or possibly an eddy over the seamount imbedded in general cyclonic flow. In the subsurface waters underlying the upper layer where the isopycnals are depressed, dramatic shoaling of the isopycnals occurs. The rising isopycnals produce impressive doming features that persist as deep as 1000 m. This subsurface representation may be indicative of a large cyclonic gyre system circumscribing the mid-basin seamount.

The temperature - salinity (T-S diagram) and density anomaly - salinity (σ_t -S diagram) relationships for this cruise (Figures 10a and 10b, respectively) reveal both expected and some surprising results. The associated insolation increase of April and May increased SSTs as expected, with maximum temperatures reaching about 26.5 °C. However, a more interesting observation is the apparent lack of Gulf of California Water in the region. Both diagrams

indicate salinity maxima of about 34.85 psu, clearly below the 34.9‰ used to isolate Gulf Water. Waters at the surface are a probable mixture of Tropical Surface Water with some influence from California Current Water ($S \leq 34.6\text{‰}$). Near-surface waters of the upper 50 m layer indicate far greater influence from California Current Water. These waters correlate with the immense across-gulf expansion of low-salinity cores seen previously in Figure 8b. Underlying this layer and descending to depths where temperature cools to 11 °C and density anomaly increases to 26.50 kg/m³ (approximately 250 m) is a regime showing some California Current Water influence, but which is more characteristic of Subtropical Subsurface Water. The deep layer regime, as with the PESCAR 02 diagrams, shows the distinct deep salinity minimum of the Pacific Intermediate Water occurring at a corresponding depth of about 650 m.

The velocity transection of the April 1992 cruise placed outflowing current from the Gulf occurring over

a range of 10-60 km from the Baja shores (Figure 9d). Maximum velocities in excess of 70 cm/sec are observed near the surface, with less intense velocities contoured as deep as 400 m. A transition region, centered over the Alarcon Seamount and defined where the vertical descension of the 0 cm/sec isotach occurs, is observed separating this equatorward flow from an even broader poleward flow to the east. Surface cores within the latter show maximum speeds in excess of 60 cm/sec. As observed with the equatorward flow, this current penetrates deeply into the water column's upper layer. Even below 500 m, there's still some indication of significant current flow occurring around the transition region, as evidenced by the 15 cm/sec isotach to the east and hatched areas west. The associated volume transports of the PESCAR 01 cruise are provided and compared against the PESCAR 02 transports in Table 3. Using DCD method, the calculated PESCAR 01 volume transports include: a net

inflow of 11.7 Sv, net outflow of 9.2 Sv and an overall net transport of +2.5 Sv.

B. Differences Between April and December 1992

Perhaps the most obvious distinction between the April and December 1992 cruise results is observed in the velocity transections (Figures 9d and 3d, respectively). Two distinct and large regimes of current characterized the April results. In the upper 500 m layer, east of the Alarcon seamount (feature centered at 70 km from Baja), a broad cross section of inflowing (poleward) current was observed. West of the seamount, a correspondingly large cross section of outflow occurs. This depiction differs conspicuously from the December results where similarly intense but frequently alternating bands of current flow were observed. During the December cruise at least three transition zones separating narrower cores of inflowing and outflowing currents were observed. The most prominent of the cores was the outflowing (equatorward) core centered 40 km from the Baja coastline. Penetrating deeper and more structurally defined than the outflowing section observed during

the April cruise, this core is similarly unique in that it entrained the more saline ($S \geq 34.9\%$) Gulf Water, which was not apparent in the April cruise. The stronger winds and higher seas of the December cruise are undoubtedly related to the greater variability observed in the upper layer currents.

Why was Gulf Water not observed during the April cruise? One possible explanation is derived from the predicted time it would take for Gulf Water to appear at the Gulf's entrance following its formation in the northern basins (Bray, 1988b). Assuming an average flow speed of 20 cm/sec, it would take about 50 days for the subject water mass to transit the estimated 900 km. Along with the seasonal formation (Gulf Water is first formed from intense summer and fall heating), this may account for the December prominence of Gulf Water at the mouth. Alternatively, the lack of wind forcing during the April cruise, may lead to a reduction of Gulf Water being pushed southward.

Another distinction related to the baroclinic flow results involves the volume transports calculated for the two cruise periods (Table 3). Focusing on the results using DCD method, the table shows an increase in transport for the April-May cruise (PESCAR 01). This includes a net influx that is 20% larger than that determined from the December cruise. Outside of the seasonal variability that leads to density modification, the reasons for this additional transport are uncertain. However, from the comparison of the two cruises' velocity transections and volume transport results, it's reasonable to assume that more water was exchanged at the Gulf's entrance during the April-May period.

The temperature and salinity transections along with the corresponding T-S diagrams likewise delineate marked differences between the two cruise periods. The April SST's were 3-5 °C warmer than those observed during December. This elevation in temperatures was expected, a consequence of the associated seasonal

heating. A related feature was the increase in the near-surface stratification. The differences in the salinity transections were particularly pronounced and included at least one very distinct difference: the absence of Gulf Water. Besides shoaling of the shallow water salinity maximum and minimum layers, the April transection also revealed a low-salinity core water in the upper 50 m, again suggesting stronger stratification in the upper layers. These broad, low-salinity cores with salinities ranging from 33.3 - 33.6 psu likely reflect the influence of California Current Water and are gravitationally maintained in the strongly stratified near-surface layer. As previously discussed, the most striking difference between the cruise sets may have been the absence of high-salinity Gulf Water from the April transection! Such could infer that Gulf Water at the mouth is seasonal in occurrence; and hence, outflowing waters leaving the western Gulf in April may represent simple recirculation of eastern Gulf waters.

Salinities typical of sections in the Gulf can be used to calculate an estimate of the water mass ratios integral to the formation of Gulf Water. Taking the outflow at the mouth to have a salinity of 34.9 psu, inflow at the mouth on the same density surface to average 34.65 psu and the salinity of the northern basin waters to average 36 psu, it's then estimated that there is a 1 to 4 ratio of highly saline northern waters to fresh, Pacific-origin inflow involved in the formation process. This value points to the importance of mixing in the Gulf, in addition to providing an idea of the exchange balance required to drive the Gulf's thermohaline circulation.

V. CONCLUSIONS

The circulation pattern observed at the entrance to the Gulf of California was generally cyclonic and characterized by occasional and opposing eddies in the near-surface layers and by consistent deep cyclonic circulation around the mid-basin Alarcon Seamount. Water generally entered the Gulf east of the seamount and exited the Gulf leaving the seamount to the east.

