1 **Summary**

2

3 **Background** Hand–foot–and–mouth disease (HFMD) is a common childhood illness
4 caused by enteroviruses. Increasingly it imposes a substantial disease burden
5 throughout East and Southeast Asia. To better inform vaccine and other interventions,
6 we characterized the epidemiology of HFMD in China based on enhanced
7 surveillance.

8 **Methods** We extracted epidemiological, clinical and laboratory data from reported
9 HFMD cases during 2008–2012 and compiled climatic, geographic and demographic
10 information. All analyses were stratified by age, disease severity, laboratory
11 confirmation status and enterovirus subtype.

12 **Findings** The surveillance registry captured 7,200,092 probable HFMD cases
13 (annualized incidence, 1·2 per 1,000), of whom 3·7% were laboratory–confirmed and
14 0·03% died. Incidence and mortality were highest in children aged 12–23 months (in
15 2012: 38·2 cases per 1,000 and 1·5 death per 100,000). Median durations from onset
16 to diagnosis and death were 1·5 days and 3·5 days respectively. The risk of
17 cardiopulmonary or neurological complications was 1·1% and the severe-case fatality
18 risk was 3·0%, with >90% of deaths associated with enterovirus 71. HFMD peaked
19 annually in June in the North, whereas Southern China experienced semi-annual
20 outbreaks in May and September/October. Geographic differences in seasonal
21 patterns were weakly associated with climate and demographic factors (variance

1 explained 8-23% and 3–19%, respectively).

2 **Interpretation** This is the largest population-based study to date of the epidemiology
3 of HFMD. Future mitigation policies should take full account of the heterogeneities of
4 disease burden identified. Additional epidemiologic and serologic studies are
5 warranted to elucidate local HFMD dynamics and immunity patterns and optimize
6 interventions.

1 **Introduction**

2 Hand-foot-and-mouth disease (HFMD) is a common infectious condition caused by a
3 variety of enteroviruses, with enterovirus 71 (EV-A71) and Coxsackie virus A16
4 (CA-V16) being the most commonly reported.¹ Children under five years are
5 particularly prone to HFMD, and most patients show self-limiting illness typically
6 including fever, skin eruptions on hands and feet, and vesicles in the mouth. However,
7 a small proportion has been known to rapidly develop neurological and systemic
8 complications that can be fatal, particularly in cases associated with EV-A71.²
9 EV-A71 was first identified in 1969 in California, USA³ and has become more
10 predominant across the Asia–Pacific region in the past 15 years.^{4–11}

11 China established a national enhanced surveillance system for HFMD in May 2008
12 partly in response to several large HFMD outbreaks during 2007 and early 2008.⁹
13 Here we describe the enhanced HFMD surveillance system and characterize the
14 epidemiology of the disease in China, focusing on age, seasonal, and geographic
15 patterns from 2008 to 2012.

16

17 **Methods**

18 **Enhanced national surveillance program**

19 Beginning on January 1, 2008, all probable and laboratory–confirmed HFMD cases
20 were reported on a voluntary basis to the Chinese Centre for Disease Control and

1 Prevention (China CDC) in Beijing. On May 2, 2008, HFMD was made statutorily
2 notifiable.

3

4 **Case definitions**

5 A probable HFMD case was defined as a patient with papular or vesicular rash on
6 hands, feet, mouth, or buttocks, with or without fever. A confirmed case was defined
7 as a probable case with laboratory evidence of enterovirus infection (including
8 EV-A71, coxsackievirus A16 (CA-V16), or other non-EV-A71 and non-CA-V16
9 enteroviruses) detected by reverse-transcriptase polymerase chain reaction (RT-PCR),
10 real-time RT-PCR, or virus isolation.

11 HFMD patients, whether probable or confirmed, were classified as severe if they
12 experienced any neurological complications (aseptic meningitis, encephalitis,
13 encephalomyelitis, acute flaccid paralysis, or autonomic nervous system dysregulation)
14 and/or cardiopulmonary complications (pulmonary oedema, pulmonary haemorrhage,
15 or cardiorespiratory failure); otherwise, they were categorized as mild cases.

