<b>Abstract:</b>	<p>The Spanish late Miocene locality of Batallones-1 yielded a rich sample of large carnivorans, including saber-toothed felids, amphicyonids, and ailurids, but also of smaller species, with the small cats being especially interesting. Two species are known from Batallones-1, one of them the size of a wildcat, <i>Felis silvestris</i>, the other one the size of a caracal, <i>Caracal caracal</i>. The former is represented by skulls, mandibles, and postcranial bones, whereas the latter is known from a collection of long bones. Both species are less abundant than their larger relatives, the saber-toothed felids <i>Promegantereon ogygia</i> and <i>Machairodus aphanistus</i>, but the available sample allows us to assess body proportions and adaptations of the smallest species, and to propose a new genus for this feline, <i>Leptofelis vallesiensis</i>. Its limb bones are remarkably gracile compared to fossils of the earlier genera <i>Pseudaelurus</i>, <i>Miopanthera</i>, and <i>Styriofelis</i>, and comparable in cursorial adaptations to the wildcat, very different from extant arboreal cats. While middle Miocene felids were likely semi-arboreal forest dwellers, <i>L. vallesiensis</i> would be mostly terrestrial, climbing essentially for protection. This indicates an adaptation to a mosaic of habitats, including relatively open terrain, and may be related to the climatic changes detected in Eurasia during the late Miocene.</p>

## Introduction

Fossils of primitive felids are recorded in several early and middle Miocene sites of Europe, Africa, and North America (Thenius 1949; Viret 1951; Crusafont-Pairó 1952; de Beaumont 1961; Ginsburg 1961a, 1983, 1999, 2002; Crusafont-Pairó and Ginsburg 1973; Rothwell 2001, 2003; Morales et al. 2003; Werdelin et al. 2010). Concerning those showing feline affinities, there are up to four species classically included in the genus *Pseudaelurus* Gervais, 1850: *Ps. romieviensis* Roman and Viret, 1934, from La Romieu (France, MN4), *Ps. turnauensis* (Hoernes, 1882) from Göriach (Germany, MN 5), *Ps. transitorius* Depéret, 1892 and *Ps. lorteti* Gaillard, 1899, both from La Grive-Saint-Alban (France, MN 7/8). All of them are mostly known from cranial and dental fragments, which show a quite similar pattern, but unfortunately, very few postcranial bones are known from these early felines, and thus it is difficult to make inferences about their locomotor adaptations. A fifth species of primitive felid from Sansan (France, MN 6) was also included in *Pseudaelurus* as *Ps. quadridentatus* (Blainville, 1843) (in fact this form is the type species of the genus), but based on its particular features (moderately elongated and laterally flattened upper canines and relatively robust Mc I) it is currently considered as the first known saber-toothed felid, hence the genus *Pseudaelurus* should be included within the subfamily Machairodontinae (de Beaumont 1978; Werdelin et al. 2010; Salesa et al. 2012a; Peigné 2012). Considering this, and the feline dental characters (basically, relatively short upper canines with rounded section) that they displayed, most of the other species of *Pseudaelurus* (i.e., *Ps. lorteti*, *Ps. turnauensis*, and *Ps. transitorius*, the last being a junior synonym of *Ps. turnauensis*) mentioned above were assigned in different genera, *Styriofelis* Kretzoi, 1929, for *Ps. turnauensis*, and *Miopanthera* Kretzoi, 1938, for *Ps. lorteti* (Geraads and Peigné 2016). To

1  
2  
3  
4 summarize, in the middle Miocene at least three different taxa are known in Western  
5  
6 Europe: the primitive machairodontine *Ps. quadridentatus*, the lynx-sized feline *M. lorteti*,  
7  
8 and the wild cat-sized feline *S. turnauensis*. Nonetheless, we should consider that the  
9  
10 scarcity of postcranial bones of these taxa is probably concealing a greater generic diversity  
11  
12 and preventing an in-depth taxonomic knowledge of these early Felinae.  
13  
14

15  
16 Cranial remains of European late Miocene Felinae are much better known than  
17  
18 those from the lower and middle Miocene, and several skulls and mandibles are known  
19  
20 from different Turolian European localities (Wagner 1857; Schlosser 1924; de Mecquenem  
21  
22 1924; Riabinin 1927; Kretzoi 1951, 1952; de Beaumont 1961; Schmidt-Kittler 1976;  
23  
24 Solounias 1981; Forsten and Kaya 1995; Morlo 1997; Ginsburg 1999; Roussiakis 2002; de  
25  
26 Bonis 2005). All of them were classically assigned to the wildcat-sized *Felis attica*  
27  
28 Wagner, 1857, but separated by Salesa et al. (2012a) into the new genus *Pristifelis* as *P.*  
29  
30 *attica*. Nevertheless, the postcranial skeleton of this animal is as poorly known as those  
31  
32 from the earliest Felinae. In fact, few papers including comparative descriptions or  
33  
34 functional inferences on the postcranial anatomy of these Miocene felines have been  
35  
36 published (de Beaumont 1961, 1986; Salesa et al. 2011). Finally, a new species was  
37  
38 described from the Vallesian of Batallones-1 and Batallones-3 (Madrid, Spain) by Salesa et  
39  
40 al. (2012a) under the name of *Styriofelis vallesiensis*. This is the smallest of the two species  
41  
42 of Felinae known from these Spanish localities. When Salesa et al. (2012a) assigned the  
43  
44 small feline from Batallones-1 and Batallones-3 to the genus *Styriofelis* as the new species  
45  
46 *S. vallesiensis*, they chose the most conservative taxonomic point of view based on a set of  
47  
48 dental similarities between the Batallones sample and the Middle Miocene feline *S.*  
49  
50 *turnauensis*, although in their cladogram these two species are not sister-taxa.  
51

1  
2  
3  
4 Here, we describe the postcranial anatomy of *S. vallesiensis*, based on a well-  
5  
6 documented sample from Batallones. The objective of our study is first to address the  
7  
8 generic affinities of the two species of *Styriofelis*: do their postcrania provide an additional  
9  
10 support of their **close** generic relationships? At a wider scale, we also want to address the  
11  
12 systematic relationships and postcranial functional anatomy of the small- to medium-sized  
13  
14 felines of the **m**iddle and **l**ate Miocene of Europe mentioned above: *Miopanthera lorteti*,  
15  
16 *Styriofelis turnauensis*, *Styriofelis vallesiensis*, and *Pristifelis attica*. We posit that their  
17  
18 postcranial anatomy presents marked differences that, in addition to their particular cranio-  
19  
20 dental features, supports both their taxonomic distinction and different adaptations and  
21  
22 ecology. Thus, in the Systematic Palaeontology section we provide with a proper  
23  
24 discussion on this issue, and the proposal of the new genus *Leptofelis* for the species *S.*  
25  
26 *vallesiensis*. In consequence, we will refer throughout the text to the species from  
27  
28 Batallones-1 with the new name of *Leptofelis vallesiensis*.

## 38 **Material and methods**

39  
40  
41 The studied postcranial fossils of *Leptofelis vallesiensis* come from the fossil site of  
42  
43 Batallones-1, which is part of the Cerro de los Batallones paleontological complex, located  
44  
45 in a low hill of around 700 m of elevation, 30 km south of the city of Madrid (Spain). Up to  
46  
47 **nine** localities have been found since 1991 thanks to the exploitation of the hill as an  
48  
49 opencast mine of sepiolite. The sites were formed through a geological process of piping,  
50  
51 which consisted in the erosion of the sepiolite levels by water flowing along fractures,  
52  
53 causing collapses and the development of karst-like ('pseudokarst') topography (Pozo et al.  
54  
55 2004; Calvo et al. 2013). These cavities acted as natural traps for the animals inhabiting the  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 area, mostly carnivorous vertebrates that entered the holes attracted by the carcasses of  
5  
6 other previously trapped animals (Antón and Morales 2000; Morales et al. 2000). One of  
7  
8 them, Batallones-1, excavated during 1991-2008, has provided an amazing assemblage of  
9  
10 Carnivorans, including the ailurid *Simocyon batalleri*, the amphicyonid *Magericyon*  
11  
12 *anceps*, three species of mustelids, the primitive hyaenid *Protictitherium crassum*, the  
13  
14 machairodont felids *Machairodus aphanistus* and *Promegantereon ogygia*, and two species  
15  
16 of felines (Morales et al. 2000, 2004; Antón et al. 2004; Peigné et al. 2005, 2008; Salesa et  
17  
18 al. 2005, 2006a, b, 2008, 2010a, b; Siliceo et al. 2015, 2017). In their revision of the late  
19  
20 Miocene felines, Salesa et al. (2012a) proposed the new species *Styriofelis vallesiensis* for  
21  
22 the smaller of these two species of Felinae, mainly based on the relative dental similarities  
23  
24 of this species with the Middle Miocene *S. turnauensis*. *Leptofelis vallesiensis* is present in  
25  
26 two localities of Batallones: Batallones-1 and Batallones-3, separated by no more than one  
27  
28 hundred meters, and with their saber-toothed felids populations showing enough  
29  
30 morphological differences to support also a temporal separation between them (Monescillo  
31  
32 et al. 2014; Siliceo et al. 2014).

33

39  
40  
41 The fossils of *L. vallesiensis* described here are housed at the Museo Nacional de  
42  
43 Ciencias Naturales-CSIC (Madrid, Spain). They were found during the excavation  
44  
45 campaigns of 1991-2008 at the late Vallesian locality of Batallones-1 (Torrejón de Velasco,  
46  
47 Spain), coordinated by J. Morales. The list of studied material is as follows: BAT-1'06 D4-  
48  
49 64a, BAT-1'06 D4-64b and BAT-1'06 D4-64c, L7-L4; B-4968, right humerus; BAT-1'02  
50  
51 D6-58, left humerus; B-2074 (5), right radius; B/S-575, left radius; B-2074 (6), BAT-1'08  
52  
53 C8-24, and BAT-1'06 E5-50, right ulnae; BAT-1'03 D4-239, right Mc I; B-2849, left Mc I;  
54  
55 BAT-1'03 D5-162, right Mc II; BAT-1'04 D4-184, right Mc III; BAT-1'03 E4-164, right  
56  
57 Mc IV; BAT-1'04 E5-129, right Mc V; BAT-1'04 E5-212, left Mc V; BAT-1'06 D4-66a,  
58  
59  
60  
61  
62  
63  
64  
65

1

3  
4 left and right coxae; BAT-1'06 D4-66b, sacrum; BAT-1'06 D4-67a, right femur; BAT-1'06  
5  
6 D4-67b, left femur; BAT-1'06 D4-103, right tibia; BAT-1'06 D4-110, left tibia; BAT-1'04  
7  
8 D6-173, right talus; BAT-1'03 D6-300, left talus; BAT-1'04 D6-173 and BAT-1'06 F5-61,  
9  
10 right calcanei; BAT-1'04 D6-62 and BAT-1'03 D6-301, left calcanei.  
11  
12

13  
14 Nine species of small extant Felidae were used for anatomical comparisons:

15  
16 *Caracal caracal* (Schreber, 1776), *Felis silvestris* Schreber, 1775, *Felis lybica* Forster,  
17  
18 1780, *Leopardus wiedii* (Schinz, 1821), *Leopardus geoffroyi* (d'Orbigny and Gervais,  
19  
20 1844), *Leptailurus serval* (Schreber, 1776), *Lynx pardinus* (Temminck, 1827), *Lynx lynx*  
21  
22 (Linnaeus, 1758), and *Lynx rufus* (Schreber, 1777). We also used specimens from other  
23  
24 families of Carnivora: the viverrids *Genetta genetta* Linnaeus, 1758, and *Civettictis civetta*  
25  
26 (Schreber, 1776), and the mustelid *Martes martes* (Linnaeus, 1758). All this material  
27  
28 belongs to the collections of the Museo Anatómico, Facultad de Medicina, Universidad de  
29  
30 Valladolid (Spain), and the Comparative Anatomy Collections of the Museo Nacional de  
31  
32 Ciencias Naturales-CSIC. We also compared the fossils of *Leptofelis vallesiensis* from  
33  
34 Batallones-1 with the sample of *Miopanthera lorteti* (Blainville, 1842) from the classical  
35  
36 fossil site of Sansan (MN 6, France), belonging to the collections of the Muséum national  
37  
38 d'Histoire naturelle (Paris, France); comparisons were also made with published material of  
39  
40 *Styriofelis turnauensis* (Gaillard 1899; de Beaumont 1961) and *M. lorteti* (Ginsburg and  
41  
42 Antunes 1995; Salesa et al. 2011) and the late Miocene feline *Pristifelis attica* (Roussiakis  
43  
44 2002). The anatomical descriptions follow the terminology used by Barone (2010), Evans  
45  
46 (1993), Julik et al. (2012) and the Nomina Anatomica Veterinaria (2012). The  
47  
48 measurements were taken with digital calipers, and are shown in Fig. 1 and Tables 1–2.

### 33 Use of cladistic terminology

34  
35 Unfortunately, and due to the scarcity of postcranial fossils of Miocene felines, no cladistic  
36  
37 analysis could be performed in the present study. Nevertheless, the discussed characters are  
38  
39 polarized by outgroup comparisons to non-felid Feliformia or Caniformia on one end, and  
40  
41 crown-group felids on the other. Given this, and in absence of a proper cladistic analysis,  
42  
43 we cannot rule out the possibility that apparently plesiomorphic features are actually  
44  
45 reversals, and that features that appear to be derived are convergences with crown taxa  
46  
47 (instead of shared derived characters). Only a future cladistic analysis could elucidate these  
48  
49 issues, but we have considered of interest to use the terms “primitive” and “derived” in the  
50  
51 context of our discussion on functional adaptations.

11 **Anatomical descriptions and comparisons**  
12  
13  
14

15 In general, the postcranial bones of *L. vallesiensis* from Batallones-1 show a good state of  
16 preservation, and practically, all their anatomical structures can be observed. In this section,  
17 we describe the most remarkable features of this material.  
18  
19  
20  
21  
22  
23  
24

25 Lumbar vertebrae  
26  
27  
28  
29

30 Four articulated lumbar vertebrae of *L. vallesiensis*, the cranial one just preserving its  
31 caudal half, are known from Batallones-1 (Fig. 2). The most caudal of these vertebrae has a  
32 craniocaudally shorter body and wider caudal articulation processes than the others, which  
33 identifies it as the seventh lumbar vertebra, and so the rest are the sixth, the fifth, and a  
34 caudal fragment of the fourth lumbar vertebrae (formally, L7-L4). Comparing this lumbar  
35 series with those of the comparative sample of extant felines, the L7 of *L. vallesiensis* is  
36 relatively shorter than those of the other species, especially those of *F. silvestris*, *F. lybica*  
37 and *Lp. geoffroyi*, whereas the L7 of *Le. serval*, *C. caracal*, *Ly. lynx*, *Ly. pardinus*, and *Ly.*  
38 *rufus* are only slightly craniocaudally longer than that of *L. vallesiensis*. The costal  
39 processes are severely broken in all the specimens, but the preserved portions show that  
40 they were flat and cranially curved. The spinous processes were developed from the cranial  
41 to the caudal border of the dorsal surface, and at least in the sixth and fifth vertebrae were  
42 triangular (in the seventh lumbar just the base is preserved), although their tips are broken

65

1  
2  
3  
4 (Fig. 2a). Both the cranial and caudal articular processes are elliptical and dorsocranially or  
5  
6 dorsocaudally oriented, respectively; they show this same morphology and orientation in  
7  
8 the rest of the compared species. In the ventral surface of the body, a shallow central ridge  
9  
10 is observed in all the compared felines (Fig. 2b).  
11  
12  
13  
14

## 15 16 Humerus 17 18 19 20

21 The overall morphology of the humerus of *L. vallesiensis* is similar to that of other small-  
22  
23 sized felines. The diaphysis is quite straight in cranial view, whereas in lateral view it is  
24  
25 gently craniocaudally curved (Fig. 3). Among the compared felines, only *Le. serval* shows  
26  
27 a slightly straighter diaphysis. In proximal view, the proximal epiphysis of *L. vallesiensis*  
28  
29 shows an elliptic articular head, slightly laterally flattened, with a smooth greater tubercle  
30  
31 developed along the cranio-lateral margin, and a craniomedially projected lesser tubercle  
32  
33 on the medial margin. The greater tubercle of *Lp. geoffroyi* is less cranially expanded onto the  
34  
35 articular head than those of *L. vallesiensis* and the other extant compared felines. Also, the  
36  
37 articular head is rounded (not elliptic) in *Lp. wiedii*, *C. caracal*, *Ly. lynx*, *Ly. pardinus*, and  
38  
39 *Ly. rufus*. The intertubercular groove of *L. vallesiensis* is well developed and relatively  
40  
41 wide, very similar to that of the compared felines.  
42  
43  
44  
45  
46  
47