The late December 1992 - early January 1993 cruise results (PESCAR 02) show a system largely influenced by the strong seasonal winds (directed south). The surface waters at the Gulf's entrance during this period appeared to be well-mixed, and the upper layer currents banded. Just below the surface and extending down to about 200 m, the vertical temperature and density structure showed strong stratification. Within these layers, independent cores of both warm, saline and cooler, less saline water

were observed. The salinity signature of the warm water cores ($S \geq 34.9$ psu), suggest they originated from the inner-Gulf. The most pronounced of these warm, equatorward flows was observed along the southern flanks of the Baja banks, positioned 25-40 km offshore with maximum velocities of 68-72 cm/sec. Satellite imagery taken near the time of the December cruise supports this presumed movement of inner-Gulf water (Gulf Water) towards the mouth. During the 21 April-08 May 1992 cruise (PESCAR 01), a period when weather and sea conditions were generally calm, the high-salinity signature marking this core was not evident, even though a similarly positioned and broader equatorward flow existed. This April-May outflow likely represents simple recirculation of the waters comprising the eastern Gulf. The presence of Gulf Water at the entrance appears to be seasonally influenced, and could be related to either: 1) a temporal effect, due to the period between the water's formation in the northern Gulf and its estimated time

of transit to the entrance, or 2) simply the presence (or lack thereof) of wind forcing to drive upper layer water masses. Both conclusions support the observed Gulf Water at the entrance in December.

East of the Alarcon Seamount (centered approximately 70 km offshore from Baja), independent cores of cooler, low-salinity ($S \leq 34.7$ psu) water dominated the near-surface stratified layer. These poleward flowing cores, believed to consist of admixtures of California Current Water and subsurface composites of Eastern Tropical Pacific Water (often referred as Subtropical Subsurface Water), are undoubtedly a partial source for the advection of cooler and fresher water into the Gulf. The cores appear dispersed and only marginally organized during the December cruise, but broad and uniform during April-May. Current speeds were comparable in intensity to those of the outflowing cores, with slightly stronger currents (maximum speeds of 70 cm/sec) observed for April-May.

The deepest common depth (DCD) method proved to be the most suitable of three techniques compared in determining the geostrophic velocities. Besides suggesting a more complete depiction of the currents running through this highly diverse bathymetric region, it also gave the most reasonable results for volume and salinity transports.

Volume transports calculated for the two cruise periods indicated less transport occurring during the December-January period. For PESCAR 02, a net inflow of +1.9 Sv, the difference between a northward transport of 8.4 Sv and a southward transport of 6.5 Sv, was determined. Corresponding salinity transports were a net inflow of $+6.0 \times 10^4$ tonne/sec, the difference between a northward transport of 2.9×10^5 tonne/sec and a southward transport of 2.3×10^5 tonne/sec. Why more water was exchanged over the April-May period was not readily apparent. The differences are presumably due to seasonal processes.

This experiment opened new ground and raised additional questions concerning the circulation and exchange processes occurring at the Gulf's entrance. The inclusion of the deep layer structure in this examination established the importance of the processes occurring at depth. Unaccounted for in past studies, the deep layer structure revealed both interesting hydrography and appreciable transports relative to the transections analyzed. It was from the deep hydrography sections that the cyclonic flow pattern influencing the region was determined. Likewise, it was found that the largest percentage of the transports were gained from the deep layers. These observations suggest that the deep layer sections at the Gulf's entrance are very dynamic, and thus integral to the overall exchange balances occurring in the Gulf. The caveat to the above remarks is that the calculated transports for this experiment contained excessive imbalances between inflows and outflows. The problem that remains is how to best account for the

dynamics characterizing the deep layer. Suspected error in the results appears to have resulted from the inclusion of the deep layer analyses; and, none of the geostrophy techniques used in the experiment were totally effective in resolving the deep layer. It may be that the sluggish flows and reversing fields associated with the deep layer regime cannot be accurately measured by CTDs or resolved through simple geostrophic examination. Direct current measuring techniques may be the best approach for resolving the velocity structure.

Many of the hydrography sections indicated possible influence from the presence of the Alarcon Seamount. Were these observations real, and, if so, to what degree does the seamount affect the flow processes there? The answers to these questions are outside the scope of this examination. Perhaps a more detailed look utilizing direct measurements (e.g., Pegasus) can solve this newest of the Gulf's riddles.

APPENDIX A: LITERATURE REVIEW

Water Mass Formation and Thermohaline Circulation in the Gulf of California

This appendix is intended to be a more complete review of research reports investigating the Gulf. This includes summary of the extensive work done in the northern Gulf.

I. INTRODUCTION

The Gulf of California is a semi-enclosed, narrow sea basin bordered by the western shores of Mexico and the east coast of Baja California. The Gulf is the only evaporative basin of the Pacific Ocean and is a very dynamic body of water even though it is comparatively small. Surface currents generally follow seasonal variations of the winds, which are predominantly southeasterly in winter and spring and northwesterly in summer and fall (Roden, 1964). Subsurface circulation is far more complex and is characterized by flow exchanges with the adjoining Pacific Ocean, with outflow occurring between the surface layer and about 250 m and inflow occurring between 250 m and roughly 500 m (Bray, 1988b). This paper examines the regional climatology, underwater topography and water mass formation within the Gulf in

order to examine their influences on thermohaline circulation in the Gulf of California.

Bray (1988a) states the Gulf is uniquely characterized by a vertical salinity gradient (salinity decreases with depth) over the top 700 m water column with only occasional exceptions. This condition occurs as a result of the unusual atmospheric forcing over the Gulf, which leads to a net loss of moisture from the ocean surface but a net gain of heat from the atmosphere. She adds that this process is unlike those observed in similar sea basin enclosures such as the Mediterranean and Red seas, where heat is lost to the atmosphere.

The small heat gain (estimated to be $20-50 \text{ W m}^{-2}$) received in the Gulf of California is balanced by an advective flux of colder, fresher Pacific Intermediate Water into the Gulf as warmer, saline Gulf water is transported out (Bray, 1988a). The warm "Gulf Water", as coined by Roden (1964), transported out is a product of water mass formation occurring within the

Gulf. According to Bray (1988b), water mass formation in the Gulf is a result of the following set of complex mechanisms: winter convection; southern transport of newly convected waters via eddylike features; large-scale anticyclonic circulation of northern shelf waters south; and tidal mixing.

Due to restrictions imposed by the Gulf's topography (i.e., transverse ridges or sills) it is assumed that the thermohaline circulation is constrained to depths above 500 m. This corresponds to the controlling sill depth located between the northern and central regions of the Gulf. Observations suggest that the Gulf's thermohaline circulation is a distinctive three-layered system, comprised of: a seasonally driven surface layer; high-saline outflow layer flowing alongshelf the eastern shores of the Baja peninsula; and a deeper, relatively fresh inflow layer entering the central part of the Gulf's mouth (Bray, 1988a).

II. CLIMATOLOGY

The Gulf of California is located between the arid peninsula of Baja California to the west and the equally arid Mexican states of Sonora and Sinaloa to the east. An almost unbroken chain of mountains, 1-3 km high, situated along the Baja peninsula acts to channel seasonal winds along the length of the Gulf. Additionally, these mountains isolate the Gulf from the oceanic climate of the nearby Pacific to the west (Roden, 1964).