16

17 **Collection and testing of specimens**

18 Given limited laboratory capacity during the first year of enhanced surveillance (from
19 May 2008 through June 2009), clinical samples were collected from the first five mild,
20 probable cases who visited hospital outpatient departments each week in each of 31

1 Chinese provinces (Appendix Figure 1). We also attempted to collect specimens from
2 all severe cases. With enhanced capacity after June 2009, samples were collected from
3 the first five mild, probable cases who visited hospital outpatient departments each
4 month in each of the 3,074 counties or districts and from all severe cases (Appendix
5 Figure 1).¹² Depending on the symptoms and clinical status of each case, the
6 appropriate clinical specimens, including throat swab, rectal swab, fecal sample,
7 vesicular fluid, and/or cerebrospinal fluid, were collected. Sampling was systematic
8 and did not follow community outbreaks.

9 Specimens were placed in sterile viral transport medium and sent to provincial– or
10 prefecture–level CDCs (n=425) for PCR or virus isolation, according to standardized
11 protocols disseminated by the national CDC.¹³ Viral ribonucleic acid (RNA) was
12 extracted using available commercial kits (most frequently, QIAamp Viral RNA Mini
13 Kit, Qiagen, Valencia, CA, USA, and Geneaid Viral RNA Mini Kit, Geneaid Biotech,
14 Taiwan China) as per the manufacturer’s protocols. RNA from each sample was tested
15 for specific primers and probes that targeted pan-enterovirus, EV-A71, and CA-V16.
16 Testing was carried out in biosafety level 2 facilities. Test results were classified into
17 four categories: enterovirus negative, EV-A71 positive, CA-V16 positive, or positive
18 for another enterovirus without further serotype identification.

19 A small number of samples underwent virus isolation at provincial–level CDCs.
20 According to national guidelines,¹² at least ten enterovirus strains should be identified

1 in each province every month. Specimens were inoculated into human
2 rhabdomyosarcoma (susceptible to EV-A71 and CA-V16) and Hep-2 (susceptible to
3 other enteroviruses) cells. If cultures showed cytopathic effect (CPE), serotype
4 identification was obtained by sequencing analysis¹⁴. A blind passage was done with
5 all cultures showing no CPE after 7 days.

6

7 **Clinical and epidemiologic data**

8 Probable and confirmed case were reported on-line to the national CDC within 24
9 hours of diagnosis, using a standardized form including basic demographic
10 information (sex, date of birth, and address), case classification (probable or
11 confirmed), severity (mild or severe), death status, date of symptoms onset, date of
12 diagnosis, and date of death (if applicable), and virus type (EV-A71, CA-V16, other
13 enterovirus) for confirmed cases.

14

15 **Climate, geographic, and demographic data**

16 To analyze the potential drivers of HFMD seasonality, we collected demographic,
17 economic, geographic, and climatic information for all provinces from 2008 to 2012,
18 including: 1) age-specific population denominators, population density, Gross
19 Domestic Product, and Gross Regional Product;¹⁵ 2) latitude and longitude of
20 province capitals; 3) air, rail, road, and boat passenger data;¹⁶ 4) meteorological data

1 including daily temperature, rainfall, relative humidity, air pressure, average vapor
2 pressure, and hours of sunshine (Appendix Text 1 for details).¹⁷ Climate variables
3 were aggregated by season (spring: April–June; autumn: September–November), to
4 reflect the seasonal occurrence of HFMD peaks in surveillance data. The 31 provinces
5 were further grouped into six climatic regions (Appendix Figure 2A).

6

7 **Data analysis**

8 *Disease burden and severity of disease*

9 We included all cases with illness onset from January 1, 2008 through December 31,
10 2012 in the analysis. We estimated age-specific rates of incidence, severe illness, and
11 mortality by combining probable and confirmed cases. 95% confidence intervals (CIs)
12 for rates were estimated with Poisson methods. For rates with denominator >100,000
13 and numerator ≥ 20 , we calculated 95% CIs assuming a normal distribution. We
14 assessed the geographic distribution of cases across all 31 provinces, grouped into
15 seven regions as shown in Appendix Figure 2B. We estimated the age specific
16 case–severity risk (no. of severe cases/no. of probable and confirmed cases),
17 case–fatality risk (no. of deaths/no. of probable and confirmed cases), and
18 case–fatality risk of severe HFMD cases (no. of deaths/no. of severe cases), overall
19 and stratified by serotype. In serotype-specific analyses, we estimated the number of
20 serotype-specific HFMD cases by applying the distribution of serotypes among

1 specimens positive for enteroviruses and further serotyped to the universe of probable
2 and confirmed cases.