48 In medial view, the greater tubercle of *L. vallesiensis*, as well as those of *F.*  
49  
50 *silvestris*, *Le. serval*, *Ly. lynx*, *Ly. pardinus*, and *Ly. rufus* is more proximally projected than  
51  
52 those of *Lp. wiedii* and *Lp. geoffroyi*, clearly surpassing the level of the articular head. A  
53  
54 right humerus of *S. turnauensis* from La Grive-Saint-Alban illustrated by Galliard (1899),  
55  
56 with the catalogue number L. Gr. 1216 shows a reduced greater tubercle, similar to those of  
57  
58 *Lp. wiedii* and *Lp. geoffroyi*. In cranial view, the lesser tubercle of *L. vallesiensis* is  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 medially projected (Fig. 3a), with an almost vertical medial border, and a small, round  
5  
6 proximal tuberosity that is part of the attachment area of the m. subscapularis, located on  
7  
8 the medial surface of the lesser tubercle. *Leopardus wiedii*, *Lp. geoffroyi*, *F. silvestris*, *Le.*  
9  
10 *serval*, *Ly. lynx*, *Ly. pardinus*, and *Ly. rufus* show this pattern, although the lesser tubercle  
11  
12 is much more medially projected than in *L. vallesiensis*. Just distally to the lesser tubercle,  
13  
14 there is a short crest that barely extends distally onto the diaphysis, similarly developed in  
15  
16 all the compared species. The attachment area for the m. subscapularis, which occupies the  
17  
18 cranial margin of the lesser tubercle, is much more distally elongated in *L. vallesiensis*, *F.*  
19  
20 *silvestris*, *Le. serval*, *Ly. lynx*, *Ly. pardinus*, and *Ly. rufus* than in *Lp. wiedii*, whereas *Lp.*  
21  
22 *geoffroyi* shows an intermediate pattern. In cranial view, two different orientations of the  
23  
24 proximal margin of the greater tubercle can be clearly observed: in *L. vallesiensis*, *F.*  
25  
26 *silvestris*, *Le. serval*, *Ly. lynx*, *Ly. pardinus*, and *Ly. rufus*, this margin is more cranially  
27  
28 inclined than those of *Lp. wiedii* and *Lp. geoffroyi*, probably due to the lesser development  
29  
30 of the greater tubercle. From the illustration by Gaillard (1899), the primitive *S. turnauensis*  
31  
32 shows a close morphology to that of these latter South American felines. The crest of the  
33  
34 greater tubercle of *L. vallesiensis* is very gentle, and it extends along the cranial border of  
35  
36 the humerus until the middle part of the diaphysis, where a very smooth deltoid tuberosity  
37  
38 is developed; this morphology is also observed in *F. silvestris*, *Lp. wiedii*, *Lp. geoffroyi*, *C.*  
39  
40 *caracal*, and *Le. serval*, whereas in *Ly. lynx*, *Ly. pardinus*, and *Ly. rufus* the crest is much  
41  
42 more marked, even ridged. This crest is the attachment area for the mm. pectorales  
43  
44 (superficialis and profundus) and m. deltoideus, this latter attaching on the deltoid  
45  
46 tuberosity (Davis 1964; Evans 1993; Barone 2010; Ercoli et al. 2015).  
47  
48  
49  
50  
51  
52  
53  
54  
55  
56

57 On the middle of the lateral surface of the greater tubercle of *L. vallesiensis*, there is  
58  
59 a marked elliptical scar for the attachment of the m. infraspinatus (Fig. 3b); it has ridged  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 margins, and it is oriented with its proximal border slightly inclined caudally, as in *F.*  
5  
6 *silvestris* and *Le. serval*, and also as in *S. turnauensis*; on the contrary, in *Ly. lynx*, *Ly.*  
7  
8 *pardinus*, *Ly. rufus*, *Lp. wiedii*, and *Lp. geoffroyi*, the scar is almost rounded and sub-  
9  
10 parallel to the diaphysis, although in the two *Leopardus* species, the scar is relatively  
11  
12 smaller than those of the other compared felines. In all the compared taxa, the articular  
13  
14 head is projected caudally, and the neck is marked, clearly distinguished from the head. The  
15  
16 tricipital line of *L. vallesiensis* (for the attachment of the lateral branch of the m. triceps  
17  
18 brachii) is marked, slightly ridged, and it develops from the attachment area for the m.  
19  
20 infraspinatus, to the distal tip of the deltoid tuberosity. In the compared sample, the line is  
21  
22 only absent in *Lp. wiedii*, being especially marked in *Le. serval* and *Ly. pardinus*. In *L.*  
23  
24 *vallesiensis*, just **distal** to the attachment area for the m. infraspinatus, and on the proximal  
25  
26 end of the tricipital line, there is a rough and irregular scar for the attachment of the m. teres  
27  
28 minor, similarly marked in *F. silvestris* and *Lp. wiedii*, less evident in *Lp. geoffroyi*, and  
29  
30 much more developed, even showing a strong ridge, in *Le. serval*, *Ly. lynx*, *Ly. pardinus*,  
31  
32 and *Ly. rufus*. **Caudal** to this attachment area, *L. vallesiensis* shows a strongly excavated  
33  
34 groove for the accessory branch of the m. triceps brachii; this area is shallower in *F.*  
35  
36 *silvestris*, *Lp. wiedii*, and *Lp. geoffroyi*, whereas in *Le. serval*, *Ly. lynx*, *Ly. pardinus*, *Ly.*  
37  
38 *rufus*, and *S. turnauensis*, it is more excavated, with a proximal strongly ridged border.

39  
40  
41  
42  
43  
44  
45  
46  
47  
48 In the distal epiphysis, the medial epicondyle of *L. vallesiensis*, *Le. serval*, and *Ly.*  
49  
50 *lynx* is moderately medially expanded (Fig. 3a), whereas those of *F. silvestris*, *Lp. wiedii*,  
51  
52 *Lp. geoffroyi*, *C. caracal*, *Ly. pardinus*, and *Ly. rufus* are much more projected. The fossil  
53  
54 species *S. turnauensis* and *M. lorteti* show **well-developed** medial epicondyles too, much  
55  
56 more projected than that of *L. vallesiensis*, as shown by the specimen L. Gr. 1216 (Gaillard  
57  
58 1899) and an almost complete humerus of the larger *M. lorteti* from the Portuguese site of  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 Quinta das Flamengas (Ginsburg and Antunes 1995); finally, a distal fragment of a left  
5  
6 humerus of the Turolian species *Pristifelis attica* (AMPG PA 2803/91) published by  
7  
8 Roussiakis (2002) shows a medial epicondyle very similarly developed as that of *L.*  
9  
10 *vallesiensis*. On the other hand, the lateral epicondyle, which shows less projection than the  
11  
12 medial one, is clearly less expanded in *L. vallesiensis* than in any of the compared species,  
13  
14 which are quite similar in the development of this structure (including *S. turnauensis*, *M.*  
15  
16 *lorteti*, and *P. attica*). There is a well-developed supracondylar foramen in all the compared  
17  
18 species, including *L. vallesiensis* and *P. attica*. In cranial view, the trochlea is strongly  
19  
20 distally projected in all the species, although less in *Lp. wiedii* and *Lp. geoffroyi*. In medial  
21  
22 view, the cranial margin of the trochlea is craniodistally oriented in all the species, but  
23  
24 more projected in *Ly. lynx* and *Ly. rufus* than in *L. vallesiensis*, *Lp. wiedii*, *Lp. geoffroyi*, *Le.*  
25  
26 *serval*, *Ly. pardinus*, and *C. caracal*. In *L. vallesiensis*, *Lp. geoffroyi*, and *Le. serval*, the  
27  
28 scar for the attachment of the m. pronator teres, located on the distal end of the  
29  
30 supracondylar bar, is relatively smaller than those of *F. silvestris*, *Lp. wiedii*, *C. caracal*,  
31  
32 *Ly. pardinus*, *Ly. rufus*, and *Ly. lynx*, mainly because in all these latter species it is  
33  
34 proximally extended, significantly increasing the attachment surface of this muscle. Just  
35  
36 **distal** to the attachment area for the m. pronator teres there is a similarly sized surface for  
37  
38 the attachment of the m. flexor carpi radialis; this surface is relatively larger in *Lp. wiedii*  
39  
40 than in the rest of the compared species, including *L. vallesiensis*. In the caudal face of the  
41  
42 distal epiphysis, the olecranon fossa of *L. vallesiensis* is deep, with a ridged lateral border,  
43  
44 as observed in the rest of the compared taxa. This olecranon fossa is relatively wider in *F.*  
45  
46 *silvestris*, *Ly. rufus*, *Lp. wiedii*, and *Lp. geoffroyi* than in *L. vallesiensis*, *Ly. lynx*, *Ly.*  
47  
48 *pardinus*, *C. caracal*, and *Le. serval*, mostly because the medial margin of the olecranon  
49  
50 fossa is much more vertical in the latter group, whereas in the former, it opens distally.  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 Also in caudal view, *L. vallesiensis* shows a relatively mediolaterally narrower distal  
5  
6 epiphysis than those of the compared felines. The caudal surface of the medial epicondyle  
7  
8 shows a small round attachment surface for the medial branch of the m. triceps brachii,  
9  
10 very similarly developed in all the compared species except in *Ly. lynx*, in which it is very  
11  
12 smooth, almost unnoticeable. In the distal tip of the medial epicondyle there are a couple of  
13  
14 elliptical and rough attachment surfaces for the m. flexor carpi radialis and m. palmaris  
15  
16 longus, which do not show remarkable differences among the studied sample. In the caudal  
17  
18 surface of the lateral epicondyle of *L. vallesiensis* there is an excavated groove for the  
19  
20 articular capsule, especially marked in *Le. serval*, *Ly. lynx*, *Ly. pardinus*, and *Ly. rufus*. The  
21  
22 lateral supracondylar crest of *L. vallesiensis* is slightly ridged, mostly in its distal portion,  
23  
24 although it continues proximally to the middle of the diaphysis as a smooth but marked  
25  
26 crest; this pattern is observed in *F. silvestris*, *Lp. wiedii*, and *Lp. geoffroyi*, and in the fossil  
27  
28 species *S. turnauensis* and *P. attica*, whereas in *Ly. pardinus*, *Ly. rufus*, *C. caracal*, and,  
29  
30 especially in *Le. serval*, the crest is expanded forming a bony wall; on the other hand, in *Ly.*  
31  
32 *lynx* the crest, although present does not project from the bone surface, and it is formed  
33  
34 more as a cord rather than as a real crest. On the caudal surface of the crest there is a flat  
35  
36 and smooth surface for the attachment of the m. anconeus; the size of this surface is related  
37  
38 to the different development of the lateral supracondylar crest, and thus it is relatively  
39  
40 larger in *Ly. pardinus*, *Ly. rufus*, *C. caracal*, and, especially in *Le. serval*.  
41  
42  
43  
44  
45  
46  
47  
48  
49  
50  
51  
52

### 53 Radius

54  
55  
56  
57 The radius of *L. vallesiensis* is slender, with a straight and strongly craniocaudally flattened  
58  
59 diaphysis (Fig. 3c, d). The proximal epiphysis is slightly medially inclined; its proximal  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 articulation facet is concave and elliptical, with a marked notch in the middle of its cranial  
5  
6 margin forming a clear capitular eminence; the lateral margin of this facet is ridged,  
7  
8 whereas the medial one is inclined distally, developing a smooth and slightly concave  
9  
10 surface. This pattern is similar in all the compared species, although in *Le. serval* and *F.*  
11  
12 *lybica* both the cranial notch and capitular eminence are absent, they being less developed  
13  
14 in *C. caracal*, *Ly. rufus*, and *Ly. lynx*. The proximal epiphysis is inclined medially in all the  
15  
16 compared species, with the medial border markedly medially projected, whereas the lateral  
17  
18 one does not stand out from the diaphysis border. The radial tuberosity of *L. vallesiensis* is  
19  
20 proximodistally elongated (Fig. 3d), located on the lateral border of the caudal face, and it  
21  
22 shows a slightly ridged lateral margin; its development is similar in all the compared  
23  
24 species. The diaphysis of *L. vallesiensis*, as that of the other compared species, is  
25  
26 craniocaudally flattened, elongated and quite straight, showing few muscular scars on the  
27  
28 cranial and caudal faces.

29  
30  
31  
32  
33  
34  
35  
36 The distal epiphysis of *L. vallesiensis* shows a slightly convex cranial face,  
37  
38 developed as a continuation of the diaphysis, and a concave caudal face, separated from the  
39  
40 diaphysis by means of a marked ridge; this pattern is also observed in the compared sample  
41  
42 of felines. The medial border of the distal epiphysis of *L. vallesiensis* is distally projected in  
43  
44 a moderate styloid process, very similarly developed in the rest of the studied species. In *L.*  
45  
46 *vallesiensis*, the lateral facet for articulation with the ulna is elliptical and located in the  
47  
48 craniodistal border of this lateral face; the compared felines show this morphology,  
49  
50 although in *Ly. lynx*, *Ly. pardinus*, *Ly. rufus*, *C. caracal*, and *Le. serval*, the facet is laterally  
51  
52 projected; also, in the **last** species, the facet is not elliptical, but round. In *L. vallesiensis*, the  
53  
54 medial border of this distal epiphysis has a ridge, as a continuation of the medial margin of  
55  
56 the radius, for the attachment of the m. brachioradialis; this ridge is slightly more medially  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 projected in *F. silvestris*, *F. lybica*, and *Lp. geoffroyi*, and much more projected in *Ly. lynx*,  
5  
6  
7 *Ly. pardinus*, *Ly. rufus*, *C. caracal*, and *Le. serval*. The cranial face of the distal epiphysis  
8  
9 of *L. vallesiensis* shows a couple of bony ridges, proximodistally oriented, developed for  
10  
11 separating the passages of the tendons of several extensor muscles: a central,  
12  
13  
14 proximodistally shorter but thicker ridge separates a medial groove for the tendon of the m.  
15  
16 extensor carpi radialis from a lateral one for the tendon of the m. extensor digitorum  
17  
18 communis, whereas a lateral ridge separates this latter tendon from that of the m. extensor  
19  
20 digitorum lateralis, placed into a groove located on the lateral border of the distal epiphysis  
21  
22 (Evans 1993; Vollmerhaus and Roos 2001; Barone 2010). The development of these bony  
23  
24 ridges shows differences within the studied feline sample: in *F. lybica* and *Le. serval*, the  
25  
26 lateral ridge is markedly displaced medially in relation to its position in *L. vallesiensis*, *F.*  
27  
28 *silvestris*, *Ly. lynx*, *Ly. rufus*, *Ly. pardinus*, *C. caracal*, and *Lp. geoffroyi*. The distal  
29  
30 articular facet of *L. vallesiensis* is well developed, but it does not occupy the whole distal  
31  
32 surface of the epiphysis; it is strongly concave, sub-elliptical, with a marked ridge on its  
33  
34 craniolateral margin. This pattern is common to the other felines, although it is remarkable  
35  
36 that in *Le. serval* and *F. lybica*, the lateral border of the facet is expanded in both lateral and  
37  
38 caudal directions, thus producing an overall slightly larger articular surface for the  
39  
40 scapholunar than in the rest of the species.  
41  
42  
43  
44  
45  
46  
47  
48  
49

## 50 Ulna

51  
52  
53  
54  
55 The ulna of *L. vallesiensis* is slender, very similar to that of other felines. The diaphysis  
56  
57 shows a gentle caudal convex curvature in its distal half, and it is markedly mediolaterally  
58  
59 flattened (Fig. 3e, f). The olecranon of *L. vallesiensis* is well developed, similarly elongated  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 as those of the compared felines; its proximal border, in both lateral and medial views, is  
5  
6 clearly caudally inclined, as in *F. silvestris*, *F. lybica*, *Lp. wiedii*, and *Lp. geoffroyi*, whereas  
7  
8 in *Ly. lynx*, *Ly. rufus*, *Ly. pardinus*, *C. caracal*, and *Le. serval*, the proximal border of the  
9  
10 olecranon is almost horizontal due to the greater proximal projection of its caudal border.  
11  
12 The length of the olecranon is similar in all the compared species, although in *Ly. lynx*, *Le.*  
13  
14 *serval*, and *C. caracal*, it is slightly shorter. The olecranon has a pair of proximal tubercles,  
15  
16 lateral and medial, that correspond to the attachment areas for two muscles involved in the  
17  
18 extension of the forearm: the m. anconeus, which attaches on the lateral tubercle, expanding  
19  
20 its attachment surface onto the caudal border of the lateral face of the proximal epiphysis,  
21  
22 and the medial branch (caput mediale) of the m. triceps brachii, which attaches on the  
23  
24 medial tubercle (Gonyea 1978; Barone 2010; Julik et al. 2012). In *L. vallesiensis*, *F.*  
25  
26 *silvestris*, *F. lybica*, and *Le. serval*, the medial tubercle is well developed, markedly  
27  
28 projected proximally, and surpassing the level of the lateral tubercle. *Lynx pardinus* shows  
29  
30 the opposite morphology, with the lateral tubercle much more proximally projected than the  
31  
32 medial one, whereas in *Ly. lynx*, *Ly. rufus*, *C. caracal*, *Lp. wiedii*, and *Lp. geoffroyi* both  
33  
34 tubercles show a similar proximal projection. In cranial view, the tubercles of *L.*  
35  
36 *vallesiensis*, *F. lybica*, *Lp. wiedii*, *Lp. geoffroyi*, *Le. serval*, *Ly. rufus*, and *Ly. pardinus* are  
37  
38 separated by means of a shallow groove, whereas in *F. silvestris*, *Ly. lynx*, and *C. caracal*  
39  
40 this groove has a similar width, but it is much deeper.  
41  
42  
43  
44  
45  
46  
47  
48  
49