There is a large variation of atmospheric temperature over the Gulf between summer and winter periods. Variations are extreme and may exceed 15°C in the northern Gulf region. In the late summer evaporation rates are at a maximum and correlate with increased sea surface temperatures.

Roden (1964) states that precipitation in the region is more prevalent in the south than in the dry,

desert-like northern Gulf, where precipitation is less than 10 cm/yr. In the southern Gulf precipitation can increase to as much as 100 cm/yr, with most of the rain falling during the rainy season months from June to October. The year-to-year variation of precipitation is large. Also, winds in the Gulf of California are extremely variable. The winds blow predominantly out of the northwest from November to May, and out of the southeast during the rest of the year (Roden, 1964). The winter winds are stronger and less humid than the southerly summer winds and are associated with significant upwelling (≈ 3 m/day) along the western shores of the Mexican mainland. The southerly summer winds also induce upwelling along the eastern coast of the Baja peninsula.

Roden (1964) mentions that the Gulf region is noted for its seasonal storms. Northwest gales of two-three days duration are commonly experienced in the northern Gulf between December and February. Their southern counterparts, *chubascos*, violent gales of

short duration, occur in the rainy season from June to October. Also, the Gulf - particularly the extreme southern region - is susceptible to hurricanes during the period between late May and early November.

Isolated from the Pacific Ocean, the Gulf of California is more continental than oceanic in climate. With a related extreme seasonal variation of temperature and wind, the Gulf behaves as the only evaporative basin of the vast Pacific. According to Bray (1988b), the atmosphere over the Gulf influences oceanic circulation through the wind field, which reverses seasonally, through surface heating and cooling, and through evaporation.

III. TOPOGRAPHY

Bray (1988b) explains: the Gulf of California is approximately 1000 km long and 150 km wide, lying between the mountainous Baja California peninsula and the western shores of Mexico. The bathymetry of the Gulf is quite complex, characterized by numerous basins separated by transverse ridges or sills. Most of the basins are deep and in open communication with the Pacific. Progressing northward, the sills become increasingly shallow. Sills located in the southern and central basins are deeper than 1500 m, thus allowing open exchange between the deeper waters of the Pacific and the Gulf waters. South of the region's midriff islands, the San Esteban sill, rising to about 500 m, effectively isolates the northern Gulf from the central region basins (Figure 1).

Bray (1988b) continues, stating the highest salinities found in the Gulf are in the tidal flats of

the north, where evaporation is the greatest and the Gulf is the shallowest. Interestingly, maximum salinities (≈ 36‰) are observed at the head of the Gulf in the Colorado River delta. Due to the low fresh water discharge from the river, river runoff has little influence on diluting the salinity of the Gulf waters there.

IV. WATER MASS FORMATION

As defined by Bray (1988b), the term water mass formation refers to processes which convert surface waters of the ocean into deeper waters removed from direct atmospheric forcing. In this context, a water mass is characterized by a temperature versus salinity relationship, T-S, traceable to some observable set of surface conditions.

Evaporation over the Gulf (0.95 m/yr) is comparable to that of the Mediterranean and Red seas, with surface salinities in the northern Gulf 1-2 psu higher than those found along the same latitude in the open Pacific. But the Gulf differs from the aforementioned evaporative basins in that it **gains heat** at an annually estimated average rate of 20-80 W/m² (Bray, 1988b). An accompanying vertical instability condition is possible because temperature and salinity both decrease with depth (Figure 2). This

vertical structure precludes the expected two-layer thermohaline system of warm, fresh subsurface inflow and cold, salty surface outflow. Water mass formation in the Gulf must somehow compensate for the unusual air-sea forcing occurring there. To balance the air-sea heat gain and the evaporative moisture loss, there must be a net upward transport of cold, fresh inflow water and a net downward transport of warm, saline waters, to intermediate depth. Bray (1988b) states that "these constraints force the new water mass to be intermediate (in depth as well as in T-S properties) between the deep, relatively fresh inflow and the surface layer which has been made saline by evaporation." She adds, the following mechanisms are responsible for this process: 1) winter convection, 2) dispersion of convected water in small eddylike features, 3) an anticyclonic circulation in the northern Gulf, and 4) tidal mixing.

An interpretation of Bray's (1988a) detailed explanation of the water mass formation process begins

by stating that evaporation reaches a maximum in the northern Gulf in late summer and early fall following a summer of intense surface heating. This results in a warm, saline surface mass. Localized winter convection transforms some of this saline surface water into a cold, dense, salty bottom water found only in the deep basins of the northern Gulf. Inclusive, there are associated processes relative to winter convection that are key to the entire process. That is, there must be an explanation for the characteristic destabilizing vertical salinity gradient established as a result of less saline Central Gulf Water (CGW) underlying the high-salinity Colorado Delta Water (CDW). Such occurs as a result of cyclonic inflow of CGW at depth into the deep basins of the far north. At depths greater than 100 m, the only conduit for inflow of CGW into the northern Gulf is through the channel connecting Wagner Basin, via depressions to Delfin Basin. Then, as the surface waters of the northern Gulf (CDW) cool in the winter, thus increasing their

density above that of the advected underlying CGW, the CDW sinks below the CGW. If this "penetrative" convection occurs, an identifiable T-S signature of a subsurface salinity minimum (CGW) overlying a deeper salinity maximum (convected CDW) should be observed. Additional properties of this traceable Wagner Basin Water (WBW) are that surface and bottom salinities should be nearly equal, surface temperatures should be warmer than bottom temperatures, and the bottom salinity maximum layer should have higher temperatures than the salinity minimum layer overlying it. Also, density should be nearly uniform with depth in the salinity minimum and maximum layers.

From evidence gathered from hydrographic data, current meter data, and meteorological data (winter '84-'85) it is suspected that at least one mechanism for dispersing Wagner Basin Water is by "Gulfies", or small diameter eddies emanating from the formation region after major cooling events. Thus, the Gulfies are responsible for advecting the newly formed WBW

away from the formation region. These isolated patches of high-salinity water have been discovered several hundred kilometers south of the convection or formation region, and have been traced back in time to specific cooling events, with patches of greater salinity anomaly associated with stronger cooling. Gulfies result from the process of water mass formation itself. Also, as the Gulfies transit south through the sill-strait system of the central-southern Gulf, they can lose much of their T-S signature via tidal mixing with central Gulf water masses.