3 We calculated the distributions of times from illness onset to diagnosis, illness onset
4 to death, and diagnosis to death by virus serotype. To identify predictors for severe or
5 fatal outcomes, we applied logistic regression and backward selection of demographic
6 and geographic variables, time from onset to diagnosis, and virus type (p-value for
7 exclusion ≥ 0.10), separately for laboratory-confirmed cases and probable cases. All
8 analyses were carried out using SAS version 9.1 (SAS Institute, Cary, USA).

9 *Geographic patterns and seasonality*

10 To quantify HFMD seasonal patterns by province, we created heatmaps of the
11 proportion of HFMD cases identified in each week of the year.¹⁸ We also fitted
12 seasonal multiple linear regression models to weekly HFMD time series, including
13 time trends and harmonic terms representing annual and semi-annual periodic cycles
14 (Appendix Text 2).^{18,19} We extracted the amplitude and peak timing of the annual and
15 semi-annual cycles based on model coefficients.¹⁸ The amplitude measures the
16 difference between the maximum and minimum of a seasonal curve.¹⁹

17 We used multivariate stepwise linear regression to study the association between
18 HFMD seasonal characteristics and putative seasonal drivers, including geography,
19 human mobility patterns, demographic, economic, and climate variables.¹⁸

20 Epidemiologically relevant HFMD regions were identified by hierarchical clustering

1 using Ward's minimum variance method, and predictors of these regions were
2 identified through discriminant analysis.¹⁸ Time series were standardized for
3 differences in sampling intensity over time and geography by dividing weekly case
4 counts by the annual number of cases.

5

6 **Results**

7 **Incidence description**

8 7,200,092 probable HFMD cases were reported to the China CDC surveillance system
9 during 2008–2012, of which 3·7% were laboratory–confirmed and 0·03% died. The
10 incidence of reported HFMD cases showed a sharp increase since the initiation of
11 surveillance in 2008 (Table 1), due to improvements in reporting and surveillance.
12 Reported disease rates reached a steady state at over 1·2 cases per 1,000 person–years
13 during 2010–2012.

14 HFMD incidence varied greatly with age, with highest rates in children aged six
15 months to two years (Table 1). The median age of reported cases was 27 months
16 (interquartile range = 18–43 months). Most cases occurred in children below the age
17 of five, and incidence was very low in young infants aged <6 months, older children,
18 and adults. The incidence of HFMD was 1·6 times higher in boys under 5 years than
19 in girls of the same age ($p < 0\cdot001$).

20 EV-A71 predominated among laboratory-confirmed cases, accounting for 45%, 80%,

1 and 93% of mild, severe, and fatal cases respectively (Figure 1). There was little
2 variation in EV-A71 predominance by age (Figure 2A). EV-A71, CA-V16, and other
3 enteroviruses co-circulated throughout the observation period in all regions
4 (Appendix Figure 3).

5

6 **Clinical course**

7 The median time from illness onset to diagnosis, illness onset to death, and diagnosis
8 to death were 1.5 days (interquartile range: 0.5–2.5 days), 3.5 days (interquartile
9 range: 2.5–4.5 days), and 0.5 day (interquartile range: 0.5–1.5 days) respectively.

10 The probability density distributions of the onset-to-diagnosis, onset-to-death, and
11 diagnosis-to-death intervals were similar between probable and laboratory-confirmed
12 cases of EV-A71 or other enteroviruses (Figure 3). However, CA-V-16 density
13 distributions showed attenuated signal-to-noise ratio given the small number of deaths
14 (n=25).

15

16 **Severity of disease**

17 Overall the case-fatality, case-severity, and severe case-fatality risks were 0.03%
18 (range across years = 0.03–0.05%), 1.1% (range = 0.2–1.6%), and 3.0% (range =
19 2.6–10.4%) respectively. Illness severity and death were inversely related to age
20 (Table 2 and Figure 2B–2D). Consistently across all age groups, EV-A71 infections

1 were much more severe than CA-V16 infections (Figure 2B–2D). We performed
2 sensitivity analyses on severity estimates by age and viral etiology limited to
3 2010-2012 (Appendix Figure 4) and only 2012 (Appendix Figure 5), and found
4 results were similar. Multivariate backward logistic regression of laboratory
5 confirmed cases identified several mortality risk factors beyond young age and
6 infection with EV-A71, including rural residence and long onset-to-diagnosis interval.
7 Further, males and rural residents experienced higher risk of severe disease. Including
8 probable cases in the analysis yielded similar risk predictors (Table 2).