50 On the lateral surface of the proximal epiphysis of *L. vallesiensis*, originated from  
51  
52 the level of the middle point of the trochlear notch, there is a proximodistally elongated  
53  
54 triangular groove for the attachment of the m. extensor digiti I et II (Fig. 3e); the groove  
55  
56 continues distally onto the diaphysis by means of a caudal ridge until the distal epiphysis,  
57  
58 thus forming an attachment surface for the m. abductor digiti I longus (=m. extensor carpi  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 obliquus) (Barone 2010; Julik et al. 2012); the most proximal portion of this groove is also  
5  
6 well marked in *F. lybica*, *F. silvestris*, and *Le. serval*, and much less excavated in *Ly. lynx*,  
7  
8 *Ly. pardinus*, *Ly. rufus*, *C. caracal*, *Lp. wiedii*, and *Lp. geoffroyi*, probably indicating a  
9  
10 more powerful m. extensor digiti I et II in the former group. On the medial surface of the  
11  
12 proximal epiphysis, close to the beginning of the diaphysis there is a proximodistally  
13  
14 elongated scar for the common attachment of the m. brachialis and m. cleidobrachialis, very  
15  
16 similarly developed in all the compared species. On the medial surface of the diaphysis  
17  
18 there is a caudal proximodistally elongated groove for the attachment of the ulnar branch of  
19  
20 the m. flexor digitorum profundus (Fig. 3f); also, in the distal half of the diaphysis, a  
21  
22 marked ridge is developed, forming a cranially oriented surface for the attachment of the m.  
23  
24 pronator quadratus; this structure does not show differences among the compared felines.  
25  
26  
27  
28  
29

30  
31 The distal epiphysis of *L. vallesiensis* shows the basic feline morphology: that is  
32  
33 mediolaterally flattened with a distocaudally oriented styloid process.  
34  
35  
36  
37

### 38 Metacarpal I

39  
40  
41  
42 The Mc I of *L. vallesiensis* shows similar proportions as in *F. silvestris* and *F. lybica*,  
43  
44 which have slenderer Mc I than *Le. serval*, *Lp. wiedii*, *Lp. geoffroyi*, *Ly. lynx*, *Ly. rufus*, and  
45  
46 *Ly. pardinus*. A marked, dorsopalmarly developed ridge (Fig. 4a) divides the base into a  
47  
48 smooth and dorsally expanded articular surface for the trapezium, and a medial tuberosity  
49  
50 for the attachment of the m. abductor digiti I longus and one of the dorsal carpometacarpal  
51  
52 ligaments (Fig. 4b). In proximal view, both parts show a similar width in all the compared  
53  
54 species. The body is straight and more or less cylindrical in *L. vallesiensis*, *F. silvestris*, and  
55  
56 *F. lybica*, and relatively shorter and slightly dorsopalmarly flattened in *Le. serval*, *Lp.*  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 *wiedii*, *Lp. geoffroyi*, *Ly. lynx*, *Ly. rufus*, and *Ly. pardinus*. The head is markedly  
5  
6 asymmetrical, as the lateral border is much more distally projected than the medial one; on  
7  
8 its palmar surface, there is a sharp keel, palmarly projected and similarly developed in all  
9  
10 the compared species.  
11  
12  
13  
14

## 15 16 Metacarpal II 17 18 19 20

21 The Mc II of *L. vallesiensis* shows similar proportions than those of *Lp. wiedii*, *Lp.*  
22  
23 *geoffroyi*, *C. caracal*, *Ly. lynx*, *Ly. rufus*, and *Ly. pardinus*, whereas *F. silvestris*, *F. lybica*,  
24  
25 and *Le. serval* have slenderer Mc II. The overall morphology of this bone is very similar in  
26  
27 *L. vallesiensis* and the compared felines. The proximal articular surface has a trapezoid  
28  
29 shape, with its dorsal border mediolaterally wider than the palmar one. In dorsal view, the  
30  
31 base is clearly laterally inclined, and it shows a groove for the passage of the radial artery.  
32  
33 In lateral view (Fig. 4c), the palmar tubercle is large and projected; the groove for  
34  
35 articulation with the medial face of the Mc III is proximodorsally located and well  
36  
37 excavated. In medial view (Fig. 4d), the round facet for articulation with the trapezium  
38  
39 barely surpasses the level of the proximal border in *L. vallesiensis*, *F. lybica*, and *F.*  
40  
41 *silvestris*, whereas in *Lp. wiedii*, *Lp. geoffroyi*, *C. caracal*, *Le. serval*, *Ly. lynx*, *Ly. rufus*,  
42  
43 and *Ly. pardinus* the facet is more proximally projected, widely surpassing the level of the  
44  
45 proximal border. Distal to this facet, there is a rough tubercle for the attachment of the short  
46  
47 interosseous ligament that connects Mc I and Mc II, similarly developed in *L. vallesiensis*  
48  
49 and all the compared species. In the palmar border of the base there is a small but distinct  
50  
51 scar for the attachment of the m. flexor carpi radialis, slightly more distally extended in *F.*  
52  
53 *silvestris*, *F. lybica*, *Le. serval*, *Ly. lynx*, *Ly. rufus*, *Lp. wiedii*, and *Lp. geoffroyi* than in *L.*  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 *vallesiensis*, *Ly. pardinus*, and *C. caracal*. The body is slightly curved in lateral and medial  
5  
6 view in all the species, with *Ly. lynx* and *Ly. pardinus* showing the straightest ones. The  
7  
8 distal head of *L. vallesiensis*, *Lp. geoffroyi*, *C. caracal*, and *Ly. pardinus* has a well-  
9  
10 developed proximopalmarly projected central keel, whereas in *F. silvestris*, *F. lybica*, *Le.*  
11  
12 *serval*, *Ly. lynx*, and *Ly. rufus*, this structure is clearly reduced. Also, the head is relatively  
13  
14 smaller in *F. lybica*, *F. silvestris*, and *Le. serval* than in *L. vallesiensis* and the rest of  
15  
16 compared species.  
17  
18  
19  
20  
21  
22

### 23 Metacarpal III

24  
25  
26  
27  
28 The Mc III of *L. vallesiensis* shows similar proportions as in *F. silvestris*, *F. lybica*, *C.*  
29  
30 *caracal*, *Ly. rufus*, and *Ly. pardinus*; in this group, the Mc III shows indeed an intermediate  
31  
32 robustness between that of the slenderer *Ly. lynx* and *Le. serval* (which show the most  
33  
34 gracile Mc III) and that of the more robust *Lp. wiedii* and *Lp. geoffroyi*. In all the compared  
35  
36 species, the proximal articular surface is triangular, with a marked notch on its medial  
37  
38 border; in dorsal view, the base is clearly laterally inclined. The lateral face of the base  
39  
40 shows the articulation surfaces for the Mc IV (Fig. 4e): a large dorsally located groove and  
41  
42 a dorsopalmarly elongated facet, located proximally to the former. This facet shows several  
43  
44 differences within the compared sample of felines: although it occupies the whole  
45  
46 dorsopalmar margin in all the species, in *L. vallesiensis*, *Ly. lynx*, and *Le. serval* it clearly  
47  
48 lacks the distal expansion of its palmar end observed in *F. silvestris*, *F. lybica*, *C. caracal*,  
49  
50 *Ly. rufus*, *Ly. pardinus*, *Lp. wiedii*, and *Lp. geoffroyi*; all these taxa show a central  
51  
52 constriction in the facet, more marked in *F. silvestris*, and absent in *L. vallesiensis*, *Ly. lynx*,  
53  
54 and *Le. serval*. The medial face of the base (Fig. 4f) shows two articular facets for the Mc  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 II, one dorsally and another one palmarly located, widely separated by a rough fossa. These  
5  
6 facets show subtle differences within the sample: in *Lp. wiedii*, *Lp. geoffroyi*, *Ly. pardinus*,  
7  
8 and *Ly. rufus* the dorsal facet is relatively larger than those of *L. vallesiensis*, *F. silvestris*,  
9  
10 *F. lybica*, *C. caracal*, *Le. serval*, and *Ly. lynx*, whereas the palmar facet shows less size  
11  
12 differences. Finally, the head is relatively larger in *Lp. wiedii* and *Lp. geoffroyi* than in *L.*  
13  
14 *vallesiensis* and the rest of the compared species.  
15  
16  
17  
18  
19  
20

#### 21 Metacarpal IV

22  
23  
24  
25  
26 As in the case of the Mc III, the Mc IV of *L. vallesiensis* shows similar proportions as those  
27  
28 of *F. silvestris*, *F. lybica*, *C. caracal*, *Ly. rufus*, and *Ly. pardinus*, which are more robust  
29  
30 than those of *Ly. lynx* and *Le. serval*. *Leopardus wiedii* and *Lp. geoffroyi* show a much  
31  
32 more robust Mc IV than the rest of the compared sample. All the compared species show a  
33  
34 rectangular proximal articular surface, with a medially projected facet for the Mc III; in  
35  
36 dorsal view, the proximal border of the base is laterally inclined. The lateral face of the  
37  
38 base (Fig. 4g) is occupied by the articulation surfaces for the Mc V: a large and deep central  
39  
40 groove and a curved and elongated facet developed along the dorsal, proximal, and palmar  
41  
42 margins. Except for its shorter dorsopalmar length in *Le. serval* and *Ly. lynx*, the  
43  
44 morphology of this face is very similar in all the compared species. The medial face of the  
45  
46 base (Fig. 4h) shows two articular facets for the Mc III, both located near the proximal  
47  
48 border, one dorsally and the other one palmarly located, and widely separated by a smooth  
49  
50 fossa. Whereas the dorsal facet has a similar development in all the taxa, the palmar facet of  
51  
52 *L. vallesiensis* is much less proximodistally expanded, having the shape of a narrow cord,  
53  
54 very different from the round to triangle facet seen in the rest of the compared felines.  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 Finally, the head is relatively larger again in *Lp. wiedii* and *Lp. geoffroyi* than in *L.*  
5  
6 *vallesiensis* and the rest of compared species.  
7  
8  
9

#### 10 11 Metacarpal V 12 13 14

15  
16 The Mc V of *L. vallesiensis* shows similar proportions to those of *F. silvestris*, *F. lybica*, *C.*  
17  
18 *caracal*, *Ly. lynx*, *Ly. rufus*, and *Ly. pardinus*. Once again, the Mc V of *Le. serval* is the  
19  
20 most gracile of the sample, whereas those of *Lp. wiedii* and *Lp. geoffroyi* are relatively  
21  
22 much shorter and stouter, with the latter being remarkably robust. In proximal view, the Mc  
23  
24 V of *L. vallesiensis* shows a semicircular proximal articulation surface that is divided in  
25  
26 two parts by means of a marked dorsopalmarly developed groove; this morphology is more  
27  
28 or less similar in all the compared species. On the lateral face of the base (Fig. 4i) there is  
29  
30 an elliptical attachment surface for the m. extensor carpi ulnaris, dorsopalmarly elongated  
31  
32 in *L. vallesiensis* and *Le. serval*, and round and more distally expanded in *F. silvestris*, *F.*  
33  
34 *lybica*, *Ly. lynx*, *Ly. rufus*, *Ly. pardinus*, *C. caracal*, *Lp. wiedii*, and *Lp. geoffroyi*. The  
35  
36 medial face of the base (Fig. 4j) shows a central medially expanded and proximodistally  
37  
38 elongated bony sheet, surrounded by a smooth facet occupying the proximal and dorsal  
39  
40 margins. The head is relatively larger again in *Lp. wiedii* and *Lp. geoffroyi* than in *L.*  
41  
42 *vallesiensis* and the rest of compared species.  
43  
44  
45  
46  
47  
48  
49  
50  
51  
52

#### 53 Os Coxae 54 55 56

57  
58 The Batallones-1 sample includes the complete right and left os coxae of a single individual  
59  
60 of *L. vallesiensis* (Fig. 5). Their general shape and morphology are very similar to those of  
61  
62  
63  
64  
65

1  
2  
3  
4 the compared felines. The acetabular fossa is rounded and located close to the cranial  
5  
6 margin of the obturator foramen. The wing of the ilium of *L. vallesiensis* is slender,  
7  
8 craniocaudally elongated, with more or less parallel dorsal and ventral margins and a gently  
9  
10 curved cranial border (crest of the ilium). The gluteal fossa is shallow but evident, with a  
11  
12 thickened dorsal margin. In *Ly. lynx*, *Ly. pardinus*, *Ly. rufus*, *F. lybica*, *F. silvestris*, *Lp.*  
13  
14 *wiedii*, and *Lp. geoffroyi*, the body of ilium shows a central constriction due to the ventral  
15  
16 projection of the tuber coxae and the marked expansion of the tuber sacrale, whereas in *L.*  
17  
18 *vallesiensis*, *C. caracal*, and *Le. serval*, the corpus of the ilium does not show any  
19  
20 constriction. In the cranioventral margin of the wing of *Ly. lynx*, *Ly. pardinus*, *Ly. rufus*, *F.*  
21  
22 *lybica*, *Le. serval*, and *C. caracal* there is a triangular surface, with ridged margins, for the  
23  
24 attachment of the m. sartorius; this surface is very reduced in *L. vallesiensis*, *F. silvestris*,  
25  
26 *Lp. wiedii*, and *Lp. geoffroyi*. The ischiatic spine of *L. vallesiensis*, *Le. serval*, and *C.*  
27  
28 *caracal* is located slightly more caudally than in *Ly. lynx*, *Ly. pardinus*, *Ly. rufus*, *F. lybica*,  
29  
30 *F. silvestris*, *Lp. wiedii*, and *Lp. geoffroyi*. In dorsal view, the orientation of the wings of *L.*  
31  
32 *vallesiensis* is very similar to that of the compared species, slightly laterally curved but  
33  
34 keeping the dorsoventral plane. In this dorsal view, the acetabular fossa is slightly more  
35  
36 laterally projected than in *Le. serval*, *C. caracal*, *F. lybica*, *F. silvestris*, *Lp. wiedii*, and *Lp.*  
37  
38 *geoffroyi*, and similar to that of *Ly. lynx*, *Ly. rufus*, and *Ly. pardinus*. The caudal half of  
39  
40 BAT-1'06 D4-66a is damaged, and the actual shape of the obturator foramen cannot be  
41  
42 assessed, but it probably was similar to that of the compared species. The ischiatic  
43  
44 tuberosity of *L. vallesiensis* and the compared species is rounded and rough, but the  
45  
46 ischiatic arch shows some differences within the studied sample: in *L. vallesiensis*, *F.*  
47  
48 *lybica*, *Lp. wiedii*, and *Lp. geoffroyi*, the caudal margin of the ischium is straight, and so the  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 ischiatic arch is small, whereas in *F. silvestris*, *Ly. lynx*, *Ly. pardinus*, *Ly. rufus*, *Le. serval*  
5  
6 and *C. caracal* this margin describes a gentle curvature, producing a wide and larger arch.  
7  
8  
9

## 10 11 Sacrum

12  
13  
14  
15  
16 A complete sacrum of *L. vallesiensis*, which was articulated to the left and right os coxae  
17  
18 described above, is known from Batallones-1. It is composed, as that of other felids, of  
19  
20 three fused sacral vertebrae. It is triangular in overall shape, with its maximum mediolateral  
21  
22 width at its cranial margin. This morphology is very similar to that of the compared species,  
23  
24 although *Ly. lynx*, *Ly. pardinus*, *Ly. rufus*, and *C. caracal* show a relatively more elongated  
25  
26 sacrum. The available sacrum of *L. vallesiensis* is almost complete, but it lacks the dorsal  
27  
28 spines, which only preserve their lower parts, making it impossible to assess their actual  
29  
30 development. An intermediate sacral crest, mediolaterally flattened, is preserved in the right  
31  
32 side: its cranial portion is cranially oriented, whereas the caudal one is smaller, lower, and  
33  
34 vertical (Fig. 6a). This pattern is also observed in *F. silvestris*, *F. lybica*, and *Lp. geoffroyi*,  
35  
36 whereas in *Ly. lynx*, *Ly. pardinus*, *Ly. rufus*, *Le. serval*, and *C. caracal*, the caudal process  
37  
38 is absent. In *L. vallesiensis*, the caudal portion of the lateral sacral crest (=transverse  
39  
40 process of the last sacral vertebra) is developed as a long and caudally pointed sheet of  
41  
42 bone, as in *F. silvestris* and *C. caracal*. In *F. lybica*, *Lp. geoffroyi*, *Ly. lynx*, *Ly. pardinus*,  
43  
44 and *Ly. rufus*, these processes are shorter and less pointed, whereas in *Le. serval* they are  
45  
46 extremely thin and slender. This caudal portion of the lateral crest in the Batallones feline  
47  
48 shows a central keel, also present, in more or less extent, in the rest of the compared felines.  
49  
50  
51 The lateral sacral crest is also laterally projected at the level of the second sacral vertebra in  
52  
53 *L. vallesiensis*, *C. caracal*, and *Le. serval*, it being thus much more developed than in *F.*  
54  
55  
56

58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 *silvestris*, *F. lybica*, *Ly. lynx*, *Ly. pardinus*, *Ly. rufus*, and *Lp. geoffroyi*. At least four dorsal  
5  
6 sacral formamina are observed in all the compared extant felines, but they are absent in *S.*  
7  
8 *vallesiensis*. On ventral view, the sacrum of *L. vallesiensis* shows four ventral sacral  
9  
10 foramina (Fig. 6b), as the rest of the studied felines.