Another process considered important in the transportation of high-salinity surface waters south from the northern regions of the Gulf is by means of a strong anticyclonic circulation occurring in late winter. Evident in the hydrographic data from March 1985, the gyre centered over the northern Gulf and extending across the width of the Gulf appears responsible for advecting high-salinity surface water from the shelf regions of the north well into the

central Gulf, some 150 km to the south. The water advected is observed as a horizontally isolated salinity maximum, nearly isohaline and extending to approximately 200 m deep in the gyre center (Figure 3). Consequently, the gyre provides a means of transporting high-salinity water away from the northern shelves as well as a mechanism for mixing saline surface waters with deep, fresh inflow water. As a note, the anticyclonic gyre in the northern Gulf does not appear directly related to convection. The gyre is of much larger horizontal scale and is centered far south of the origin of the Wagner Basin Water. A possible driving force for the gyre is the existence of externally imposed density gradients as a circumstance of the cooling of high-salinity surface waters, resulting in denser waters to the north, and consequently anticyclonic circulation.

Inevitably, mixing must be an important factor in water mass formation in the Gulf. Tides provide energy for mixing during water mass formation processes. In

the northern Gulf, tidal mixing is likely induced by bottom friction. Farther south in the island region, particularly near sills, mixing is probably by the breaking of large vertical scale internal waves. Water mass formation in the Gulf is directly affected by these mixing processes. The shallow waters of the northern shelves are vertically mixed during winter, facilitating convection. Likewise, mixing is responsible for reducing the high-salinity signature of northern Gulf waters as they enter the central Gulf.

Bray (1988b) summarizes her explanation of the water mass formation process, contending that water mass formation in the Gulf of California results from a requirement that there be a net upward transport of deep water properties to balance the air-sea heat gain, and a net downward transport of surface water properties to balance evaporative moisture loss. This is accomplished through a series of complex interactions involving atmospheric forcing, tidal

mixing and topographic constraints. The resultant product is a new water mass that is intermediate in depth as well as in its by T-S properties. This intermediate Gulf Water reflects the properties of both the deep, relatively fresh inflow and the salty surface layer formed by evaporation.

V. THERMOHALINE CIRCULATION

As previously discussed, unlike the Mediterranean and Red seas, the Gulf of California actually gains heat from the atmosphere on an annual average. This heat gain is presumably balanced by an advective flux of colder water into the Gulf and warmer water out of the Gulf. This theory correlates with observed vertical gradients of temperature and salinity and with baroclinically determined circulation patterns (Bray, 1988a).

Hydrographic evidence from moored observations and ship measurements suggests that the Gulf's thermohaline circulation is comprised of the following three-layered system: 1) surface layer which is approximately 50 m thick and reverses transport direction with the seasonally reversing large-scale wind field, flowing north in the summer and south in the winter, 2) baroclinic outflow occurring along the

western shores of the Gulf between the surface layer and about 250 m depth, and 3) baroclinic inflow occurring mainly in the central sector of the Gulf between 250 and 500 m depth (Bray, 1988a). There was insufficient data to resolve the circulation at depths deeper than 500 m. To this she adds, "...thermohaline circulation should be constrained to depths above about 500 m, which is the controlling sill depth between the northern and central sections of the Gulf."

The proposed three-layer system has several implications for circulation in the Gulf. In preceding sections of this paper, the formation of an intermediate water mass was discussed. Outflow from the Gulf predominantly consists of this intermediate Gulf Water. Another point of interest is that at the mouth of the Gulf the density of the outflow is such that it forms a near-surface layer. Upon exiting the Gulf, the Gulf Water signature negligibly influences the adjoining Pacific. Also, the Gulf's receipt of

deep, subsurface, nutrient-rich inflow waters from the Pacific gives a sound explanation for the high biological productivity found in the Gulf (Bray, 1988a).

At the mouth of the Gulf, one prominent feature is a thin (10-30 m thick) but pronounced high stability layer sandwiched between the warm surface layer and cooler subsurface layer. This stability layer, depicted in Figure 4, is identified by Väisälä frequencies (where Väisälä freq. $> 0.02 \text{ sec}^{-1}$), and practically extends across the entire southern Gulf. The top of this high stability layer lies at approximately 50 m depth and may be used as an index of the depth of the upper mixed layer. Of particular interest is that breaks in this high-stability layer, clearly evident on the west side of the Gulf, are indicative of strong baroclinic flow (Roden, 1972).

Baroclinic flow across the entrance to the Gulf of California was computed from STD observations (Figure 5). According to Roden (1972), the flow is

referenced to the 1500 dbar surface or the bottom, whichever was encountered first.

Baroclinic outflow, whose origin is traced to the northern Gulf (salinity maximum $> 35.2\%$), flows near the western shores of the southern Gulf, traveling south in a narrow, high-speed velocity core. This core has a characteristic width of about 30 km and deepens to more than 1000 m at the Gulf's entrance. Maximum velocities within the core occur at the surface, reaching 55 cm/sec.

Baroclinic inflow into the Gulf takes place mainly in the central part. Here there are two observable cores of increased velocity entering the Gulf. One core is about 20 km wide and has a maximum velocity of ≈ 26 cm/sec, occurring between 50 and 450 m depth. The other, slightly wider than the first, has a maximum speed of 46 cm/sec and is confined to the upper layer.

VI. SUMMARY

The Gulf of California's hot, arid summer climate makes it the Pacific Ocean's only evaporative sea basin. Surface currents in the Gulf generally follow seasonal variations of the wind, with northwesterlies blowing from November to May and southeasterlies from June to October.

Unlike similar semi-enclosed sea basins (namely, the Mediterranean and Red seas), the Gulf of California is uniquely characterized by a destabilizing vertical salinity gradient (salinity decreases with depth) over the top 700 m water column. This condition occurs as a result of the unusual atmospheric forcing occurring over the Gulf, which results in a net loss of moisture from the ocean surface but a net gain of heat. Given this condition, an intermediate Gulf Water mass is formed. The mechanisms for the formation of this intermediate

water mass include: winter convection in the northern basins; advection of newly convected water via isolated eddies, referred to as Gulfies; transport of water south from the northern shelves by way of a large-scale anticyclonic gyre; and strong tidal mixing.

The thermohaline circulation pattern proposed for the Gulf to balance the net heat and moisture fluxes consists of three layers. There is the surface layer, whose current field is directly influenced by the seasonally varying wind. Baroclinic outflow transports warm and saline Gulf Water of northern origin out of the Gulf along its western boundary. Baroclinic inflow transports relatively fresh, cold Pacific Intermediate Water into the Gulf at the central sector of its entrance.

Figure 1. Schematic depicting topography (sills and basins) and water mass distribution in the Gulf of California. Arrows denote hypothesized thermohaline circulation: the open arrow representing the surface wind-driven layer with seasonally reversing transport; solid arrows representing subsurface inflow and outflow; dashed arrow representing deep water formation (Figure 3a., Bray, 1988b).

Figure 2. Comparison of the vertical thermohaline structure in the Gulf of California (top graphic, A), and the western Mediterranean Sea (bottom graphic, B). Note that in the case of the Gulf of California, salinity decreases with depth; thus indicating, vertical instability in the water column (Figure 2., Bray, 1988b).