9

10 **Seasonal characteristics**

11 *National and province-specific patterns*

12 At the national scale, HFMD showed semi-annual peaks of activity, including a major
13 peak in spring and early summer followed by a smaller peak in autumn, consistent
14 between probable and confirmed time series (Figure 4).

15 While Southern China experienced two outbreaks of HFMD peaking in May and
16 October of each year, Northern China experienced a single annual peak in June
17 (Figure 5-6). The annual amplitude of HFMD epidemics increased with increasing
18 latitude and semi-annual periodicity was strongest in the South (Figure 5).

19 *Seasonal characteristics by serotype*

20 All enteroviruses exhibited latitudinal gradients in the amplitude of annual and

1 semi-annual epidemics (Appendix Figures 6–8). Annual peak timing of CA-V16
2 activity occurred earlier than for other enteroviruses ($p < 0.001$).

3 *Predictors of HFMD seasonality*

4 Putative predictors of HFMD seasonal characteristics were identified through
5 multivariate stepwise regression (Appendix Table 1). We found that the annual
6 amplitude of epidemics was associated with spring rainfall and spring sunshine in
7 overall and serotype–stratified analyses ($p < 0.05$, partial R^2 : 5%–23%; $p < 0.05$,
8 8%–23%, respectively). HFMD peak timing was associated with maximum spring air
9 pressure in overall and serotype–stratified analyses ($p < 0.05$, partial R^2 : 4%–12%).

10 Predictors of semi-annual periodicity of HFMD epidemics were more varied.

11 Population and transportation factors were moderately associated with HFMD
12 seasonal characteristics, explaining 1–19% of the variance in epidemic timing and
13 periodicity. Overall, multivariate models explained a moderate-to-high fraction of the
14 variance in HFMD seasonal characteristics through multiple factors (40–92%).

15 *Epidemiological regions*

16 We identified two main geographic regions that share similar HFMD epidemiological
17 characteristics: a northern region (latitude range 35.5° – 46.2° N, plus Tibet, $n=14$) and
18 a southern region (19.5° – 34.8° N, $n=17$) (Figure 7). Serotype–specific analysis
19 revealed a broadly similar split between Northern and Southern China, with a third
20 epidemiological region including Western provinces identified for EV-A71 and

1 CA-V16 (Appendix Figures 9–11). Discriminant analysis confirmed that climate
2 factors were the dominant predictors of HFMD epidemiological regions (Figure 7C,
3 Appendix Figures 9–11).

4

5 **Discussion**

6 Our study relies on a large sample of more than 7·2 million HFMD cases reported to
7 the national enhanced surveillance system during 2008–2012 in China and gives the
8 first comprehensive account of the national burden and epidemiology of the disease
9 (panel). The estimated HFMD incidence is 1·2 per 1,000 person–years in China and
10 the disease is responsible for 350–900 reported deaths annually, predominantly among
11 young children. As in other countries, we observed a predominance of EV-A71
12 serotype among severe cases, with a particularly young median age at infection of 2·3
13 years. Our large study covers 31 climatologically diverse provinces and suggests that
14 while HFMD cases tend to occur in warmer months of the year throughout the country,
15 peak timing and periodicity of epidemics varies with latitude. All serotypes causing
16 HFMD appear to follow broadly similar geographic gradients, which are moderately
17 associated with climate differences.

18 The observed age profile of infection is in agreement with reports from other
19 countries,^{4,20–22} and the particularly young mean age at infection suggests that
20 enteroviruses causing HFMD are highly transmissible. Relative sparing of infants

1 younger than six months was most likely due to protection by maternal antibodies.^{23,24}

2 Infection with the causative viruses appears to confer lifelong immunity at least to

3 disease and possibly infection given the virtual absence of adult cases.

4 Our large-scale analysis of HFMD seasonal patterns identified two main

5 epidemiological regions corresponding to Northern China, where HFMD peaks in

6 summer, and Southern China, which experiences two HFMD peaks in spring and

7 autumn. A highly transmissible, strongly immunizing disease requires constant

8 replenishment of susceptibles to sustain semi-annual, even annual, epidemics.