11  
12  
13  
14 The wings of the sacrum of *L. vallesiensis* are very similar to those of the compared  
15  
16 felines, that is, clearly ventrally projected, with a rough lateral surface. Dorsally, the wings  
17  
18 contact with the cranial articular surfaces of the sacrum, the articulation area for the last  
19  
20 lumbar vertebra. These two cranial articular surfaces are separated by a caudally expanded  
21  
22 notch. In *L. vallesiensis*, *C. caracal*, and *Le. serval*, this notch is relatively wider and less  
23  
24 caudally expanded than those of *F. silvestris*, *F. lybica*, *Ly. lynx*, *Ly. pardinus*, *Ly. rufus*,  
25  
26 and *Lp. geoffroyi*.

### 31 32 33 Femur

34  
35  
36  
37  
38 The Batallones-1 sample includes two femora of *L. vallesiensis* belonging to the same  
39  
40 individual. The femoral head is projected proximomedially by means of a well-developed  
41  
42 neck and it is located at the same level of the greater trochanter (Fig. 7); only in *C. caracal*  
43  
44 and *Lp. geoffroyi* does the head surpass the level of the greater trochanter. In lateral view,  
45  
46 the femur of *L. vallesiensis* has a rough gluteal tuberosity with a strongly ridged cranial  
47  
48 margin that contacts proximally with the greater trochanter (Fig. 7a); distal to the gluteal  
49  
50 tuberosity, a less marked ridge continues distally on the lateral border, until the middle of  
51  
52 the diaphysis. This pattern is seen in the rest of the studied species, and the only remarkable  
53  
54 difference is the position of the gluteal tuberosity in *L. vallesiensis* and *Lp. wiedii*, located  
55  
56 distal to the lesser trochanter, whereas in the other species it is clearly proximal to this  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 structure. On the proximal tip of the greater trochanter, the attachment areas for the m.  
5  
6 gluteus profundus and m. gluteus medius show a similar pattern in all the taxa, with the  
7  
8 attachment area for the m. gluteus medius located proximal to that of the m. gluteus  
9  
10 profundus, both being restricted to the proximal surface of the greater trochanter. In caudal  
11  
12 view (Fig. 7b), the proximal epiphysis of *L. vallesiensis* shows a deep trochanteric fossa, a  
13  
14 ridged and relatively short intertrochanteric crest, and a caudally projected lesser  
15  
16 trochanter; in the Batallones feline, as well as in *F. lybica*, *Ly. lynx*, *Ly. pardinus*, *Ly. rufus*  
17  
18 and *Lp. geoffroyi*, the lesser trochanter is located close to the medial margin, but laterally  
19  
20 displaced in relation to its position in *F. silvestris*, *Le. serval*, *C. caracal*, and *Lp. wiedii*.  
21  
22 This different position of the lesser trochanter is also related to the orientation of the  
23  
24 attachment area for the m. iliopsoas, which is more or less caudally oriented in the former  
25  
26 group of felines, and medially faced in the latter.  
27  
28  
29  
30  
31  
32

33 In the distal epiphysis of *L. vallesiensis*, the lateral condyle is mediolaterally wider  
34  
35 than the medial one. In caudal view (Fig. 7b), the medial condyle is vertical, parallel to the  
36  
37 proximodistal axis of the femur, whereas the lateral one is slightly laterally inclined, with  
38  
39 its proximolateral vertex showing a proximolaterally oriented expansion. Although *F.*  
40  
41 *silvestris*, *Lp. wiedii*, and *Lp. geoffroyi* show this pattern, in *Le. serval*, *F. lybica*, *Ly. lynx*,  
42  
43 *Ly. pardinus*, *Ly. rufus*, and *C. caracal*, the medial condyle is slightly but clearly laterally  
44  
45 inclined. Also, in *L. vallesiensis*, *F. silvestris*, *F. lybica*, *Lp. wiedii*, and *Lp. geoffroyi*, both  
46  
47 condyles reach the same level distally, whereas in *Le. serval*, *Ly. lynx*, *Ly. rufus*, *Ly.*  
48  
49 *pardinus*, and *C. caracal*, the medial condyle distally surpasses the level of the lateral one.  
50  
51 In caudal view, the intercondyloid fossa of *L. vallesiensis* is well developed and shows a  
52  
53 similar mediolateral width than those of the other compared felines. In distal view, all the  
54  
55 compared taxa show a medial condyle slightly more caudally projected than the lateral one.  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 In lateral and medial views, both the craniocaudal length of the distal epiphysis, and the  
5  
6 curvature of the femoral trochlea of *L. vallesiensis* are very similar to those of the other  
7  
8 compared felines. The trochlea of *L. vallesiensis* is more proximally extended than those of  
9  
10 any of the compared feline species (Fig. 7a), which indicates a greater range of patellar  
11  
12 extension, as has been suggested for other carnivorans (Siliceo 2015).  
13  
14  
15  
16  
17

## 18 19 Tibia

20  
21  
22  
23 The two tibiae of *L. vallesiensis* from Batallones-1 are complete but strongly laterally  
24  
25 compressed, thus preventing a clear assessment of some of their characters. It is slender in  
26  
27 overall view, with a more or less straight diaphysis and a caudally curved proximal  
28  
29 epiphysis (Fig. 7c–e). The proximal epiphysis of *L. vallesiensis* shows a triangular-shaped  
30  
31 proximal surface, with the two articular condyles (medial and lateral) separated by a rough  
32  
33 and narrow intercondyloid area. In cranial or caudal views, the lateral condyle in *L.*  
34  
35  
36 *vallesiensis* is located slightly more proximal than the medial one (Fig. 7c), mainly due to  
37  
38 the ridged medial margin of the lateral condyle (the intercondyloid eminence); this pattern  
39  
40 is observed in all the compared felines. In proximal view, the cranial border is strongly  
41  
42 cranially projected, with a marked notch on its lateral margin for the passage of the tendon  
43  
44 of the m. extensor digitorum longus (Fig. 7e). The medial condyle of *L. vallesiensis* is  
45  
46 clearly less caudally projected than the lateral one, as in the rest of the compared felines.  
47  
48  
49 The tibial tuberosity has a smooth proximal surface separated by a ridge from the cranial  
50  
51 border, which runs distally until the middle of the cranial margin of the diaphysis.  
52  
53  
54  
55  
56

57 The diaphysis of *L. vallesiensis* and the compared felines is strongly mediolaterally  
58  
59 flattened on its proximal half, whereas the distal half has a square section. Also, the  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 proximal half is laterally inclined in cranial view and caudally in both lateral and medial  
5  
6 views; the distal half is quite straight. The morphology of the diaphysis is similar in all the  
7  
8 compared species, except for the development of a strong ridge, proximodistally developed,  
9  
10 on the caudal face of the diaphysis of the tibia of *L. vallesiensis* (Fig. 7c) and *Lp. geoffroyi*.  
11  
12 Interestingly, this ridge has been also observed by de Beaumont (1986) in the Asian golden  
13  
14 cat (*Catopuma temminckii*) and the fossil feline *Pristifelis attica*, whereas it is absent in the  
15  
16 tibia of *S. turnauensis* figured by de Beaumont (1961) and that of *M. lorteti* figured by  
17  
18 Salesa et al. (2011). Among the studied sample of carnivorans, it is absent in *Genetta*  
19  
20 *genetta*, *Martes foina*, *Gulo, gulo*, *Meles meles*, *Ailurus fulgens*, and *Canis lupus*, and  
21  
22 present in *Ursus americanus*. This ridge seems to have separated in life the m. flexor  
23  
24 digitorum lateralis and m. flexor digitorum medialis + m. tibialis caudalis, whose tendons  
25  
26 run together along the same groove (Barone 2010). These muscles originate on the  
27  
28 proximal epiphysis of the tibia, and are very closely disposed on the caudal surface of the  
29  
30 diaphysis (Fisher et al. 2008; Ercoli et al. 2012). Both muscles have strong and long distal  
31  
32 tendons, but the relation between the fleshy part and the tendon varies among the  
33  
34 Carnivora, with felids and canids having in general longer tendons (and then shorter fleshy  
35  
36 parts) than ailurids, ursids, procyonids, or mustelids (Davis 1964; Feeny 1999;  
37  
38 Vollmerhaus and Roos 2001; Fisher et al. 2008; Ercoli et al. 2012). Thus, the described  
39  
40 ridge in the caudal face of the tibia of *L. vallesiensis* and *Lp. geoffroyi*, which in the former  
41  
42 reaches the proximal border of the distal epiphysis, would be actually forming a groove for  
43  
44 the accommodation of the tendons of both muscles, m. flexor digitorum medialis + m.  
45  
46 tibialis caudalis on the medial side of the ridge, and m. flexor digitorum lateralis on its  
47  
48 lateral side.  
49

60  
61  
62  
63  
64  
65

1  
2  
3  
4 The distal epiphysis of *L. vallesiensis* strongly resembles that of the compared  
5  
6  
7 felines, with no feature showing significant differences.  
8  
9

## 10 11 Talus

12  
13  
14  
15  
16 The overall morphology and proportions of the talus of *L. vallesiensis* are quite similar to  
17  
18 those of the compared felines. The trochlea is wide, with a shallow central groove that  
19  
20 divides it into two asymmetrical lips (Fig. 8a), as the medial one is narrower than the lateral  
21  
22 one; the distal border of the lateral lip projects distally surpassing the level of the medial  
23  
24 one, which does not expand onto the neck. In proximal view, the lateral lip is more dorsally  
25  
26 projected than the medial one in *L. vallesiensis* and all the compared felines. The proximal  
27  
28 surface of the trochlea of *L. vallesiensis* shows a transversal shallow groove and a small,  
29  
30 medially located talar foramen for the posterior tibial artery, as in *F. silvestris*, *F. lybica*,  
31  
32 *Le. serval*, *Lp. wiedii*, *Ly. pardinus*, and *Ly. rufus*, whereas in *C. caracal*, *Lp. geoffroyi*, and  
33  
34 *Ly. lynx* it is absent. In plantar view (Fig. 8b), a relatively narrow sulcus tali separates two  
35  
36 large articular facets for the calcaneus: the lateral facet is rectangular and strongly concave,  
37  
38 whereas the medial one is elliptical, convex, and occupies most of the plantar surface of the  
39  
40 neck, joining the distal articular surface of the talus head by means of a narrow projection;  
41  
42 this morphology is observed in most of the compared species, although in *F. silvestris*, *F.*  
43  
44 *lybica*, *C. caracal*, and *Le. serval* the medial facet is not connected to the distal facet for the  
45  
46 navicular. The neck of *L. vallesiensis* is as long as those of *F. silvestris*, *F. lybica*, *C.*  
47  
48 *caracal*, *Le. serval*, *Lp. wiedii*, and *Lp. geoffroyi*, and longer than those of *Ly. lynx*, *Ly.*  
49  
50 *pardinus*, and *Ly. rufus*. The head of the talus in all the species is well distinguished from  
51  
52 the neck as it has a gently ridged dorsal margin; in distal view, the head is elliptical in *L.*  
53  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 *vallesiensis*, with the lateral border being slightly orientated dorsally relative to the medial  
5  
6 one; this orientation is more or less the same in the compared felines, although the head is  
7  
8 round rather than elliptical in all the species.  
9

#### 10 11 12 13 14 Calcaneus

15  
16  
17  
18 The calcaneus of *L. vallesiensis* and the compared feline species shows a very similar  
19  
20 morphology and relative proportions. In dorsal view (Fig. 8c), the fibular tubercle  
21  
22 (distolateral expansion for the attachment of the ligament calcaneofibular or collaterale tarsi  
23  
24 laterale longum) shows little lateral projection, and is located close to the distolateral  
25  
26 border; its morphology is very similar in all the compared species. The sustentaculum tali is  
27  
28 well medially projected in all the compared species, showing a rounded medial talar facet  
29  
30 that continues distally through a narrow and long talar facet until the distomedial border of  
31  
32 the talar surface; this facet is almost dorsally oriented in *L. vallesiensis*, *Lp. wiedii*, *Lp.*  
33  
34 *geoffroyii*, *F. silvestris*, and *F. lybica*, whereas in *C. caracal*, *Le. serval*, *Ly. lynx*, *Ly. rufus*,  
35  
36 and *Ly. pardinus*, it is clearly dorsomedially oriented. The tuber calcanei is relatively  
37  
38 slender and mediolaterally flattened in all the compared species. Also, the medial tubercle  
39  
40 of the tuber is more proximally projected than the lateral one, although in *Le. serval* and *Ly.*  
41  
42 *rufus* the difference is not so marked. In plantar view (Fig. 8e) the sustentaculum tali shows  
43  
44 a similar medial projection in all the compared felines, although in *C. caracal* and *Le.*  
45  
46 *serval*, this structure is slightly more proximally located; the groove for the tendon of the  
47  
48 m. flexor digitorum lateralis is similarly marked in all the species. On the distal end of this  
49  
50 plantar face, a scar for the ligament plantare longum is observed. In lateral view, the fibular  
51  
52 tubercle of *L. vallesiensis* is located very close to the distal border of the lateral margin, it  
53  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 showing a marked oblique groove, also seen in *F. silvestris*, *F. lybica*, *C. caracal*, *Le.*  
5  
6 *serval*, and *Ly. lynx*. Plantar to this tubercle, there is a shallow depression with fairly ridged  
7  
8 plantar and dorsal margins for the attachment of the m. quadratus plantae (Fig. 8e); in *L.*  
9  
10 *vallesiensis* and *Lp. geoffroyii*, this attachment area is proximally developed until the level  
11  
12 of the coracoid process, whereas in *Lp. wiedii* and *F. silvestris*, it is even more proximally  
13  
14 elongated, reaching the middle point of the tuber calcanei; on the contrary, the attachment  
15  
16 surface is reduced in *F. lybica*, *C. caracal*, *Le. serval*, *Ly. lynx*, *Ly. rufus*, and *Ly. pardinus*,  
17  
18 as it barely surpasses the level of the fibular tubercle. In proximal view, the tuber calcanei  
19  
20 shows an elliptical shape, dorsoplantarly elongated, with the medial tubercle larger than the  
21  
22 lateral one. In distal view, the articular facet for the cuboid is almost round in all the  
23  
24 compared feline species.  
25  
26

28  
29  
30  
31  
32

### 33 **Comparative anatomy and biomechanical implications**

#### 34 Lumbar vertebrae

35  
36  
37  
38  
39  
40  
41  
42  
43 Both the overall morphology and relative proportions of the L7-L5 of *L. vallesiensis* are  
44  
45 very similar to those of the compared felines: in all of them the L7 is shorter than the rest of  
46  
47 the lumbar vertebrae, with *F. silvestris*, *F. lybica*, and *Lp. geoffroyi* showing the relatively  
48  
49 longest L7 (Fig. 9). In felids and other carnivorans, the extension and flexion movements of  
50  
51 the lumbar region (and the vertebral column in general) are very important in galloping  
52  
53 (Hildebrand 1959; Goslow et al. 1973; Gambaryan 1974; Taylor 1978; English 1980;  
54  
55 Alexander and Jayes 1981). These movements of the column basically contribute to stride  
56  
57 length and limb speed through the action of the epaxial and abdominal muscles (Hildebrand  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 1959; Goslow et al. 1973; English 1980). Thus, a great flexibility of the lumbar series in  
5  
6 felines is necessary for increasing both stride length and limb speed, something critical in  
7  
8 cursorial species such as *Acinonyx jubatus* (Hildebrand 1959; Gambaryan 1974). A  
9  
10 relatively short L7 is typical of arboreal viverrids and mustelids, such as *G. genetta* or  
11  
12 *Martes foina*, animals that do not move primarily on the ground, but the relative length of  
13  
14 this vertebra in *A. jubatus* is very similar to that of these carnivorans, and slightly shorter  
15  
16 than those of *F. silvestris*, *F. lybica*, and *Lp. geoffroyi*. In consequence, there are only subtle  
17  
18 differences in the relative length of L7 among the compared sample of felines, and the  
19  
20 significance of a relative short L7 in *L. vallesiensis* (Fig. 9), similar to those of viverrids  
21  
22 (but also mustelids) should be considered as a primitive feature with no clear functional  
23  
24 implications.  
25  
26  
27  
28  
29  
30  
31  
32