Figure 3. Anticyclonic gyre found in the northern Gulf in March 1985. Plots include: (a) salinity at 10 m, (b) dynamic height at 10 m relative to 100 m, and (c) velocity vectors derived from the dynamic height field. The gyre is presumed to be partially responsible for moving high-salinity waters south from the northern shelf regions. It is also believed to contribute to the mixing processes occurring in the northern Gulf (Figure 15., Bray, 1988b).

Figure 4. Vertical distribution of Väisälä frequency (sec^{-1}) across the entrance to the Gulf of California. The layer of high stability water is shaded. Breaks in the high stability regions are indicative of baroclinic flow (Figure 2., Roden, 1972).

Figure 5. Baroclinic flow (cm/sec) across the entrance to the Gulf of California. The flow is referenced to the 1500 dbar surface. The transection runs from Arroyo de Vinorama, Baja California, to approximately Mazatlán, Sinaloa and was occupied on 5-6 December 1969 (Figure 4., Roden, 1972).

of transit to the entrance, or 2) simply the presence (or lack thereof) of wind forcing to drive upper layer water masses. Both conclusions support the observed Gulf Water at the entrance in December.

East of the Alarcon Seamount (centered approximately 70 km offshore from Baja), independent cores of cooler, low-salinity ($S \leq 34.7$ psu) water dominated the near-surface stratified layer. These poleward flowing cores, believed to consist of admixtures of California Current Water and subsurface composites of Eastern Tropical Pacific Water (often referred as Subtropical Subsurface Water), are undoubtedly a partial source for the advection of cooler and fresher water into the Gulf. The cores appear dispersed and only marginally organized during the December cruise, but broad and uniform during April-May. Current speeds were comparable in intensity to those of the outflowing cores, with slightly stronger currents (maximum speeds of 70 cm/sec) observed for April-May.

The deepest common depth (DCD) method proved to be the most suitable of three techniques compared in determining the geostrophic velocities. Besides suggesting a more complete depiction of the currents running through this highly diverse bathymetric region, it also gave the most reasonable results for volume and salinity transports.

Volume transports calculated for the two cruise periods indicated less transport occurring during the December-January period. For PESCAR 02, a net inflow of +1.9 Sv, the difference between a northward transport of 8.4 Sv and a southward transport of 6.5 Sv, was determined. Corresponding salinity transports were a net inflow of $+6.0 \times 10^4$ tonne/sec, the difference between a northward transport of 2.9×10^5 tonne/sec and a southward transport of 2.3×10^5 tonne/sec. Why more water was exchanged over the April-May period was not readily apparent. The differences are presumably due to seasonal processes.

This experiment opened new ground and raised additional questions concerning the circulation and exchange processes occurring at the Gulf's entrance. The inclusion of the deep layer structure in this examination established the importance of the processes occurring at depth. Unaccounted for in past studies, the deep layer structure revealed both interesting hydrography and appreciable transports relative to the transections analyzed. It was from the deep hydrography sections that the cyclonic flow pattern influencing the region was determined. Likewise, it was found that the largest percentage of the transports were gained from the deep layers. These observations suggest that the deep layer sections at the Gulf's entrance are very dynamic, and thus integral to the overall exchange balances occurring in the Gulf. The caveat to the above remarks is that the calculated transports for this experiment contained excessive imbalances between inflows and outflows. The problem that remains is how to best account for the

dynamics characterizing the deep layer. Suspected error in the results appears to have resulted from the inclusion of the deep layer analyses; and, none of the geostrophy techniques used in the experiment were totally effective in resolving the deep layer. It may be that the sluggish flows and reversing fields associated with the deep layer regime cannot be accurately measured by CTDs or resolved through simple geostrophic examination. Direct current measuring techniques may be the best approach for resolving the velocity structure.

Many of the hydrography sections indicated possible influence from the presence of the Alarcon Seamount. Were these observations real, and, if so, to what degree does the seamount affect the flow processes there? The answers to these questions are outside the scope of this examination. Perhaps a more detailed look utilizing direct measurements (e.g., Pegasus) can solve this newest of the Gulf's riddles.

APPENDIX A: LITERATURE REVIEW

Water Mass Formation and Thermohaline Circulation in the Gulf of California

This appendix is intended to be a more complete review of research reports investigating the Gulf. This includes summary of the extensive work done in the northern Gulf.

I. INTRODUCTION

The Gulf of California is a semi-enclosed, narrow sea basin bordered by the western shores of Mexico and the east coast of Baja California. The Gulf is the only evaporative basin of the Pacific Ocean and is a very dynamic body of water even though it is comparatively small. Surface currents generally follow seasonal variations of the winds, which are predominantly southeasterly in winter and spring and northwesterly in summer and fall (Roden, 1964). Subsurface circulation is far more complex and is characterized by flow exchanges with the adjoining Pacific Ocean, with outflow occurring between the surface layer and about 250 m and inflow occurring between 250 m and roughly 500 m (Bray, 1988b). This paper examines the regional climatology, underwater topography and water mass formation within the Gulf in

order to examine their influences on thermohaline circulation in the Gulf of California.

Bray (1988a) states the Gulf is uniquely characterized by a vertical salinity gradient (salinity decreases with depth) over the top 700 m water column with only occasional exceptions. This condition occurs as a result of the unusual atmospheric forcing over the Gulf, which leads to a net loss of moisture from the ocean surface but a net gain of heat from the atmosphere. She adds that this process is unlike those observed in similar sea basin enclosures such as the Mediterranean and Red seas, where heat is lost to the atmosphere.

The small heat gain (estimated to be $20-50 \text{ W m}^{-2}$) received in the Gulf of California is balanced by an advective flux of colder, fresher Pacific Intermediate Water into the Gulf as warmer, saline Gulf water is transported out (Bray, 1988a). The warm "Gulf Water", as coined by Roden (1964), transported out is a product of water mass formation occurring within the

Gulf. According to Bray (1988b), water mass formation in the Gulf is a result of the following set of complex mechanisms: winter convection; southern transport of newly convected waters via eddylike features; large-scale anticyclonic circulation of northern shelf waters south; and tidal mixing.

Due to restrictions imposed by the Gulf's topography (i.e., transverse ridges or sills) it is assumed that the thermohaline circulation is constrained to depths above 500 m. This corresponds to the controlling sill depth located between the northern and central regions of the Gulf. Observations suggest that the Gulf's thermohaline circulation is a distinctive three-layered system, comprised of: a seasonally driven surface layer; high-saline outflow layer flowing alongshelf the eastern shores of the Baja peninsula; and a deeper, relatively fresh inflow layer entering the central part of the Gulf's mouth (Bray, 1988a).

II. CLIMATOLOGY

The Gulf of California is located between the arid peninsula of Baja California to the west and the equally arid Mexican states of Sonora and Sinaloa to the east. An almost unbroken chain of mountains, 1-3 km high, situated along the Baja peninsula acts to channel seasonal winds along the length of the Gulf. Additionally, these mountains isolate the Gulf from the oceanic climate of the nearby Pacific to the west (Roden, 1964).