9 Experience from Asia–Pacific countries has shown biennial²⁵ or triennial^{20,21}

10 outbreaks against a background total fertility rate of 1·3–3 births per woman,²⁶

11 compared to China’s 1·6 births per woman under the longstanding one–child policy.²⁷

12 In contrast, annual epidemics were reported in Japan and Malaysia,^{6,25} consistent with

13 observed patterns in Northern China, while semi-annual epidemics were reported in

14 Hong Kong SAR, South Taiwan of China, and Vietnam,^{8,10,21}, in line with our

15 Southern China data. Further, our data indicate that EV-A71 epidemics occur annually

16 in China, in contrast to Japan and Malaysia where this serotype circulates every three

17 or four years.^{6,25} HFMD periodicity may be complicated by interference between the

18 causative enterovirus serotypes, perhaps associated with cross–serotype immunity.

19 Overall, the drivers of HFMD periodicity are not fully understood and worthy of

20 further study.

1 Although HFMD seasonal patterns were associated with precipitations, sunshine,
2 temperature, and air pressure, no single climatic variable explained the complexity of
3 HFMD seasonality across China. Our results confirm those of previous time series
4 analyses suggesting a relationship between HFMD and climatic factors in Singapore,
5 Hong-Kong, Southern China, and Japan.^{29–32} Moreover, the occurrence of
6 poliomyelitis, a disease caused by another enterovirus, may be associated with
7 humidity.³³ Humidity was a weak predictor of HFMD seasonal patterns in our large
8 Chinese study, which encompasses a greater diversity of climate zones and
9 populations than previously studied. The HFMD epidemiological patterns in Hainan
10 and Tibet were apparently different from those in the other provinces (Fig. 4). This
11 divergence could be due to the extreme, unique climate of these two outliers: Hainan
12 is the only tropical region of China; while the climate in Tibet is very particular and
13 complex because of the great altitude. We cannot rule out artefactual surveillance
14 biases, in part due to the lack of financial and human resources (in Tibet in particular).
15 Clearly, more work is needed to clarify the local drivers of HFMD seasonality in
16 South East Asia.
17 Systematic, population–representative seroepidemiology studies across the age
18 spectrum from mother–infant pairs through the first ten years of life would greatly
19 refine our understanding of HFMD dynamics in different regions. Previous
20 cross–sectional serosurveys have provided age-specific estimates of the cumulative

1 incidence of infection at certain ages.^{34–37} Prospective longitudinal serological studies
2 could provide more detailed information on age-specific incidence of infection and
3 disease, risk factors for infection, and the protection against new infections conferred
4 by previous infections with the same or different viruses. Longitudinal serosurveys
5 were instrumental to elucidate the acquisition of infection and immunity in other
6 complex disease systems involving competition between viruses, which in turn
7 informed vaccination strategies.³⁸

8 EV-A71 infection in early infancy conferred the gravest risks for clinical severity and
9 fatality.^{21,39} Several candidate vaccines against EV-A71 are currently undergoing
10 regulatory vetting in China.⁴⁰ Whether and how these should be deployed require
11 further assessment of cost-effectiveness, feasibility and contextual considerations in
12 different regions. Transmission models are needed to fully assess the direct and
13 indirect benefits of vaccination, and the risk of serotype replacement given use of a
14 monovalent vaccine.

15 Our severity data highlight two independent risk factors: 1) each extra day since
16 symptom onset was associated with a 1% higher risk of mortality, and 2) those living
17 in a rural area had a one-quarter excess risk of death from infection. In addition to
18 rural-urban disparity in health care access and advanced life-sustaining technology,⁴¹
19 widespread and inappropriate use of glucocorticoids and pyrazolones in mild HFMD
20 stages^{42,43} could have precipitated critical illness and death.

1 Several limitations bear mention. First, as for any common, self-limiting illness,
2 surveillance only captures the tip of the clinical iceberg while most cases go
3 undetected because their condition is asymptomatic, or the patient does not seek
4 formal care, or he/she is not diagnosed and reported. Second, access to and provision
5 of health care as well as technical capacity varied between and sometimes within
6 provinces and there was no formal quality assurance or systematic audit for HFMD
7 surveillance. In particular, we cannot rule out that surveillance bias explained the
8 marked differences in HFMD patterns observed in Hainan and Tibet, relative to other
9 provinces (Fig. 4). Third, data collected during the first year of rollout are likely less
10 reliable than in more recent years. Fourth, we did not have data on mixed enterovirus
11 infections⁴⁴ and were unable to serotype enteroviruses beyond CV-A16 and EV-A71.
12 In particular, we were unable to monitor serotype CV-A6, which has become more
13 predominant in Southern China.⁴⁵ Fifth, some of severe neurological illnesses caused
14 by EV-A71 may have been missed by using a strict HFMD case definition. Sixth, our
15 study was based on a descriptive analysis of surveillance data. We unfortunately
16 cannot yet determine/estimate a threshold for yearly epidemic –this is beyond the
17 scope of our study.