### 33 Humerus 34 35 36 37

38 The differences in the lateral width of the humeral head observed among our sample of  
39  
40 felines have been previously described in other carnivorans; for example, Taylor (1974)  
41  
42 already noticed it in his study on herpestids and viverrids, with the more terrestrial species  
43  
44 having mediolaterally flattened heads and a relatively limited range of movement in the  
45  
46 shoulder, both in the craniocaudal and mediolateral planes. Argot (2001), and Argot and  
47  
48 Babot (2011) proposed that a similar lateral compression of the humeral head observed in  
49  
50 Paleocene and Eocene marsupials suggested that movements of the glenohumeral  
51  
52 articulation were restricted to flexion/extension, indicative of terrestrial habits. This would  
53  
54 be the case of *L. vallesiensis*, which has a less rounded humeral head than other compared  
55  
56 felines, a probable indication of a mostly terrestrial way of life. Other humeral structures  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 have been revealed as good indicators of terrestrial versus arboreal habits in several groups  
5  
6 of mammals, including the development of the greater tubercle (Jolly 1967; Taylor 1974;  
7  
8 Fleagle and Simons 1982; Ciochon 1986; Larson and Stern 1989; Gebo and Rose 1993;  
9  
10 Siliceo et al. 2015). All these authors concluded that the more arboreal species had less  
11  
12 projected tubercles than those moving mainly on the ground. Focusing on the sample of  
13  
14 Felinae studied here, *Lp. wiedii* and *Lp. geoffroyi* show greater tubercles that are less  
15  
16 proximally projected than that of *L. vallesiensis* and those extant species with typically  
17  
18 terrestrial lifestyles, such as the lynxes and the wildcat (Fig. 10); this is interesting, as *Lp.*  
19  
20 *wiedii* is one of the most arboreal felines, and although *Lp. geoffroyi* occupies a great  
21  
22 diversity of habitats, it is often found in woodlands (Sunquist and Sunquist 2009). The  
23  
24 greater tubercle is the attachment area for the m. supraspinatus, which originates on the  
25  
26 supraspinous fossa of the scapula (Barone 2010; Julik et al. 2012), extending the humerus  
27  
28 and rotating it laterally (Taylor 1974; Barone 2010; Ercoli et al. 2015). The proximal  
29  
30 expansion of the greater tubercle produces the lengthening of the moment arm of the m.  
31  
32 supraspinatus at the glenohumeral articulation (Jolly 1967; Larson and Stern 1989) and it  
33  
34 has been interpreted in baboons as a way of achieving a more economical locomotion on  
35  
36 the ground (Jolly 1967); on the contrary, a less projected greater tubercle produces a shorter  
37  
38 lever arm for the m. supraspinatus, which favours fast (although weak) flexion of the  
39  
40 humerus during arboreal locomotion (Jolly 1967; Larson and Stern 1989). It is remarkable  
41  
42 that the middle Miocene feline *S. turnauensis* resembles *Lp. wiedii* and *Lp. geoffroyii* in this  
43  
44 feature, suggesting an important arboreal component in its locomotor behavior. On the  
45  
46 contrary, the development of the greater tubercle of the late Miocene *L. vallesiensis*  
47  
48 indicates a primarily terrestrial locomotion, in a similar way to other extant felines. These  
49  
50 different locomotor adaptations would reflect the climate changes at the beginning of the  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 late Miocene in Europe, which produced the predominance of drier, less structured  
5  
6 landscapes than those from the more humid middle Miocene (Agustí and Moyà-Solà 1990;  
7  
8 Agustí et al. 1997; Fortelius and Hokkanen 2001; Hernández-Fernández et al. 2006).

9  
10  
11         Among the Carnivora, the medial epicondyle of the humerus is the attachment area  
12  
13 for several pronator and flexor muscles of the forearm and carpus (Davis 1964; Barone  
14  
15 1967, 2010; Taylor 1974; Salesa et al. 2008; Fisher et al. 2009; Julik et al. 2012; Ercoli et  
16  
17 al. 2015). The degree of medial projection of this humeral structure is an indicator of the  
18  
19 development of these muscles in fossil carnivorans, and thus it has been used to infer  
20  
21 several aspects of their paleoecology: those species with reduced medial epicondyles show  
22  
23 smaller flexor muscles, and have slender limbs, are cursorial hunters, and use to live in  
24  
25 open, low-structured habitats, whereas those with well-developed medial epicondyles have  
26  
27 more robust proportions, hunt by ambush, and inhabit highly-structured environments, such  
28  
29 as woodlands (Argot 2001, 2004; Salesa et al. 2008; Argot and Babot 2011). Thus, the  
30  
31 smaller development of the medial epicondyle of *L. vallesiensis* (Fig. 11a) (similar to those  
32  
33 of *Le. serval* and *Ly. lynx*) suggests that this feline was a capable runner, occupying the less  
34  
35 structured, more open patches of the mixed landscape inferred for the Batallones sites  
36  
37 (Antón and Morales 2000; Salesa et al. 2006a, 2008; Morales et al. 2008). The extant feline  
38  
39 *F. silvestris*, a species of similar size and proportions as *L. vallesiensis*, occupies a great  
40  
41 diversity of habitats, including grasslands and more or less dense woodlands (Nowak 2005;  
42  
43 Sunquist and Sunquist 2009), but it has a more developed medial epicondyle than the  
44  
45 Batallones feline and the Turolian *P. attica*. This implies that these two latter species had a  
46  
47 more limited range of preferred habitats than *F. silvestris*, favoring more open habitats than  
48  
49 their extant relative. On the contrary, the much more projected medial epicondyles of the  
50  
51 middle Miocene species *S. turnauensis* and *M. lorteti* suggest their preference for the  
52  
53  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 densely-wooded habitats that predominated during that time. Besides this, the presence of a  
5  
6 strongly projected medial epicondyle of the humerus has been also associated in Felidae to  
7  
8 the capture of relatively large prey (Meachen-Samuels and Van Valkenburgh 2009);  
9  
10 following this interpretation, *L. vallesiensis* would take small prey, whereas the middle  
11  
12 Miocene *S. turnauensis* and *M. lorteti* would prey upon relatively larger ones.  
13  
14

15  
16 Other features observed in the humerus of *L. vallesiensis* also seem to be related to  
17  
18 its running abilities, such as the mediolaterally narrower distal epiphysis (Fig. 12), and  
19  
20 especially, the narrower olecranon fossa than those of *F. silvestris*, *Ly. rufus*, *Lp. wiedii*,  
21  
22 and *Lp. geoffroyi*. This feature groups *L. vallesiensis* with taxa showing more cursorial  
23  
24 postcranial skeletons, such as *Ly. lynx*, *Ly. pardinus*, *C. caracal*, and *Le. serval*, but also  
25  
26 with the Turolian *P. attica*, whose narrow olecranon fossa was described by Roussiakis  
27  
28 (2002). A narrower olecranon fossa prevents the lateral and medial torsion of the ulna in  
29  
30 mainly terrestrial primates and carnivorans when moving on the ground (Gonyea 1978;  
31  
32 Brundrett 2002; Argot and Babot 2011), hence the presence of this feature in the humerus  
33  
34 of *S. vallesiensis* is an additional evidence supporting an efficient terrestrial locomotion in  
35  
36 this species.  
37  
38

41  
42  
43  
44

#### 45 Radius

46  
47  
48  
49  
50 The radii of the compared sample of felines, included *L. vallesiensis*, are similar in  
51  
52 proportions and morphology. In fact, the most remarkable difference, the absence of notch  
53  
54 and capitular eminence on the proximal facet, is only shown by *Le. serval* and *F. lybica*,  
55  
56 without a clear functional explanation. Davis (1964) suggested that the capitular eminence  
57  
58 limits the rotatory mobility of the radius, but Gebo and Rose (1993) noticed its presence in  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 arboreal carnivorans (such as the procyonid *Potos flavus*), suggesting that this structure  
5  
6 could not be an impediment for the pronation-supination movements of the forearm when  
7  
8 climbing. Nevertheless, Heinrich and Rose (1997) suggested that the capitular eminence  
9  
10 might stabilize the radius when the elbow is flexed, and then its absence in terrestrial forms  
11  
12 such as *Le. serval* and *F. lybica*, which tend to maintain extended limb articulations, would  
13  
14 be more understandable.  
15  
16  
17

18  
19 The other difference observed within the studied sample of radii is the larger lateral  
20  
21 and medial development of the distal facet for the scapholunar, again seen only in *Le.*  
22  
23 *serval* and *F. lybica*. This mediolateral elongation of the facet produces a less rounded  
24  
25 facet, and thus a restriction in the rotational movements of the scapholunar on the radius,  
26  
27 and a predominance of the wrist flexion and extension actions. It is not surprising that the  
28  
29 two species that show this morphology are mostly terrestrial animals that move fast on the  
30  
31 ground, and it is not strange either that the primitive morphology, a more rounded facet, is  
32  
33 observed in *L. vallesiensis*, most of the compared felines, and *G. genetta*.  
34  
35  
36  
37  
38  
39

#### 40 Ulna

41  
42  
43  
44  
45 The caudal border of the olecranon (attachment area for the long branch of the m. triceps  
46  
47 brachii) is clearly more inflated (proximally projected) in *Ly. lynx*, *Ly. rufus*, *Ly. pardinus*,  
48  
49 *C. caracal*, and *Le. serval* than in *L. vallesiensis*, *F. silvestris*, *F. lybica*, *Lp. wiedii*, and *Lp.*  
50  
51 *geoffroyi* (Fig. 13). In Viverridae, a greater development of this caudal vertex is indicative  
52  
53 of a relatively larger long branch of the m. triceps brachii (Taylor 1974). Thus, in the  
54  
55 lynxes and lynx-like felines, this muscle should be relatively larger than those of *L.*  
56  
57  
58 *vallesiensis*, *F. silvestris*, *F. lybica*, *Lp. wiedii*, and *Lp. geoffroyi*. Among extant felids, the  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 cursorial species have relatively greater long branches of the m. triceps brachii than those  
5  
6 species with more robust proportions, as shown by Gambaryan (1974). Nevertheless,  
7  
8 although our observations seem to indicate a difference in the cursorial capacities of the  
9  
10 analyzed felines, the group showing more inflated caudal part of the olecranon is composed  
11  
12 by the largest taxa, and so the observed differences could be strongly influenced by  
13  
14 allometry. Anyway, the larger size of the long branch of the m. triceps brachii in *Ly. lynx*,  
15  
16 *Ly. rufus*, *Ly. pardinus*, *C. caracal*, and *Le. serval* is also suggested by the presence, in the  
17  
18 cranial part of the olecranon, of a marked groove for the passage of the tendon of this  
19  
20 muscle; this feature is typical of terrestrial viverrids, and is lacking in the most arboreal  
21  
22 forms (Taylor 1974; Feeney 1999).  
23  
24  
25  
26  
27

28         The degree of proximal projection of the olecranon tuberosities seems to be closely  
29  
30 related to the development of the lateral and medial branches of the m. triceps brachii in  
31  
32 fossil and extant Felidae (Gonyea 1978; Salesa et al. 2010a, 2011). In *L. vallesiensis*, *F.*  
33  
34 *silvestris*, *F. lybica*, and *Le. serval* (Fig. 14a, d), the lateral tuberosity is much less  
35  
36 proximally projected than the medial one, a morphology also observed in canids and the  
37  
38 cursorial felid *Acinonyx jubatus* (Gonyea 1978); these two latter carnivorans have larger  
39  
40 medial branches of the m. triceps brachii than those species with larger lateral tuberosities  
41  
42 in the ulna (Gambaryan 1974; Gonyea 1978). Interestingly, the lateral tuberosity is more  
43  
44 proximally projected than the medial one in those felids inhabiting woodland habitats, and  
45  
46 they have significantly larger lateral branches of the m. triceps brachii than those felids that  
47  
48 occupy low-structured, open landscapes (Gambaryan 1974; Gonyea 1978). Nevertheless,  
49  
50 Gonyea (1978) also found that several species occupying both open and close environments  
51  
52 (such as *C. caracal*, *Panthera leo*, *Ly. lynx*, or *Ly. rufus*) had olecranon tuberosities of  
53  
54 similar size. All these observations made Gonyea (1978) suggest that the development of  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 the tuberosities was actually an indicator of the degree of deviation of the anterior limb  
5  
6 from the parasagittal plane during locomotion, with those felids having larger lateral  
7  
8 tuberosities exhibiting the greatest parasagittal deviation of the elbow during locomotion,  
9  
10 and those with larger medial tuberosities having little deviation of the forelimb from a  
11  
12 'pendulum-like' motion, and thus exhibiting high cursorial abilities, such as *A. jubatus* and  
13  
14 large canids. *Felis silvestris*, *F. lybica* and *Le. serval* also belong to this latter group, and all  
15  
16 have a mostly terrestrial way of life, climbing primarily as an escape mechanism (Sunquist  
17  
18 and Sunquist 2009; Julik et al. 2012). Considering its olecranon morphology, *L. vallesiensis*  
19  
20 would fit well within the group of mostly terrestrial and gracile felines, and probably its  
21  
22 lifestyle was not very different from that of the small species of the genus *Felis*. The same  
23  
24 morphology is observed in the middle Miocene, more primitive felines such as *M. lorteti*  
25  
26 (Salesa et al. 2011). Nevertheless, this pattern might be the plesiomorphic for Felidae, as it  
27  
28 is also present in the most primitive felid, *Proailurus lemanensis*, and the earliest members  
29  
30 of the **saber**-toothed subfamily, *Pseudaelurus quadridentatus* and *Promegantereon ogygia*  
31  
32 (Salesa et al. 2010a, 2011).

33  
34  
35  
36  
37  
38  
39  
40  
41 The attachment groove for the m. extensor digiti I et II is more excavated in *L.*  
42  
43 *vallesiensis*, *F. lybica*, *F. silvestris*, and *Le. serval* than in the other species. This muscle  
44  
45 extends the thumb and assists the m. extensor digitorum communis in extending the carpus  
46  
47 and the digit II (Davis 1964; Barone 2010; Julik et al. 2012). The attachment surface is  
48  
49 much shallower in *Ly. lynx*, *Ly. pardinus*, *Ly. rufus*, *C. caracal*, *Lp. wiedii*, and *Lp.*  
50  
51 *geoffroyi*, and also in large felids such as *Puma concolor*, *Panthera pardus*, or the cursorial  
52  
53 *A. jubatus*. This similar morphology in felids with differing locomotor adaptations prevents  
54  
55 the proposal of any functional interpretation explaining the development of the muscle. In  
56  
57 fact, an ulna of *M. lorteti* from Sansan illustrated by Salesa et al. (2011) shows a similar  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 pattern to that of *L. vallesiensis*, and thus a marked groove for the m. extensor digiti I et II  
5  
6 might be the primitive condition for the Felinae.  
7  
8  
9

## 10 11 Metacarpal I 12 13 14 15

16 The Mc I of *L. vallesiensis*, *F. silvestris*, and *F. lybica* are slenderer than those of the  
17  
18 smaller species *Lp. wiedii* and *Lp. geoffroyi*, the larger felines *Le. serval*, *Ly. lynx*, *Ly.*  
19  
20 *rufus*, and *Ly. pardinus*, and the middle Miocene species *S. turnauensis* and *M. lorteti*  
21  
22 (Peigné 2012; Salesa et al. 2012). The main function of the Mc I in Felidae is grasping  
23  
24 when climbing and hunting, thanks to the abduction of the thumb from the second finger  
25  
26 (Barone 1967; Gonyea and Ashworth 1975; Gonyea 1978; Akersten 1985; Taylor 1989;  
27  
28 Anyonge 1996; Turner and Antón 1997; Julik et al. 2012). As a result of its slenderness, the  
29  
30 thumb of *L. vallesiensis*, *F. silvestris*, and *F. lybica* would be able to withstand smaller  
31  
32 forces than those of the rest of the compared felines, which has interesting implications for  
33  
34 their climbing abilities and their ability to subdue prey. For example, if *L. vallesiensis*  
35  
36 preyed upon smaller animals than those killed by its middle Miocene counterparts (as the  
37  
38 morphology of its humerus suggests), it would not be necessary to have the robust Mc I  
39  
40 observed in the latter species. The extant felines *F. silvestris* and *F. lybica* hunt mostly  
41  
42 small prey (Smithers 1971; Kingdon 1977; Roberts 1977; Sharma 1979; Palmer and Fairall  
43  
44 1988; Sunquist and Sunquist 2009) using head shaking movements that kill them very fast  
45  
46 (Leyhausen 1973, 1979; Pellis and Officer 1987). Thus, both species exemplify the  
47  
48 ecological role that *L. vallesiensis* probably played in the late Miocene faunas of Europe.  
49  
50 On the contrary, the middle Miocene primitive saber-toothed felid *Pseudaelurus*  
51  
52 *quadridentatus* had a robust Mc I (Ginsburg 1961a; Salesa et al. 2010a; Peigné 2012), even  
53  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 more than the extant large pantherin felines (Salesa et al. 2010a), in accordance with the  
5  
6 huge dewclaw and robust forelimbs present in Machairodontinae, traits developed for  
7  
8 achieving the rapid immobilization of prey (Gonyea 1976a; Emerson and Radinsky 1980;  
9  
10 Akersten 1985; Rawn-Schatzinger 1992; Turner and Antón 1997; Salesa et al. 2005, 2006a,  
11  
12 2010a, 2014). The small Mc I of *L. vallesiensis* would also help in reducing the weight of  
13  
14 the forelimb, and thus the energy employed when moving on the ground.  
15  
16  
17  
18  
19  
20