There is a large variation of atmospheric temperature over the Gulf between summer and winter periods. Variations are extreme and may exceed 15°C in the northern Gulf region. In the late summer evaporation rates are at a maximum and correlate with increased sea surface temperatures.

Roden (1964) states that precipitation in the region is more prevalent in the south than in the dry,

desert-like northern Gulf, where precipitation is less than 10 cm/yr. In the southern Gulf precipitation can increase to as much as 100 cm/yr, with most of the rain falling during the rainy season months from June to October. The year-to-year variation of precipitation is large. Also, winds in the Gulf of California are extremely variable. The winds blow predominantly out of the northwest from November to May, and out of the southeast during the rest of the year (Roden, 1964). The winter winds are stronger and less humid than the southerly summer winds and are associated with significant upwelling (≈ 3 m/day) along the western shores of the Mexican mainland. The southerly summer winds also induce upwelling along the eastern coast of the Baja peninsula.

Roden (1964) mentions that the Gulf region is noted for its seasonal storms. Northwest gales of two-three days duration are commonly experienced in the northern Gulf between December and February. Their southern counterparts, *chubascos*, violent gales of

short duration, occur in the rainy season from June to October. Also, the Gulf - particularly the extreme southern region - is susceptible to hurricanes during the period between late May and early November.

Isolated from the Pacific Ocean, the Gulf of California is more continental than oceanic in climate. With a related extreme seasonal variation of temperature and wind, the Gulf behaves as the only evaporative basin of the vast Pacific. According to Bray (1988b), the atmosphere over the Gulf influences oceanic circulation through the wind field, which reverses seasonally, through surface heating and cooling, and through evaporation.

III. TOPOGRAPHY

Bray (1988b) explains: the Gulf of California is approximately 1000 km long and 150 km wide, lying between the mountainous Baja California peninsula and the western shores of Mexico. The bathymetry of the Gulf is quite complex, characterized by numerous basins separated by transverse ridges or sills. Most of the basins are deep and in open communication with the Pacific. Progressing northward, the sills become increasingly shallow. Sills located in the southern and central basins are deeper than 1500 m, thus allowing open exchange between the deeper waters of the Pacific and the Gulf waters. South of the region's midriff islands, the San Esteban sill, rising to about 500 m, effectively isolates the northern Gulf from the central region basins (Figure 1).

Bray (1988b) continues, stating the highest salinities found in the Gulf are in the tidal flats of

the north, where evaporation is the greatest and the Gulf is the shallowest. Interestingly, maximum salinities (* 36‰) are observed at the head of the Gulf in the Colorado River delta. Due to the low fresh water discharge from the river, river runoff has little influence on diluting the salinity of the Gulf waters there.

IV. WATER MASS FORMATION

As defined by Bray (1988b), the term water mass formation refers to processes which convert surface waters of the ocean into deeper waters removed from direct atmospheric forcing. In this context, a water mass is characterized by a temperature versus salinity relationship, T-S, traceable to some observable set of surface conditions.

Evaporation over the Gulf (0.95 m/yr) is comparable to that of the Mediterranean and Red seas, with surface salinities in the northern Gulf 1-2 psu higher than those found along the same latitude in the open Pacific. But the Gulf differs from the aforementioned evaporative basins in that it **gains heat** at an annually estimated average rate of 20-80 W/m² (Bray, 1988b). An accompanying vertical instability condition is possible because temperature and salinity both decrease with depth (Figure 2). This

vertical structure precludes the expected two-layer thermohaline system of warm, fresh subsurface inflow and cold, salty surface outflow. Water mass formation in the Gulf must somehow compensate for the unusual air-sea forcing occurring there. To balance the air-sea heat gain and the evaporative moisture loss, there must be a net upward transport of cold, fresh inflow water and a net downward transport of warm, saline waters, to intermediate depth. Bray (1988b) states that "these constraints force the new water mass to be intermediate (in depth as well as in T-S properties) between the deep, relatively fresh inflow and the surface layer which has been made saline by evaporation." She adds, the following mechanisms are responsible for this process: 1) winter convection, 2) dispersion of convected water in small eddylike features, 3) an anticyclonic circulation in the northern Gulf, and 4) tidal mixing.

An interpretation of Bray's (1988a) detailed explanation of the water mass formation process begins

by stating that evaporation reaches a maximum in the northern Gulf in late summer and early fall following a summer of intense surface heating. This results in a warm, saline surface mass. Localized winter convection transforms some of this saline surface water into a cold, dense, salty bottom water found only in the deep basins of the northern Gulf. Inclusive, there are associated processes relative to winter convection that are key to the entire process. That is, there must be an explanation for the characteristic destabilizing vertical salinity gradient established as a result of less saline Central Gulf Water (CGW) underlying the high-salinity Colorado Delta Water (CDW). Such occurs as a result of cyclonic inflow of CGW at depth into the deep basins of the far north. At depths greater than 100 m, the only conduit for inflow of CGW into the northern Gulf is through the channel connecting Wagner Basin, via depressions to Delfin Basin. Then, as the surface waters of the northern Gulf (CDW) cool in the winter, thus increasing their

density above that of the advected underlying CGW, the CDW sinks below the CGW. If this "penetrative" convection occurs, an identifiable T-S signature of a subsurface salinity minimum (CGW) overlying a deeper salinity maximum (convected CDW) should be observed. Additional properties of this traceable Wagner Basin Water (WBW) are that surface and bottom salinities should be nearly equal, surface temperatures should be warmer than bottom temperatures, and the bottom salinity maximum layer should have higher temperatures than the salinity minimum layer overlying it. Also, density should be nearly uniform with depth in the salinity minimum and maximum layers.

From evidence gathered from hydrographic data, current meter data, and meteorological data (winter '84-'85) it is suspected that at least one mechanism for dispersing Wagner Basin Water is by "Gulfies", or small diameter eddies emanating from the formation region after major cooling events. Thus, the Gulfies are responsible for advecting the newly formed WBW

away from the formation region. These isolated patches of high-salinity water have been discovered several hundred kilometers south of the convection or formation region, and have been traced back in time to specific cooling events, with patches of greater salinity anomaly associated with stronger cooling. Gulfies result from the process of water mass formation itself. Also, as the Gulfies transit south through the sill-strait system of the central-southern Gulf, they can lose much of their T-S signature via tidal mixing with central Gulf water masses.