18

19 In conclusion, we found substantial HFMD illness and mortality associated with
20 co-circulating EV-A71, CA-V16, and other enterovirus in China, disproportionately

1 affecting young children aged <5 years. Younger age, infection with EV-A71, and
2 living in rural area are risk factors for severe disease. Our study also uncovered
3 intriguing differences in HFMD seasonality across China, which may be associated
4 with climate. Overall, our study provides robust, population-based, national data to
5 prioritize EV-A71 vaccination and optimize the timing of routine vaccination
6 regionally. Further, our results will serve as a pre-vaccination baseline against which
7 future interventions can be compared. More broadly, further studies are warranted to
8 elucidate the dynamics and immunity patterns of HFMD, a rising public health
9 problem in Asia.

Systematic review

We searched PubMed with the keywords “Hand, Foot and Mouth Disease”, “EV71”, “enterovirus 71” and “coxsackie virus A” for all journal articles written in English between Jan 1, 1995, and June 30, 2013. In the past 15 years, EV-A71–associated HFMD epidemics have been increasingly reported across the Asia–Pacific region, chronologically including Malaysia,⁴ Taiwan,⁵ Japan,⁶ Singapore,⁷ Vietnam,⁸ mainland China,⁹ Hong Kong SAR,¹⁰ and Cambodia.¹¹ These reports were mostly descriptive, with very few exceptions that estimated epidemiologic parameters, assessed severity or analyzed seasonality. Even fewer had sufficient power to yield definitive conclusions. No previous report had addressed all three sets of interrelated questions. Here we report the largest study to date across a wide geographic expanse through the recently enhanced national surveillance network for HFMD in China.

Interpretation

We described the enhanced HFMD surveillance system, characterized host characteristics, periodicity of epidemics, and geographic patterns from 2008 to 2012. HFMD incidence was 1·2 per 1,000 person–years with 350–900 reported deaths annually during 2009–2012, predominantly among young children. There was strong age dependency, with children aged six months to two years showing the highest rates (Table 1). Boys under five years were 1·6 times more likely than girls of the same age

bracket to register disease. Overall the case–fatality, case–severity, and severe case–fatality risks were 0·03%, 1·1%, and 3·0% respectively. Illness severity and death by enterovirus serotype were inversely related to age (Table 2 and Figure 2, panels B–D). The median time from illness onset to diagnosis, from illness onset to death, and from diagnosis to death were 1·5 days (interquartile range: 0·5–2·5 days), 3·5 days (interquartile range: 2·5–4·5 days), and 0·5 day (interquartile range: 0·5–1·5 days) respectively. HFMD tended to occur during the warmer months of the year throughout the country, although peak timing and the periodicity of epidemics varied substantially with latitude, in particular demonstrating stronger semi-annual cycles in southern China compared to annual outbreaks in the north. Seasonal variation was associated with precipitation, sunshine, temperature, and barometric pressure. However, no single climatic variable was sufficient to explain the complexity of HFMD seasonality across China.

Figure Legends

Figure 1. Proportions of enterovirus serotypes among laboratory-confirmed HFMD cases by clinical severity, 2008-2012, China. A: based on mild cases. B: based on severe cases who survived, C: based on fatal cases.

Figure 2. Age distribution and clinical severity of probable and laboratory-confirmed (EV-A71, CA-V16 or other enteroviruses) HFMD cases, 2008-2012, China. A: Age distribution of probable and lab-confirmed cases. B: Risk of fatality among cases by age group and viral etiology. C: Risk of severe illness among cases by age group and viral etiology. D: Risk of fatality among severe cases by age group and viral etiology. EV-A71, enterovirus 71; CA-V16, Coxsackievirus A16; mth, months; y, years. Severity estimates in B-D were calculated by extrapolating the serotype distribution among test-positive cases to untested and test-negative cases. That is, the number of mild cases with serotype X (= EV-A71, CA-V16 or other enteroviruses) was estimated to be (no. of mild cases test-positive for serotype X)/(no. of test-positive mild cases) x (no. of mild cases); severe cases were similarly analyzed. Results were similar if only the 2010-2012 or 2012 data were used (Appendix Figures 4&5).