## 21 Metacarpals II-V

22  
23  
24  
25  
26 The Mc II-V of *L. vallesiensis* are very similar to those of the compared felines, with minor  
27  
28 differences mainly related to their robustness. In general, the metacarpals II-V of *L.*  
29  
30 *vallesiensis* are more robust than those of the most cursorial felines, such *Ly. lynx* and *Le.*  
31  
32 *serval*, but slenderer than those of the most arboreal and forest-dwelling felines *Lp. wiedii*  
33  
34 and *Lp. geoffroyi*. But, while this observation provides an overall view of the locomotor  
35  
36 abilities of the hand, there are some features that deserve a more detailed discussion, as  
37  
38 they seem primitive traits rather than a reflection of functional adaptations. For example, in  
39  
40 the Mc II, the dorsomedial facet for the trapezium is not proximally projected in *L.*  
41  
42 *vallesiensis*, *F. lybica*, and *F. silvestris*, whereas in the rest of the compared species it is  
43  
44 strongly projected. The viverrids *C. civetta* and *G. genetta*, with different locomotor  
45  
46 adaptations, have non-projected facets, thus probably illustrating the primitive morphology.  
47  
48  
49  
50  
51 Another probable primitive feature observed in the Mc IV of *L. vallesiensi* is the palmar  
52  
53 facet for the Mc III, which is much less proximodistally expanded than in the compared  
54  
55 felines, showing the same morphology seen in the Mc IV of *G. genetta*. Interestingly, in the  
56  
57 terrestrial viverrid *C. civetta*, this palmar facet is larger, resembling those of the majority of  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 the compared felines. The presence of a large facet between Mc III and IV produces a more  
5  
6 stable and controlled articulation, an adaptation seen in several cursorial mammals  
7  
8 (Rasmussen and Simons 2000; Stevens et al. 2009), so its presence in most of the felines as  
9  
10 well as in terrestrial viverrids fits well with this idea, and would suggest a very primitive  
11  
12 state in *L. vallesiensis*, similar to arboreal viverrids. Finally, the facet for the attachment of  
13  
14 the muscle extensor carpi ulnaris, on the lateral face of the head of the McV, is less distally  
15  
16 expanded in *L. vallesiensis* and *Le. serval* than in *F. silvestris*, *F. lybica*, *Ly. lynx*, *Ly. rufus*,  
17  
18 *Ly. pardinus*, *C. caracal*, *Lp. wiedii*, and *Lp. geoffroyi*. This muscle, despite its name, is a  
19  
20 flexor of the carpus and an **external** rotator of the forearm, being developed from the lateral  
21  
22 epicondyle of the humerus to the base of the Mc V (Evans 1993; Barone 2010). Thus, the  
23  
24 distal expansion of the attachment surface on the Mc V observed in some species slightly  
25  
26 increases the length of the tendon, which given the actual size of the muscle, would suggest  
27  
28 a larger range of carpus flexion rather than a larger muscle.  
29  
30  
31  
32  
33  
34  
35  
36  
37

### 38 Os Coxae

39  
40  
41  
42  
43 The absence of constriction in the ilium of *L. vallesiensis*, *C. caracal*, and *Le. serval* is a  
44  
45 consequence of the lesser dorsoventral expansion of the wing in relation to those species  
46  
47 with a more or less developed greater ischiatic notch and an expanded spina alaris (*Ly. lynx*,  
48  
49 *Ly. pardinus*, *Ly. rufus*, *F. lybica*, *F. silvestris*, *Lp. wiedii*, and *Lp. geoffroyi*) (Fig. 15). This  
50  
51 difference affects the attachment area of the m. sartorius, which in felids originates as a thin  
52  
53 strip on the ventral border of the iliac crest, inserting onto the medial surface of the patella,  
54  
55 the tibial crest, and the medial condyle of the tibia (Reighard and Jennings 1901; Barone  
56  
57 2010; Carlon and Hubbard 2012). Its main function is to adduct and rotate the femur, and to  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 extend the tibia (Reighard and Jennings 1901; Evans 1993; Barone 2010; Carlon and  
5  
6 Hubbard 2012). Thus, in *L. vallesiensis*, *C. caracal*, and *Le. serval*, this muscle would have  
7  
8 a more dorsal origin than in *Ly. lynx*, *Ly. pardinus*, *Ly. rufus*, *F. lybica*, *F. silvestris*, *Lp.*  
9  
10 *wiedii*, and *Lp. geoffroyi*. This configuration could imply a longer muscle, as its origin is  
11  
12 more dorsally located, but the difference, when comparing in detail the coxae of *L.*  
13  
14 *vallesiensis* and *F. silvestris* (very similar in size) seems really small. In any case, the more  
15  
16 dorsally located origin of the m. sartorius could improve the flexion of the femur during the  
17  
18 recovery phase of the locomotion, when the limb is preparing for foot-strike, and this bone  
19  
20 is carried cranially by the contraction of the m. iliopsoas and m. sartorius (Argot 2002).  
21  
22 Besides this, in *L. vallesiensis*, the attachment area of the m. sartorius is not a rough and  
23  
24 dorsally ridged area, such as those of *Ly. lynx*, *Ly. pardinus*, *Ly. rufus*, *Le. serval*, and *C.*  
25  
26 *caracal*, but a thin bony sheet along the ventrocranial border of the ilium wing. This  
27  
28 probably implies a relatively weaker m. sartorius, at least regarding its insertion on the  
29  
30 wing. Nevertheless, this seems to be related to size, given the differences between small  
31  
32 and large species within the compared sample, and the largest species would need a  
33  
34 relatively stronger m. sartorius.  
35  
36  
37  
38  
39  
40  
41  
42

43 Another interesting difference in the coxal morphology of *L. vallesiensis* and the  
44  
45 compared felines is the position of the ischiatic spine. In the Batallones feline, as well as in  
46  
47 *Le. serval* and *C. caracal*, this structure is more caudally located than in *Ly. lynx*, *Ly.*  
48  
49 *pardinus*, *Ly. rufus*, *F. lybica*, *F. silvestris*, *Lp. wiedii*, and *Lp. geoffroyi* (Fig. 15). In felids,  
50  
51 the ischiatic spine is the origin surface for the m. gemellus cranialis, whereas the m.  
52  
53 gemellus caudalis originates on the dorsal border of the ischium between the ischiatic spine  
54  
55 and the cranial border of the ischiatic tuberosity; both muscles, developed as two small  
56  
57 flattened fleshy masses, attach into the trochanteric fossa of the femur (Barone 2010;  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 Carlton and Hubbard 2012). Their function is to help the m. obturatorius internus in  
5  
6 abducting and rotating the femur (Reighard and Jennings 1901; Evans 1993; Barone 2010).  
7  
8 The more caudal position of the ischiatic spine in *L. vallesiensis*, *Le. serval*, and *C. caracal*  
9  
10 produces a shorter area for the attachment of the m. gemellus caudalis, and thus a smaller  
11  
12 muscle. But also, it implies relatively longer fibers in the m. gemellus cranialis in relation  
13  
14 to those of *Ly. lynx*, *Ly. pardinus*, *Ly. rufus*, *F. lybica*, *F. silvestris*, *Lp. wiedii*, and *Lp.*  
15  
16 *geoffroyi*. In fact, in these latter species, the origin and insertion areas of this muscle are  
17  
18 located in such a way that the fibers of the muscle are more or less perpendicular to the  
19  
20 craniocaudal axis of the os coxae. The relative caudal migration of the origin area in *L.*  
21  
22 *vallesiensis*, *Le. serval*, and *C. caracal* would make the fibers longer, as well as increasing  
23  
24 the range of rotation of the femur. Although both mm. gemelli are relatively small in felids  
25  
26 (Reighard and Jennings 1901), the described difference in their disposition might have an  
27  
28 important impact on their function as assistant to the m. obturatorius internus. In primitive  
29  
30 viverrids such as *Genetta genetta*, the ischiatic spine is as caudally located as in *L.*  
31  
32 *vallesiensis*, *Le. serval*, and *C. caracal*, and although this could point towards well-  
33  
34 developed arboreal capacities (because of the greater rotation range of the femur), it could  
35  
36 be also reflecting a retained, primitive state for this character.  
37  
38  
39  
40  
41  
42  
43  
44

45 The shape of the ischiatic arch clearly distinguishes two groups, one with more or  
46  
47 less straight caudal margin of the ischium (*L. vallesiensis*, *F. lybica*, *Lp. wiedii*, and *Lp.*  
48  
49 *geoffroyi*) and another one with a curved margin, developing a marked ischiatic arch (*F.*  
50  
51 *silvestris*, *Ly. lynx*, *Ly. pardinus*, *Ly. rufus*, *Le. serval*, and *C. caracal*). Once again, *Genetta*  
52  
53 *genetta* shares the pattern observed in the former group. Feeny (1999) related the presence  
54  
55 of ischiatic arch, with a reduction in the area for the origin of the m. biceps femoris, m.  
56  
57 semitendinosus, and m. semimembranosus, and an increase in the area for the origin of the  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 m. adductor femoris (=m. adductor magnus et brevis). This muscle adducts and extends the  
5  
6  
7 coxofemoral articulation (Reighard and Jennings 1901; Evans 1993; Barone 2010). Argot  
8  
9 (2002) has noticed that the adductor muscles of the thigh are essential in stabilizing the foot  
10  
11 against the medially lying surface in arboreal forms using a wide range of femoral  
12  
13 abduction. This means that a **strong** development of these muscles would point towards  
14  
15 arboreal capacities, and that fits with the presence of a reduced ischiatic arch in *G. genetta*  
16  
17 as well as *L. vallesiensis*, *F. lybica*, *Lp. wiedii*, and *Lp. geoffroyi*. It is remarkable that *Lp.*  
18  
19 *wiedii* is one of the most arboreal felids (Alderton 1998), but the presence of a similar  
20  
21 morphology in *L. vallesiensis* could be indicating the retention of a primitive morphology  
22  
23 in a species that is not an ecological equivalent of the extant *Lp. wiedii*.  
24  
25  
26  
27  
28  
29  
30

### 31 Sacrum

32  
33  
34  
35  
36 The sacrum of *L. vallesiensis* is quite similar to that of other felines. It shows some  
37  
38 differences, but they do not seem to have a relevant importance. An exception is the wider  
39  
40 and less caudally expanded notch separating the cranial articular surfaces and by the great  
41  
42 lateral projection of the lateral sacral crest, both features observed also in *C. caracal* and  
43  
44 *Le. serval*, although to a lesser degree (Fig. 16). The presence of this wider cranial notch in  
45  
46 the sacrum of these species suggests an also wider range of lateral movements between the  
47  
48 sacrum and the lumbar series, something that is evident when these bones are articulated  
49  
50  
51 experimentally (personal observation). The sacrum of *G. genetta* shows a relatively  
52  
53 narrower notch than those of *L. vallesiensis*, *C. caracal*, and *Le. serval* (Fig. 16g), whereas  
54  
55 other arboreal carnivorans, such as *Martes foina*, exhibit a relatively wide notch (Fig. 16i),  
56  
57  
58 with its cranial articular surfaces separated in a similar way to those of these former felines.  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 A cranial fragment of sacrum of *M. lorteti* from Sansan, described by Salesa et al. (2011)  
5  
6 strongly resembles *L. vallesiensis* in the development of the notch. Unfortunately, no  
7  
8 additional sacra of early and middle Miocene felines are known, so we lack data on the  
9  
10 primitive morphology of this group. It is interesting that both *L. vallesiensis* and *M. lorteti*  
11  
12 show the morphology of the sacral cranial articulation seen in an arboreal mustelid, instead  
13  
14 of resembling that of semiarboreal viverrids such as *G. genetta*. In the phylogeny of the  
15  
16 Carnivora, the families Viverridae and Felidae are closely related, whereas the Mustelidae  
17  
18 are included in another clade (Gaubert and Veron 2003; Gaubert and Cordeiro-Estrela  
19  
20 2006; Wolsan and Sato 2010). Thus, the similar sacral morphology observed in *M. martes*,  
21  
22 *L. vallesiensis*, and *M. lorteti* probably indicates a convergent adaptation for increasing the  
23  
24 lumbosacral mobility rather than a phylogenetic relationship.  
25  
26  
27  
28  
29  
30

31 Besides this, the sacrum of *L. vallesiensis*, *C. caracal*, and *Le. serval* shows a strong  
32  
33 lateral projection of the lateral sacral crest (Fig. 16b, d), a bony sheet serving as attachment  
34  
35 surface for the dorsal sacroiliac ligaments and the m. piriformis (Evans 1993; Ercoli et al.  
36  
37 2013). This might be related with the great lateral mobility of the sacrum of these three  
38  
39 species, inferred from the morphology of the cranial articular surface, which would need  
40  
41 relatively stronger ligaments stabilizing this region.  
42  
43  
44

45 Some features of the sacrum of mammals can be associated to their tail length; for  
46  
47 example, Russo and Shapiro (2011) and Russo (2016) found that long-tailed species of  
48  
49 cercopithecoid primates and felids had significantly more circularly shaped caudal articular  
50  
51 surfaces, more acute sacrocaudal articulation angles, and more laterally expanded  
52  
53 transverse processes of the last sacral vertebra. Interestingly, the relative length of the  
54  
55 sacrum has not been found to be a good indicator of the tail length (Ankel 1965, 1972;  
56  
57 Ward et al. 1991; Nakatsukasa et al. 2004), although *Ly. lynx*, *Ly. pardinus*, *Ly. rufus*, and  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 *C. caracal* show relatively elongated and narrower sacra when comparing to those of *L.*  
5  
6 *vallesiensis*, *Le. serval*, *F. silvestris*, *F. lybica*, and *Lp. geoffroyi*.  
7  
8

9         The development of the intermediate sacral crest (bearing two mammillo-articular  
10 processes) of *L. vallesiensis* is also observed in *F. silvestris*, *F. lybica*, and *Lp. geoffroyi*,  
11 species with relatively long tails, whereas in *Ly. lynx*, *Ly. pardinus*, *Ly. rufus*, *Le. serval*,  
12 and *C. caracal*, species with relatively short tails, the caudal process is absent. These  
13 processes are part of the attachment areas for the mm. intertransversarii dorsales caudae,  
14 one of the main caudal muscular groups (Evans 1993; Ercoli et al. 2013), and thus a  
15 reduction of these structures would be expected when the tail is short. Given this, the  
16 presence of well-developed mammillo-articular processes in extant species with long tails  
17 would suggest the inclusion of *L. vallesiensis* in this group. Russo and Shapiro (2011) on  
18 their study on primates, found that the development of the caudal transverse process of the  
19 sacrum separated “long” and “tailless” groups from the “short”/“very short” groups,  
20 although the study did not distinguish “short” and “very short” groups (Tojima 2013). In  
21 the case of our compared sample of felines, there is no clear relationship between the  
22 morphology of the caudal transverse process and the length of the tail, as for example *Le.*  
23 *serval* shows an extremely thin and slender process, more developed than those of *F. lybica*  
24 and *Lp. geoffroyi*, which have longer tails. Nevertheless, given the morphology of the other  
25 discussed features of the sacrum, a relatively long tail can be inferred for *L. vallesiensis*.