Another process considered important in the transportation of high-salinity surface waters south from the northern regions of the Gulf is by means of a strong anticyclonic circulation occurring in late winter. Evident in the hydrographic data from March 1985, the gyre centered over the northern Gulf and extending across the width of the Gulf appears responsible for advecting high-salinity surface water from the shelf regions of the north well into the

central Gulf, some 150 km to the south. The water advected is observed as a horizontally isolated salinity maximum, nearly isohaline and extending to approximately 200 m deep in the gyre center (Figure 3). Consequently, the gyre provides a means of transporting high-salinity water away from the northern shelves as well as a mechanism for mixing saline surface waters with deep, fresh inflow water. As a note, the anticyclonic gyre in the northern Gulf does not appear directly related to convection. The gyre is of much larger horizontal scale and is centered far south of the origin of the Wagner Basin Water. A possible driving force for the gyre is the existence of externally imposed density gradients as a circumstance of the cooling of high-salinity surface waters, resulting in denser waters to the north, and consequently anticyclonic circulation.

Inevitably, mixing must be an important factor in water mass formation in the Gulf. Tides provide energy for mixing during water mass formation processes. In

the northern Gulf, tidal mixing is likely induced by bottom friction. Farther south in the island region, particularly near sills, mixing is probably by the breaking of large vertical scale internal waves. Water mass formation in the Gulf is directly affected by these mixing processes. The shallow waters of the northern shelves are vertically mixed during winter, facilitating convection. Likewise, mixing is responsible for reducing the high-salinity signature of northern Gulf waters as they enter the central Gulf.

Bray (1988b) summarizes her explanation of the water mass formation process, contending that water mass formation in the Gulf of California results from a requirement that there be a net upward transport of deep water properties to balance the air-sea heat gain, and a net downward transport of surface water properties to balance evaporative moisture loss. This is accomplished through a series of complex interactions involving atmospheric forcing, tidal

mixing and topographic constraints. The resultant product is a new water mass that is intermediate in depth as well as in its by T-S properties. This intermediate Gulf Water reflects the properties of both the deep, relatively fresh inflow and the salty surface layer formed by evaporation.

V. THERMOHALINE CIRCULATION

As previously discussed, unlike the Mediterranean and Red seas, the Gulf of California actually gains heat from the atmosphere on an annual average. This heat gain is presumably balanced by an advective flux of colder water into the Gulf and warmer water out of the Gulf. This theory correlates with observed vertical gradients of temperature and salinity and with baroclinically determined circulation patterns (Bray, 1988a).

Hydrographic evidence from moored observations and ship measurements suggests that the Gulf's thermohaline circulation is comprised of the following three-layered system: 1) surface layer which is approximately 50 m thick and reverses transport direction with the seasonally reversing large-scale wind field, flowing north in the summer and south in the winter, 2) baroclinic outflow occurring along the

western shores of the Gulf between the surface layer and about 250 m depth, and 3) baroclinic inflow occurring mainly in the central sector of the Gulf between 250 and 500 m depth (Bray, 1988a). There was insufficient data to resolve the circulation at depths deeper than 500 m. To this she adds, "...thermohaline circulation should be constrained to depths above about 500 m, which is the controlling sill depth between the northern and central sections of the Gulf."

The proposed three-layer system has several implications for circulation in the Gulf. In preceding sections of this paper, the formation of an intermediate water mass was discussed. Outflow from the Gulf predominantly consists of this intermediate Gulf Water. Another point of interest is that at the mouth of the Gulf the density of the outflow is such that it forms a near-surface layer. Upon exiting the Gulf, the Gulf Water signature negligibly influences the adjoining Pacific. Also, the Gulf's receipt of

deep, subsurface, nutrient-rich inflow waters from the Pacific gives a sound explanation for the high biological productivity found in the Gulf (Bray, 1988a).

At the mouth of the Gulf, one prominent feature is a thin (10-30 m thick) but pronounced high stability layer sandwiched between the warm surface layer and cooler subsurface layer. This stability layer, depicted in Figure 4, is identified by Väisälä frequencies (where Väisälä freq. $> 0.02 \text{ sec}^{-1}$), and practically extends across the entire southern Gulf. The top of this high stability layer lies at approximately 50 m depth and may be used as an index of the depth of the upper mixed layer. Of particular interest is that breaks in this high-stability layer, clearly evident on the west side of the Gulf, are indicative of strong baroclinic flow (Roden, 1972).

Baroclinic flow across the entrance to the Gulf of California was computed from STD observations (Figure 5). According to Roden (1972), the flow is

referenced to the 1500 dbar surface or the bottom, whichever was encountered first.

Baroclinic outflow, whose origin is traced to the northern Gulf (salinity maximum $> 35.2\%$), flows near the western shores of the southern Gulf, traveling south in a narrow, high-speed velocity core. This core has a characteristic width of about 30 km and deepens to more than 1000 m at the Gulf's entrance. Maximum velocities within the core occur at the surface, reaching 55 cm/sec.

Baroclinic inflow into the Gulf takes place mainly in the central part. Here there are two observable cores of increased velocity entering the Gulf. One core is about 20 km wide and has a maximum velocity of ≈ 26 cm/sec, occurring between 50 and 450 m depth. The other, slightly wider than the first, has a maximum speed of 46 cm/sec and is confined to the upper layer.

VI. SUMMARY

The Gulf of California's hot, arid summer climate makes it the Pacific Ocean's only evaporative sea basin. Surface currents in the Gulf generally follow seasonal variations of the wind, with northwesterlies blowing from November to May and southeasterlies from June to October.

Unlike similar semi-enclosed sea basins (namely, the Mediterranean and Red seas), the Gulf of California is uniquely characterized by a destabilizing vertical salinity gradient (salinity decreases with depth) over the top 700 m water column. This condition occurs as a result of the unusual atmospheric forcing occurring over the Gulf, which results in a net loss of moisture from the ocean surface but a net gain of heat. Given this condition, an intermediate Gulf Water mass is formed. The mechanisms for the formation of this intermediate

water mass include: winter convection in the northern basins; advection of newly convected water via isolated eddies, referred to as Gulfies; transport of water south from the northern shelves by way of a large-scale anticyclonic gyre; and strong tidal mixing.

The thermohaline circulation pattern proposed for the Gulf to balance the net heat and moisture fluxes consists of three layers. There is the surface layer, whose current field is directly influenced by the seasonally varying wind. Baroclinic outflow transports warm and saline Gulf Water of northern origin out of the Gulf along its western boundary. Baroclinic inflow transports relatively fresh, cold Pacific Intermediate Water into the Gulf at the central sector of its entrance.

Figure 1. Schematic depicting topography (sills and basins) and water mass distribution in the Gulf of California. Arrows denote hypothesized thermohaline circulation: the open arrow representing the surface wind-driven layer with seasonally reversing transport; solid arrows representing subsurface inflow and outflow; dashed arrow representing deep water formation (Figure 3a., Bray, 1988b).

Figure 2. Comparison of the vertical thermohaline structure in the Gulf of California (top graphic, A), and the western Mediterranean Sea (bottom graphic, B). Note that in the case of the Gulf of California, salinity decreases with depth; thus indicating, vertical instability in the water column (Figure 2., Bray, 1988b).