Figure 3. Estimates of onset-to-diagnosis, onset-to-death, and diagnosis-to-death

distributions of probable and laboratory-confirmed (EV-A71, CA-V16 or other enteroviruses) HFMD cases, 2008-2012, China. A: Onset-to-diagnosis distribution by viral etiology (n=7,200,092). B: Onset-to-death distribution by viral etiology (n=2457). C: Diagnosis-to-death distribution by viral etiology (n=2457). Note that some intervals are negative because diagnosis occurred after death.

Figure 4. Heatmap of HFMD surveillance data from 2008 to 2012 by Chinese province. The provinces were ordered by latitude from Northernmost (top) to Southernmost (bottom). A: Time series of weekly probable and lab-confirmed HFMD cases, standardized by the number of annual cases. B: Seasonal distribution of HFMD cases, plotted as the median value of proportion of cases in each week of the year from 2008 to 2012. C: Number of HFMD cases by week of illness onset. The insert is a superposition of the number of cases without probable HFMD cases by week of illness onset.

Figure 5. Latitudinal gradients in periodicity and peak timing of HFMD. A: Amplitude of the annual periodicity. B: Annual peak timing. C: Contribution of the semi-annual periodicity, measured by the ratio of the amplitude of the semi-annual periodicity to the sum of the amplitudes of annual and semi-annual periodicities (higher ratio indicates a stronger semi-annual periodicity). Symbol size is proportional to the number of cases in each province. Black solid line represent linear regression fit

(regression weighted by mean annual number of HFMD cases). P-values are given on the graphs. Colors represent different climatic zones (black: cold-temperate, blue mid-temperate, green warm-temperate, orange subtropical, red tropical).

Figure 6. Amplitude and timing of primary HFMD epidemics in China. A: Amplitude of the annual cycle from yellow (low) to red (high), as indicated in the legend. B: Importance of the semi-annual periodicity, measured by the ratio of the amplitude of the semi-annual cycle to the sum of the amplitudes of annual and semi-annual cycles. Pale green indicates strongly annual influenza epidemics, while dark green indicates dominant semi-annual activity. C: Timing of primary annual HFMD peak, in weeks from Jan 1st. Timing is color coded from pale blue to dark blue.

Figure 7. HFMD epidemiological regions and predictors. A: Identified epidemiological regions based on hierarchical clustering, using the Euclidian distance between weekly standardized HFMD time series. Provinces are color-coded by climatic region (black: cold-temperate, blue: mid-temperate, green: warm temperate, orange: subtropical, red: tropical). B: Map of the three epidemiological regions identified in panel A. C: Climate predictors of the two main clusters identified in panel A, based on stepwise discriminant analysis.

Appendix Text 1. Additional information regarding climate variables

Meteorological data collected included daily temperature (min, max, mean), rainfall, relative humidity (min, mean), air pressure (min, max, mean), average vapor pressure, and hours of sunshine recorded at 756 Chinese ground weather stations from 2008–2012.¹

In order to aggregate daily- station-specific meteorological data at the weekly and province level, we first averaged station-specific daily values at the weekly level (except for rainfall where the weekly sum was taken) and took the average across all stations located within a province. Preliminary analysis of HFMD surveillance data revealed that two HFMD peaks were typically observed in recent years in China in spring and autumn. Therefore, province-specific climatic variables were further summarized for relevant seasons, by averaging the weekly values corresponding to the spring (April–June) and autumn (September–November).

Appendix Text 2. Additional information regarding the estimation of seasonal parameters

1. Regression model

We used the following linear regression model to estimate the peak timing and amplitude of the annual and semi-annual periodicities of influenza activity in each province, as described in^{1,2}:

$$hfmdi(t) = a + b_i \cos(2\pi t/52.17) + c_i \sin(2\pi t/52.17) + d_i \cos(4\pi t/52.17) + e_i \sin(4\pi t/52.17) + \varepsilon(t)$$

where $hfmdi(t)$ are the weekly standardized counts of HFMD cases (or EV-A71, or CV-A16, or other enterovirus) isolates in province i , where standardization is obtained by dividing weekly values by the annual number of HFMD cases, t is a running index for week, and a, b, c, d and e are the intercept and seasonal terms to be estimated from the data.