52

### 53 Femur

54  
55  
56  
57 The femur of *L. vallesiensis* fits very well within the feline pattern, although it shows some  
58 differences when compared to those of other felines. The gluteal tuberosity, for instance, is  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 located, like in *Lp. wiedii*, clearly **distal** to the lesser trochanter, whereas in the rest of the  
5  
6 compared species of Felinae it is clearly proximal to this structure (Fig. 17). This  
7  
8 configuration relates to the relative length of the m. gluteus superficialis, which originates  
9  
10 on the iliac crest and sacrocaudal aponeurosis, and attaches, after partial fusion with the m.  
11  
12 gluteofemoralis, onto the gluteal tuberosity (Fisher et al. 2008; Barone 2010; Ercoli et al.  
13  
14 2013). Given these origin and insertion areas, the distal displacement of the gluteal  
15  
16 tuberosity in *L. vallesiensis* and *Lp. wiedii* would increase the relative length of an  
17  
18 important part of the **fibers** of the m. gluteus superficialis. The cranial **fibers** of the m.  
19  
20 gluteus superficialis flex and weakly abduct the hip joint, while the caudal ones weakly  
21  
22 extend and abduct the hip joint (Fisher et al. 2008). Basically, the pattern observed in *L.*  
23  
24 *vallesiensis* and *Lp. wiedii* could be reflecting a relatively longer m. gluteus superficialis in  
25  
26 relation to other felines, and its importance in the flexion and extension of the hind limb  
27  
28 during locomotion. The m. gluteus superficialis is relatively larger in those mammals that  
29  
30 need a powerful flexion of the hip joint (Endo et al. 2006), and thus, it is especially  
31  
32 developed in otters and other aquatic species (Gambaryan 1974; Endo et al. 2006).  
33  
34 Nevertheless, among the sample of large extant felids dissected by Gambaryan (1974),  
35  
36 there were no significant differences in the relative weight of the m. gluteus superficialis  
37  
38 with the exception of the jaguar (*Panthera onca*), which showed a relatively smaller muscle  
39  
40 (2.7% vs. more than 4.0% in the rest). Thus, the relatively longer m. gluteus superficialis of  
41  
42 *L. vallesiensis* and *Lp. wiedii*, rather than suggesting the presence of a heavier muscle  
43  
44 would indicate a capacity for rapid movements, as relatively longer muscles produces faster  
45  
46 contractions (Kardong 2002).  
47  
48  
49  
50  
51  
52  
53  
54  
55  
56

57  
58 The position of the lesser trochanter also affects the function of other important  
59  
60 muscle, the m. iliopsoas, which basically flexes the coxofemoral articulation, drawing the  
61  
62  
63  
64  
65

1  
2  
3  
4 pelvic limb forward (Evans, 1993; Barone, 2010). *Leptofelis vallesiensis*, *F. lybica*, *Ly.*  
5  
6 *lynx*, *Ly. pardinus*, *Ly. rufus*, and *Lp. geoffroyi* show a lesser trochanter located close to the  
7  
8 medial margin of the femur, but laterally displaced in relation to its position in *F. silvestris*,  
9  
10 *Le. serval*, *C. caracal*, and *Lp. wiedii* (Fig. 17). As has been noted, a laterally-located lesser  
11  
12 trochanter produces lateral rotation as well as flexion at the coxofemoral articulation during  
13  
14 the contraction of the m. iliopsoas (Howell 1944; Munthe 1989). On the contrary, in those  
15  
16 carnivorans with more medially placed lesser trochanters, such as canids and hyaenids, the  
17  
18 pull of the m. iliopsoas is produced primarily in the sagittal plane (Munthe 1989).  
19  
20 According to this, *F. silvestris*, *Le. serval*, *C. caracal*, and *Lp. wiedii* would be favouring  
21  
22 those movements of the femur in the sagittal plane, whereas the others, including *L.*  
23  
24 *vallesiensis*, would be able of a higher rank of femur movements. Within the first group, *F.*  
25  
26 *silvestris*, *Le. serval*, and *C. caracal* are slender animals, with relatively long limbs and  
27  
28 terrestrial habits (Nowak 2005; Sunquist and Sunquist 2009), whereas *Lp. wiedii* has, on  
29  
30 the contrary, a more robust proportions and strong climbing abilities (Alderton 1998;  
31  
32 Sunquist and Sunquist 2009). Nevertheless, if the medially located lesser trochanter were  
33  
34 indicative of a m. iliopsoas acting close to the sagittal plane and producing strong jumping  
35  
36 impulse, the observed morphology would fit well with the ecology of *F. silvestris*, *Le.*  
37  
38 *serval*, *C. caracal*, and *Lp. wiedii*, all of them proficient jumpers (Alderton 1998; Sunquist  
39  
40 and Sunquist 2009). At this respect, it is remarkable that the semiarboreal viverrid *Genetta*  
41  
42 *genetta*, also a good jumper (Jennings and Veron 2009) shows a medially located lesser  
43  
44 trochanter, as *F. silvestris*, *Le. serval*, *C. caracal*, and *Lp. wiedii*. The feline from  
45  
46 Batallones would exhibit a morphology also observed in other extant felines, but derived  
47  
48 from that of the more primitive viverrids. The same pattern observed in *L. vallesiensis* is  
49  
50 present in the femora of *S. turnauensis* from La Grive-Saint-Alban (LGR 4042) and *M.*  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 *lorteti* from Sansan (SAN 879), thus indicating that this character derived as early in the  
5  
6 evolution of Felinae as the middle Miocene.  
7  
8

9         One of the few differences observed in the distal epiphysis of the femur is the  
10 orientation of the medial condyle in caudal view, rather vertical in *L. vallesiensis*, *F.*  
11 *silvestris*, *Lp. wiedii*, and *Lp. geoffroyi*, and slightly laterally inclined in *Le. serval*, *F.*  
12 *lybica*, *Ly. lynx*, *Ly. pardinus*, *Ly. rufus*, and *C. caracal*. Also, in all these latter species,  
13  
14 except *F. lybica*, the medial condyle distally surpasses the level of the lateral one. When the  
15  
16 tibia flexes on the femur, both the inclination and the distal projection of the medial  
17  
18 condyle makes the tibia rotate laterally when it flexes on the femur, which all at once  
19  
20 makes the talus be placed in a more parasagittal position, and so the foot; on the contrary,  
21  
22 when both the lateral and medial femoral condyles reach the same level distally, the talus is  
23  
24 located in a more lateral position when the tibia flexes on the femur, which makes the foot  
25  
26 **be** rotated laterally. The position of the foot has an enormous importance when running, so  
27  
28 the observed differences would be separating more cursorial felids from those inhabiting  
29  
30 **more closed** environments, and thus retaining full climbing abilities. The morphology of  
31  
32 the femoral condyles in *G. genetta*, similar to those of *L. vallesiensis* strongly supports this  
33  
34 interpretation.  
35  
36  
37  
38  
39  
40  
41  
42  
43  
44

45         But maybe the most striking feature in the femur of *L. vallesiensis* is the  
46 proximal development of the trochlea, greater than that of any other of the compared  
47  
48 felines (Fig. 18). Argot (2003) noticed that the femoral trochlea of canids was  
49  
50 proximal higher than those of other carnivorans including ursids, mustelids, and  
51  
52 felids, a feature that, following this author, reflected the great range of excursion of the  
53  
54 patella in cursorial forms. Previously, Howell (1944) had stated that jumping and cursorial  
55  
56 mammals required stronger extensor muscles of the tibia and have a well-developed  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 trochlea, with high marginal ridges. Arboreal viverrids such as *G. genetta* also show a  
5  
6 proximodistally high femoral trochlea, very similar to that of *L. vallesiensis*, which  
7  
8 probably indicates a good ability for jumping in both species. Nevertheless, the femoral  
9  
10 trochlea of the first known felid, the early Miocene *Proailurus lemanensis* from Saint  
11  
12 Gérard-le-Puy (MN 2), although being proximodistally higher than those of extant felines,  
13  
14 it is mediolaterally much wider than that of *L. vallesiensis*. If this is the primitive  
15  
16 morphology for Felidae, the pattern seen in extant felines had been achieved by reducing  
17  
18 the proximodistal height of the trochlea. The middle Miocene felines *M. lorteti* from  
19  
20 Sansan (MN 6) and *S. turnauensis* from La Grive-Saint-Alban (MN 7/8) (de Beaumont  
21  
22 1961; Salesa et al. 2011), both show a proximodistally shorter trochlea than that of *L.*  
23  
24 *vallesiensis*. Thus, these former species, older than the Batallones feline, already show a  
25  
26 modern femoral trochlea, very similar to that of extant felines.  
27

31  
32  
33  
34  
35

## 36 Tibia

37  
38  
39  
40 The tibia of *L. vallesiensis* shows a similar morphology and proportions to those of other  
41  
42 compared felines, except for the remarkable development of a strong bony ridge on the  
43  
44 caudal face of the diaphysis (Fig. 7c, 19a). This structure seems to separate the attachment  
45  
46 surfaces for the belly masses of the m. flexor digitorum lateralis and m. flexor digitorum  
47  
48 medialis + m. tibialis caudalis, and it could be helpful in increasing their area (as the  
49  
50 sagittal crest in the skull increases the attachment area for the m. temporalis), as well as  
51  
52 stabilizing the muscles by forming a groove to accommodate them. Although the main  
53  
54 function of both the m. flexor digitorum lateralis and m. flexor digitorum medialis is to flex  
55  
56 the foot phalanges (Evans 1993; Barone 2010) and, although the latter is an accessory of  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 the former, both have an important participation in the propulsion of the body (Barone  
5  
6 2010). If these two muscles were relatively larger in *L. vallesiensis* than in other felines,  
7  
8 they would have produced stronger propulsive forces in the hind limb. Among our studied  
9  
10 sample of felines, this ridge is also present in *Lp. geoffroyi* (Fig. 19b), but de Beaumont  
11  
12 (1986) described it also in *Pristifelis attica* and in the Asian golden cat (*Catopuma*  
13  
14 *temminckii*), which means that at least two species of extant felines that do not have either a  
15  
16 close relationship nor marked ecological differences (Ximenez 1975; Johnson and Franklin  
17  
18 1991; Mattern and McLennan 2000; Sunquist and Sunquist 2009) do retain this feature  
19  
20 exhibited by these two late Miocene felines. The sharing of this character by *L. vallesiensis*  
21  
22 and *P. attica*, and its absence in the middle Miocene *Styriofelis turnauensis* (Fig. 19c) and  
23  
24 *Miopanthera lorteti* poses an interesting question of the phylogenetic relationships of these  
25  
26 taxa (see Taxonomic Discussion section). The caudal crest is also present, although much  
27  
28 less marked, in ursids (Fig. 19e), which agrees with the great development in this group of  
29  
30 the attachment area for the m. flexor digitorum medialis + m. tibialis caudalis, something  
31  
32 that has been associated to plantigrady (Ginsburg 1961b). Nevertheless, when considering  
33  
34 its presence in some extant species of Felinae whose locomotion probably does not differ  
35  
36 from that of other species, the developed caudal crest of the tibia of *L. vallesiensis* cannot  
37  
38 be considered as an indication of plantigrady in this feline, moreover when the rest of the  
39  
40 hind limb elements are relatively slender.  
41  
42  
43  
44  
45  
46  
47  
48  
49  
50  
51  
52

### 53 Calcaneus

54  
55  
56  
57 The dorsal orientation of the talar facet of the sustentaculum tali in *L. vallesiensis*, *Lp.*  
58  
59 *wiedii*, *Lp. geoffroyii*, *F. silvestris*, and *F. lybica* is an important feature (Fig. 20), as it  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 would theoretically imply a greater restriction in the lateral movements of the talus when  
5  
6 articulating with the calcaneus, an expected feature of the most cursorial species.  
7  
8 Nevertheless, when calcaneus and talus are experimentally articulated in our sample of  
9  
10 felines, there are not marked differences in the relative orientation of the talus, as in those  
11  
12 species having a dorsally oriented talar facet (*L. vallesiensis*, *Lp. wiedii*, *Lp. geoffroyii*, *F.*  
13  
14 *silvestris*, and *F. lybica*), the matching facet on the talus is less excavated than in felines  
15  
16 having a dorsomedially oriented talar facet in the sustentaculum tali (*C. caracal*, *Le. serval*,  
17  
18 *Ly. lynx*, *Ly. rufus*, and *Ly. pardinus*). The dorsal orientation of the facet is observed in both  
19  
20 terrestrial and arboreal small felines, as well as in *L. vallesiensis*, whereas the most  
21  
22 cursorial taxa, *C. caracal*, *Le. serval*, *Ly. lynx*, *Ly. rufus*, and *Ly. pardinus*, show a more  
23  
24 dorsomedial orientation. Interestingly, *G. genetta* shows a similar pattern to that observed  
25  
26 in the former group, as well as the primitive felids *Proailurus lemanensis* from Saint  
27  
28 Gerand-Le-Puy (SG 3532), *Promegantereon ogygia* from Batallones-1 (B/S-341) (Siliceo  
29  
30 et al. 2014), and the taxa from Sansan *Pseudaelurus quadridentatus* (Sa 2427) (Peigné  
31  
32 2012), *S. turnauensis* (Sa744) (Peigné 2012), and *M. lorteti* (Sa 671) (Salesa et al. 2011)  
33  
34 thus suggesting that this is the primitive condition for Felidae, which later derived in larger  
35  
36 felines.  
37  
38  
39  
40  
41  
42  
43  
44

45 The attachment area for the m. quadratus plantae shows its greatest size in *L.*  
46  
47 *vallesiensis*, *Lp. geoffroyii*, *Lp. wiedii*, and *F. silvestris*, suggesting the presence of a large  
48  
49 and fully operative muscle (Fig. 20e, h), whereas it would be reduced (given the  
50  
51 development of its attachment area) in *F. lybica*, *C. caracal*, *Le. serval*, *Ly. lynx*, *Ly. rufus*,  
52  
53 and *Ly. pardinus* (Fig. 20f, g). In several mammals, the m. quadratus plantae is a wide band  
54  
55 arising from the lateral surface of the calcaneus, and extending obliquely across the sole to  
56  
57 its insertion on the tendinous sheet of the mm. flexores digitorum profundi, formed by the  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 m. flexor digitorum medialis and m. flexor digitorum lateralis (Davis 1964; Barone 1967;  
5  
6 Ercoli et al. 2013), thus constituting an accessory of it. The m. quadratus plantae has two  
7  
8 main functions: adjusting the oblique pull of the mm. flexores digitorum profundi, and  
9  
10 flexing the foot without the involvement of this latter muscle (Reighard and Jennings 1901;  
11  
12 Barone 1967; Turner and Antón 1997; Vollmerhaus and Roos 2001; Benjamin et al. 2008).  
13  
14 Ginsburg (1961b) linked the great development of this muscle with plantigrady, but in the  
15  
16 case of felids, which are digitigrade carnivorans, the presence of a well-developed m.  
17  
18 quadratus plantare is clearly a primitive feature most likely related to the retention of the  
19  
20 grasping function of the hind limb (Turner and Antón 1997), and a reduced capacity for  
21  
22 pedal inversion but powerful flexion capability of the distal phalanges of the foot (Cifelli  
23  
24 1983). A well-developed depression for the attachment of the m. quadratus plantae is found  
25  
26 in many fossil felids, such as *P. lemanensis*, *Ps. quadridentatus*, *M. lorteti*, *Pr. ogygia*, and  
27  
28 *Metailurus major* (Ginsburg 1961a; Salesa et al. 2011, 2012b; Siliceo et al. 2014)  
29  
30 indicative of a relative large muscle. Thus, these fossil species did probably exhibit a good  
31  
32 climbing ability, with the m. quadratus plantae muscle providing extra force and precision  
33  
34 to the flexion of the foot during this activity (Turner and Antón 1997). In more cursorial  
35  
36 felids, such as *F. lybica*, *C. caracal*, *Le. serval*, *Ly. lynx*, *Ly. rufus*, and *Ly. pardinus*, both  
37  
38 the necessity for decreasing the weight of the distal elements of the limbs and the restriction  
39  
40 of the lateral movements of the foot (Sooriakumaran and Sivananthan 2005) probably  
41  
42 explain the reduction in the size of the m. quadratus plantae (Ginsburg 1961b). Then, in  
43  
44 these cursorial felids, the mm. flexores digitorum profundi (m. flexor digitorum medialis  
45  
46 and m. flexor digitorum lateralis) became primarily flexors of the toes in relation to the  
47  
48 tibia, their function then changing from grasping to propulsion (Turner and Anton 1997).

## Taxonomic discussion on “*Styriofelis*” *vallesiensis*

When Salesa et al. (2012a) assigned the small feline from Batallones-1 and Batallones-3 to the genus *Styriofelis* as the new species *S. vallesiensis*, they chose the most conservative taxonomic alternative based on a set of dental similarities between the Batallones sample and the middle Miocene feline *S. turnauensis*, although their cladogram did not imply a generic identity between both taxa. Nevertheless, the present new study reveals important morphological differences in the postcranial skeleton of *S. vallesiensis* and *S. turnauensis*, strongly suggesting a generic separation between these two Miocene felines. These features are: 1) the humerus of *S. turnauensis* and *M. lorteti* has a less proximally projected greater tubercle, and a much more medially projected medial epicondyle than those of *S. vallesiensis*, both features indicating a strong difference in the locomotion of these felines, with the two former species being much less cursorial than the feline from Batallones; 2) the Mc I of *S. vallesiensis* is slenderer than those of *S. turnauensis* and *M. lorteti*; 3) both *S. turnauensis* and *M. lorteti* have proximodistally shorter femoral trochleae than that of *S. vallesiensis*, a feature that links the former species with the extant felines, whereas the Batallones feline shows the same morphology observed in some extant viverrids; 4) in *S. turnauensis* and *M. lorteti*, the attachment area of the m. quadratus plantae is much more proximally extended than in *S. vallesiensis*, suggesting a much larger muscle, typical of arboreal felids inhabiting vegetated ecosystems; and 5) the caudal face of the tibiae of *P. attica* and *S. vallesiensis* shows a marked proximodistally developed ridge, a feature completely absent in *S. turnauensis* and *M. lorteti*.