Figure 3. Anticyclonic gyre found in the northern Gulf in March 1985. Plots include: (a) salinity at 10 m, (b) dynamic height at 10 m relative to 100 m, and (c) velocity vectors derived from the dynamic height field. The gyre is presumed to be partially responsible for moving high-salinity waters south from the northern shelf regions. It is also believed to contribute to the mixing processes occurring in the northern Gulf (Figure 15., Bray, 1988b).

Figure 4. Vertical distribution of Väisälä frequency (sec^{-1}) across the entrance to the Gulf of California. The layer of high stability water is shaded. Breaks in the high stability regions are indicative of baroclinic flow (Figure 2., Roden, 1972).

Figure 5. Baroclinic flow (cm/sec) across the entrance to the Gulf of California. The flow is referenced to the 1500 dbar surface. The transection runs from Arroyo de Vinorama, Baja California, to approximately Mazatlán, Sinaloa and was occupied on 5-6 December 1969 (Figure 4., Roden, 1972).

APPENDIX B: SPICINESS (π)

Flament (1986) defined spiciness, π (θ, s), as a state variable which is most sensitive to isopycnal thermohaline variations. He explains that spiciness contributes to examination of double diffusive processes and serves as a tracer for water mass identification. Munk (1981) stated that the largest values of spiciness were indicative of hot and salty water.

γ_θ - π Diagram

The γ_θ - π diagram (Figure B1) shows that spiciness is a monotonic decreasing function of density in this location. Greatest spiciness ($\pi \geq 3.75$) was observed at the surface near the lowest densities, where the effects of insolation are greatest.

The mid-layer regime, where densities range between 24.75 - 26.50 kg/m³, again is a region of variability. From the definition of spiciness, the

variability is associated with contrasts in Gulf, California Current and Tropical Water masses. Because Gulf Water is mostly constrained to and admixed with Tropical Surface Water in the surface layer, this suggests that the variability of the mid-layer is between California Current and Subtropical Subsurface Water masses. One would expect California Current Water, marked by lesser salinity, to coincide with the lesser spiciness in the layer.

The deep-layer regime, where densities are greater than 26.50 kg/m^3 , is uniform, and spiciness decreases more slowly as density increases.

Spiciness (π)

The 500 dbar spiciness transection, shown in Figure B2, supports earlier interpretation of the temperature and salinity structures. Warm, saline surface waters are found across the entire Gulf, with maximum spiciness values ($\pi \geq 3.75$) concentrated at the surface. Depressed curves of spiciness along the Baja banks infer protrusion of warm, saline water down

to 175 m depth there. Positioned east of and fronting this warm, saline water is a ridge centered approximately 55 km offshore. East of the ridge, the spiciness lines exhibit a slight shoaling trend towards the east, indicating cooler and less saline water. Evident within this broad section are two independent cores of cool, fresh water observed via doming features. At 50 to 100 m depth, slight doming occurs 80-100 km offshore from the Baja shore. More pronounced doming of the spiciness curves is observed with the sudden upward protrusion of the 1.5 curve from 150 m depth at 130 km offshore. The doming pushes well into the near-surface layer, with a slight offset east beginning at spiciness curve 3.0. Across the Gulf, the spiciness structure of the upper layer correlates with the locations of the salinity pools previously discussed. In summary, the upper structure shows a frontal ridge centered 55 km offshore from the Baja peninsula separating warm, salty water to the

west from cores of cooler, less saline water to the east.

With depth, spiciness values uniformly decrease (Figure B3). Negative values of spiciness, denoting water of cold and fresher salinity, are not observed until 1000 m depth. Minimum values of spiciness ($\pi \leq -0.1$) are observed at depths greater than 1500 m.

A sense of the along-gulf distribution is accomplished by examining the Leg III transection (Figures B4 and B5). Spiciness curves in the upper layer show similar structuring to the south and up to 32 km north of the transections' intersection (denoted by vertical line on plots). The spiciness contour beyond this northernmost position indicates simultaneous deepening and spreading of the warm, saline surface waters. Such is consistent with Roden's (1964) explanation that Gulf Water, characterized by high salinity and temperature, has its origin in the northern Gulf. In the subsurface layer, the 2.0 and 2.5 spiciness contours shoal at station #59,

suggesting the presence of cooler, less saline water there. Below 200 m the contours tilt downward towards the north, again implying overall warmer and more saline water north of where the transections intersect.

Figure B(1). Full section scatter plot for PESCAR 02 (28 December 1992 - 02 January 1993). Plot is subdivided into sections by water mass: 1) **TSW** denotes Tropical Surface Water, 2) **GW** denotes Gulf Water, 3) **CCW** denotes California Current Water, and 4) **SSW** denotes Subtropical Subsurface Water. The top 10 m section is denoted by circles. Density anomaly - Spiciness ($\gamma_{\theta} - \pi$) diagram.

Figure B(2). Spiciness. 500 dbar across-gulf transection for PESCAR 02 (28 December 1992 - 02 January 1993). Cast location and number are given at the top of the figure. Vertical line at cast #25 marks the position of intersection with along-gulf intersection. It also denotes the location of the Alarcon Seamount. Contour spacing is 0.5.

Figure B(3). Spiciness. 3000 dbar across-gulf transection for PESCAR 02 (28 December 1992 - 02 January 1993). Cast location and number are given at the top of the figure. Vertical line at cast #25 marks the position of intersection with along-gulf transection. It also denotes the location of the Alarcon Seamount. Dashed line has spiciness = -0.1.

Figure B(4). Spiciness. 500 dbar along-gulf transection for PESCAR 02 (03 - 08 January 1993). Cast location and number are given at the top of the figure. Vertical line at cast #52 marks the position of intersection with the across-gulf transection. It also denotes the location of the Alarcon Seamount. Contour spacing is 0.5.

Figure B(5). Spiciness. 3000 dbar along-gulf transection for PESCAR 02 (03 - 08 January 1993). Cast location and number are given at the top of the figure. Vertical line at cast #52 marks the position of intersection with across-gulf transection. It also denotes the location of the Alarcon Seamount. Dashed line has spiciness = -0.1.

APPENDIX C: CTD DATA PROCESSING AND LISTINGS

Tables C1 and C2 summarize dates, locations and bottom depths for across- and along-gulf transections, respectively. In Table C3, hydrographic data are listed for these transections. The specific volume anomaly (δ) is calculated using algorithms found in Volume 4 of the International Oceanographic Tables (UNESCO, 1987). The units for δ are $10^{-8} \text{ m}^3 \text{ kg}^{-1}$. The summation of dynamic height ($\Sigma\Delta D$) is made from the surface, and the units are in dynamic meters ($\text{m}^2 \text{ s}^{-2}$). Spiciness is calculated using an algorithm provided by Flament (1986). Table C4 lists salts used for CTD calibration.