All these differences, besides suggesting a different lifestyle (with *S. vallesiensis* being a more cursorial animal) support the separation of these felines in different genera.

1  
2  
3  
4 Recently, Geraads and Peigné (2016) have discussed the status of the genus *Styriofelis*,  
5  
6 proposing the inclusion of the species *lorteti* in the genus *Miopanthera*, which would also  
7  
8 include the late Miocene *Felis pamiri* as *M. pamiri*. This increases the previously assumed  
9  
10 diversity of the felids from the middle Miocene, as at least three different taxa were present  
11  
12 at this time: the primitive machairodontine *Pseudaelurus quadridentatus*, the lynx-sized  
13  
14 feline *Miopanthera lorteti*, and the wild cat-sized feline *Styriofelis turnauensis*. Of these  
15  
16 three lineages, at least the first two had a continuity in the late Miocene, with  
17  
18 *Promegantereon ogygia* (a primitive saber-toothed felid very similar to *Ps. quadridentatus*)  
19  
20 and *M. pamiri*, which would be very close to the pantherin felid clade (Geraads and Peigné  
21  
22 2016). In both cases, several dental and skeletal similarities support a phylogenetic  
23  
24 relationship between those forms included in the same lineage (de Beaumont 1975;  
25  
26 Ginsburg 1983; Salesa et al. 2010b, 2012; Peigné 2012; Geraads and Peigné 2016), but the  
27  
28 assumption of *S. vallesiensis* as being part of the *S. turnauensis* lineage is quite doubtful, as  
29  
30 now it is clear that both species represent two different felid models characterized by a  
31  
32 combination of unique dental and skeletal features. Besides this, the other late Miocene  
33  
34 feline known in the European faunas, the larger *P. attica* shows a more derived dentition  
35  
36 than that of *S. vallesiensis*, which points towards a different generic status (Salesa et al.  
37  
38 2012). In the present study, we have shown the existence of shared features in the  
39  
40 postcranial skeleton of *P. attica* and *S. vallesiensis* (such as the proximodistally developed  
41  
42 ridge in the caudal face of the tibia), but there are also some others that distinguish both late  
43  
44 Miocene felines (such as the smaller projection of the lateral epicondyle of the humerus in  
45  
46 *S. vallesiensis*). In absence of a proper cladistic analysis (unapproachable due to the  
47  
48 scarcity of fossils), these similarities and differences are difficult to assess, but combining  
49  
50 the results of the phylogenetic tree proposed by Salesa et al. (2012) with the observations of  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 the present study, it seems quite probable that *S. vallesiensis* and *P. attica* belonged to the  
5  
6 same lineage of terrestrial felines, although representing two different genera. For example,  
7  
8 the presence of a P2 in *P. attica*, whereas *S. vallesiensis* retains **two small upper deciduous**  
9  
10 **premolars**, D1 and D2 (see discussion in Salesa et al. 2012) gives an idea of the marked  
11  
12 phylogenetic separation existing between both taxa. In consequence, a different generic  
13  
14 name should be proposed for *S. vallesiensis* in order to separate it from the primitive and  
15  
16 much more robust *S. turnauensis*, and from the contemporary and more derived *P. attica*. In  
17  
18 absence of any available name, we propose the new genus *Leptofelis*, with the following  
19  
20  
21  
22  
23  
24 diagnosis:

25  
26  
27  
28 Order Carnivora Bowdich, 1821

29  
30 Suborder Feliformia Kretzoi, 1945

31  
32 Family Felidae Fischer, 1817

33  
34 Subfamily Felinae Fischer, 1817

35  
36 Genus *Leptofelis*, **new genus**

37  
38  
39  
40 *Leptofelis vallesiensis* (Salesa, **et al.**, 2012)

41  
42  
43  
44  
45 *Holotype*: BAT-3'09 1576, an almost complete skull from Batallones-3.

46  
47  
48  
49  
50  
51 *Type locality*: Batallones-3 (late Miocene, Vallesian, MN 10) (Madrid, Spain).

52  
53  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65  
*Other localities*: Maragheh (MN 11–12, Iran), and Batallones-1 (MN 10, Madrid).

1  
2  
3  
4 *Etymology:* from the Greek *λεπτός* (*leptós*), meaning “slender”, and from the Latin *felis*,  
5  
6  
7 cat.

8  
9  
10  
11 *Diagnosis:* That provided by Salesa et al. (2012) and also, postcranial skeleton with a  
12  
13  
14 combination of primitive and derived features: humerus with a well proximally projected  
15  
16 greater tubercle and an almost non-projected medial epicondyle; medial tubercle of the ulna  
17  
18 well developed, markedly proximally projected, and surpassing the level of the lateral  
19  
20 tubercle; slender Mc I, much less robust than those of middle Miocene felines such as *S.*  
21  
22 *turnauensis* and *M. lorteti*; mediopalmar facet of the Mc IV base relatively less  
23  
24 proximodistally expanded than in most felines; relatively short L7; dorsal sacral foramina  
25  
26 absent; relatively proximodistally elongated femoral trochlea; relatively reduced attachment  
27  
28 area for the m. quadratus plantae on the lateral face of the calcaneus; presence of a marked  
29  
30 proximodistally developed ridge on the caudal face of the tibia.

31  
32  
33  
34  
35  
36  
37  
38 *Differential diagnosis:* Only postcranial features are considered. Compared to *S.*  
39  
40 *turnauensis* and *M. lorteti*, humerus with a more proximally projected greater tubercle, and  
41  
42 a much less medially projected medial epicondyle; Mc I slenderer; proximodistally longer  
43  
44 femoral trochlea; attachment area of the m. quadratus plantae much less proximally  
45  
46 extended; caudal face of the tibiae with a marked proximodistally developed ridge.  
47  
48 Compared to *P. attica*, lesser projection of the lateral epicondyle of the humerus.  
49  
50  
51  
52  
53  
54

55 **Palaeobiology of *Leptofelis vallesiensis***  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 The postcranial anatomy of the late Miocene small feline *Leptofelis vallesiensis* is  
5  
6 characterized by a combination of derived and primitive characters, a good example of the  
7  
8 mosaicism typically exhibited by the intermediate forms of several groups of Carnivora. In  
9  
10 this case, whereas the forelimb of *L. vallesiensis* is relatively modern, resembling that of  
11  
12 some extant felines, its hind limb shows a set of primitive features in the pelvis, femur, and  
13  
14 calcaneus, some of them shared with arboreal extant viverrids, and absent in the living  
15  
16 felines. This unique combination of traits is different from that seen in the extant members  
17  
18 of Felinae, but also from that present in the middle Miocene earliest felines.  
19  
20  
21  
22

23  
24 *Leptofelis vallesiensis* had a body mass of around 7–9 kg (see Appendix 1), that is, a  
25  
26 little larger than the extant *F. silvestris* and *F. lybica*, and particular proportions, as its  
27  
28 brachial index (BIn) was within the range of *C. caracal* and *Lp. geoffroyi*, its crural index  
29  
30 (CIn) is close to those of *F. silvestris* and *Ly. lynx*, and its intermembral index (IIn) is  
31  
32 similar to that of *C. caracal* and *G. genetta* (Table 3). These indexes provide information  
33  
34 on the locomotor adaptations (see Appendix 2), with the most cursorial species of  
35  
36 Carnivora having relatively longer radii and tibiae than the corresponding humerii and  
37  
38 femora (Taylor 1974, 1989; Gonyea 1978; Van Valkenburgh 1985, 1987; Anyonge 1996),  
39  
40 that is, they show BIn and CIn higher or close to 100. In the case of felids, the BIn has also  
41  
42 been related to habitat complexity, with those species inhabiting highly structured habitats,  
43  
44 with dense vegetational cover, having relatively shorter forearms (and thus BIn between  
45  
46 80–90) than those occupying low structured habitats (and showing BIn close to 100)  
47  
48 (Gonyea 1976a, b, 1978). Considering this, *L. vallesiensis* would have inhabited highly  
49  
50 structured habitats, which does not always mean dense-vegetated areas, but a landscape  
51  
52 composed of relatively open areas mixed with densely-vegetated patches (Fig. 21). This  
53  
54 kind of environments allows greater species diversity than less structured habitats, by  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 reducing predation efficiency and enabling predator/prey coexistence, and by increasing the  
5  
6 number of available niches (Menge and Sutherland 1976; Petren and Case 1998). This  
7  
8 would be an optimal habitat for a small feline such as *L. vallesiensis*, where it could find  
9  
10 both refuge and a high diversity of available prey.  
11  
12

13  
14 On the other hand, the IIn provides information on the relative length of the limbs,  
15  
16 and in most felids, whose hind limb is longer than the forelimb, this index shows values  
17  
18 below 100. A lower IIn (between 70–80) indicates a particularly long hind limb (Fig. 21),  
19  
20 which has been related to jumping capacities (Howell 1944; Gonyea 1976b; Taylor 1976).  
21  
22 The IIn of *L. vallesiensis* is almost 81, which supports a well development of its jumping  
23  
24 capacities, as inferred from the morphology of its pelvic limb (see above).  
25  
26  
27

28  
29 In summary, *L. vallesiensis* was very likely a mostly terrestrial species, as shown by  
30  
31 the morphology and proportions of its forelimb, but retained both primitive knee and ankle,  
32  
33 associated with efficient jumping, an ability that was probably essential for eluding the  
34  
35 large carnivorans that inhabited Batallones, such as saber-toothed felids, amphicyonids,  
36  
37 ursids, ailurids, etc., all of them much larger than *L. vallesiensis*. This feline would forage  
38  
39 on the ground, preying upon relatively small vertebrates, and occupying patched areas with  
40  
41 moderate to dense vegetational cover, which provided the necessary protection to avoid  
42  
43 detection by other predators, as well as allowing the stalking and hunting of prey. In this  
44  
45 respect, its adaptation for jumping could improve the ability of *L. vallesiensis* for capturing  
46  
47 fast animals, including birds, which would be caught by way of a powerful leap, thus  
48  
49 resembling the sophisticated hunting method of extant servals and caracals (Sunquist and  
50  
51 Sunquist 2009).

3  
4 APPENDIX 1  
5  
6

7 **Body mass estimation in *Leptofelis vallesiensis***  
8  
9

10  
11 For the estimation of the body mass of *L. vallesiensis* we used the specific formulae for the  
12 family Felidae of Rodríguez (1997) and Anyonge (1993), both based on the following  
13 measurements of the appendicular skeleton: proximal width of the tibia (PW) and width of  
14 the femoral head (FHW) (Rodríguez, 1997), and distal articular (condylar) area of femur  
15 (FDA) (Anyonge, 1993). The results are:  
16  
17  
18  
19  
20  
21  
22

23 For the proximal width of the tibia (PW), the formula is:  $\text{Log Body Mass} = 2.8581$   
24  $(\log \text{PW}) - 0.0786$ . The PW of the tibia BAT-1'06 D4-110 is 25.32 mm, which results in a  
25  
26 body mass of 8.5 kg.  
27  
28  
29

30 For the width of the femoral head (FHW), the formula is:  $\text{Log Body Mass} = 2.9968$   
31  $(\log \text{FHW}) + 0.5668$ . The FHW of the femur BAT-1'06 D4-67a is 12.54 mm, which results  
32  
33 in a body mass of 7.21 kg.  
34  
35  
36  
37

38 For the femoral distal articular (condylar) area (FDA) the formula is:  $\text{Log Body}$   
39  $\text{Mass} = 1.32 (\log \text{FDA}) - 2.16$ . The FDA was calculated following the methodology of  
40  
41 Anyonge (1993) for the femora BAT-1'06 D4-67a and BAT-1'06 D4-67b, obtaining areas  
42  
43 of 222.63 mm<sup>2</sup> and 229.168 mm<sup>2</sup>, respectively. This results in a body mass of 8.68 kg from  
44  
45 the femur BAT-1'06 D4-67a, and 9.02 kg from the specimen BAT-1'06 D4-67b.  
46  
47  
48  
49

50 Thus, the estimated body mass of *L. vallesiensis* from Batallones-1 is between 7.21  
51  
52 and 9.02 kg. The published data on the body weight of extant felines shows wider ranges,  
53  
54 as they take into account the size variation within each species, mostly due to sexual  
55  
56 dimorphism. Anyway, the estimated body weight of *L. vallesiensis* is close to the maximum  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 weights of several species of extant small felines such as *Felis silvestris*, *F. chaus*,  
5  
6 *Leopardus geoffroyi* and *Puma yaguarondi* (Sunquist and Sunquist, 2009).  
7  
8  
9

## 10 11 APPENDIX 2 12

### 13 14 **Body proportions in *Leptofelis vallesiensis*** 15

16  
17  
18 The body proportions of the feline from BAT-1 have been calculated using the brachial,  
19 crural and intermembral indexes (Gonyea, 1976a, 1976b; Taylor, 1976; Anyonge, 1996;  
20  
21 Iwaniuk *et al.*, 1999). The formulae for these indexes are:  
22  
23

24  
25  
26 Brachial index (BIn) = (Length radius/Length humerus) x 100.  
27

28  
29 Crural index (CIn) = (Length tibia/ Length femur) x 100.  
30

31  
32 Intermembral index (IIn) = (Length thoracic limb/ Length pelvic limb) x 100.  
33

34 The corresponding measurement were taken on the following bones of *L.*  
35  
36 *vallesiensis* from Batallones-1: Femora (BAT-1'06 D4-67a and BAT-1'06 D4-67b), Tibiae  
37  
38 (BAT-1'06 D4-110 and BAT-1'06 D4-103), Humeri (BAT-1'02 D6-58 and B-4968) and  
39  
40 Radii (B/S-575 and B-2074(5)).  
41

42  
43 The results of the different indexes for *L. vallesiensis* are as follows: BIn: 89.16–  
44  
45 91.13; CIn: 103.01–104.04; IIn: 80.23–80.93.

Right Mc V	BAT-1'04 E5-129	29.24	5.18	5.58	
Left Mc V	BAT-1'04 E5-212	29.01	5.17	5.63	

**Table 2.** Measurements of the postcranial bones of *L. vallesiensis* from Batallones-1.

<b>Element</b>	<b>Number</b>	<b>tl</b>	<b>oh</b>	<b>ah</b>	<b>aw</b>
Right ulna	BAT-1'08 C8-24	131.06	15.02	16.67	-
Right ulna	BAT-1'06 E5-50	123.73	13.06	14.80	-
Right ulna	B-2074(6)	128.12	13.44*	14.84	-
Sacrum	BAT-1'06 D4-66b	33.94	-	-	-
Left talus	BAT-1'03 D6-300	19.42	-	12.46	13.11
Right calcaneus	BAT-1'06 F5-61	33.19	-	16.36	14.18
Left calcaneus	BAT-1'04 D6-62	31.34	-	15.68	14.93
Left calcaneus	BAT-1'03 D6-301	34.40	-	16.10	14.39

**Table 3.** Brachial, Crural and Intermembral indexes of *L. vallesiensis* and several species of Felidae and Viverridae. Data taken from Salesa (2002).

<b>Species</b>	<b>BIn</b>	<b>CIn</b>	<b>IIn</b>
<i>Felis lybica</i>	98.75	95.35	85.08
<i>Caracal caracal</i>	91.34	95.45	80.73
<i>Leopardus pardalis</i>	88.39	95.50	85.14
<i>Puma yaguarondi</i>	81.86	95.58	77.33
<i>Profelis aurata</i>	86.11	95.97	80.31
<i>Prionailurus viverrinus</i>	89.79	96.97	82.92
<i>Lynx pardinus</i>	96.31	99.72	82.11
<i>Leopardus wiedii</i>	85.48	100.55	81.05
<i>Leopardus tigrinus</i>	84.50	100.49	81.07
<i>Leopardus geoffroyi</i>	89.34	100.09	84.73
<i>Prionailurus planiceps</i>	88.87	101.69	81.97
<i>Pardofelis marmorata</i>	83.19	102.69	80.65
<i>Prionailurus bengalensis</i>	86.90	102.77	83.49
<i>Lynx lynx</i>	97.89	103.30	82.75
<i>Felis silvestris</i>	94.59	104.81	86.01
<i>Leptailurus serval</i>	95.78	101.87	87.38
<i>Felis chaus</i>	97.66	111.72	93.36
<i>Catopuma temminckii</i>	87.40	118.42	73.95
<i>Neofelis nebulosa</i>	81.92	99.21	82.47
<i>Puma concolor</i>	83.90	93.72	82.70
<i>Uncia uncia</i>	91.41	103.12	84.93
<i>Panthera pardus</i>	82.24	92.63	84.95
<i>Panthera onca</i>	80.80	86.61	87.71
<i>Acinonyx jubatus</i>	103.30	105.00	90.10
<i>Panthera leo</i>	95.35	88.77	91.91
<i>Genetta genetta</i>	85.77	106.05	80.55
<i>Civettictis civetta</i>	88.64	96.44	81.88
<i>Leptofelis vallesiensis</i>	89.16–91.13	103.01–104.04	80.23–80.93