Specifically,

the amplitude of the annual periodicity is estimated as $AnnAmp_i = \sqrt{b_i^2 + c_i^2}$,

the annual peak timing is estimated as $AnnPeakTiming_i = -\text{atan}(c_i / b_i)$,

the amplitude of the semi-annual periodicity is estimated as

$$SemiAnnAmp_i = \sqrt{c_i^2 + d_i^2}$$

To evaluate the relative importance of annual and semi-annual HFMD periodicities by province, we calculated the ratio between the amplitude of the semi-annual periodicity and the sum of the amplitudes of annual and semi-annual periodicities. A ratio close to 1 is indicative of dominant semi-annual periodicity while a ratio close to 0 indicates

dominant annual periodicity.

The ratio is estimated as $\text{Ratio}_i = \text{SemiAnnAmpi} / (\text{SemiAnnAmpi} + \text{AnnAmpi})$

To control for different levels of HFMD activity across provinces, we compare the relative amplitudes of annual and semi-annual periodicity, obtained by dividing AnnAmpi and SemiAnnAmpi by the mean of the hfmdi(t) time series.

2. Sensitivity analyses

We considered alternative seasonal regression models using a Poisson distribution and a log link (given that we were using modified disease counts), with or without an offset for the number of specimens tested. Given that all three approaches gave sensibly similar results, we elected to use the linear model in the main analysis for the sake of simplicity.

Appendix Figure 6. Latitudinal and longitudinal gradients in seasonality of EV71, CV-A16 and other enterovirus

Figure shows that all enteroviruses exhibited latitudinal gradients in the amplitude of annual and semiannual epidemics. Annual peak timing of CA-V16 activity occurred earlier than for other enteroviruses ($p=0.0148$). Southern provinces experienced earlier spring and fall epidemics of EV71 and other enterovirus than Northern provinces (difference between the annual peak timing of epidemics in Northern and that in Southern in EV71: $p=0.031$, in other enterovirus: $p=0.21$; difference between the semiannual peak timing of epidemics in Northern and that in Southern in EV71: $p=0.0008$, in other enterovirus: $p=0.0008$). The timing of fall EV71 epidemics was also associated with longitude, with later occurrence in coastal provinces.

EV71=enterovirus 71. CV-A16=Coxsackievirus A16.

Appendix Figure 7. Periodicity of EV71, CV-A16 and other enterovirus epidemics in China

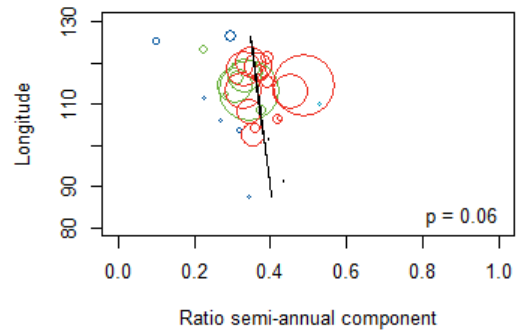

Importance of the semiannual periodicity, measured by the ratio of the amplitude of the semiannual cycle to the sum of the amplitudes of annual and semiannual cycles. EV71=enterovirus 71. CV-A16=Coxsackievirus A16.

EV71 epidemics

Ratio semi-annual component vs latitude

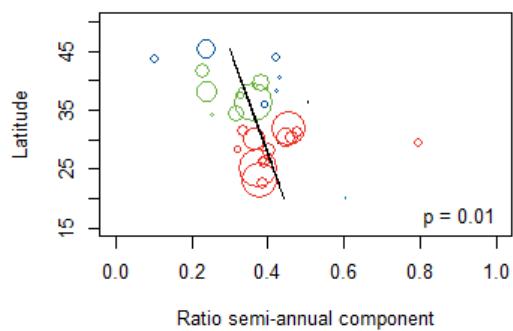

Ratio semi-annual component vs longitude

CV-A16 epidemics

Ratio semi-annual component vs latitude

Ratio semi-annual component vs longitude

Other enterovirus epidemics

Ratio semi-annual component vs latitude

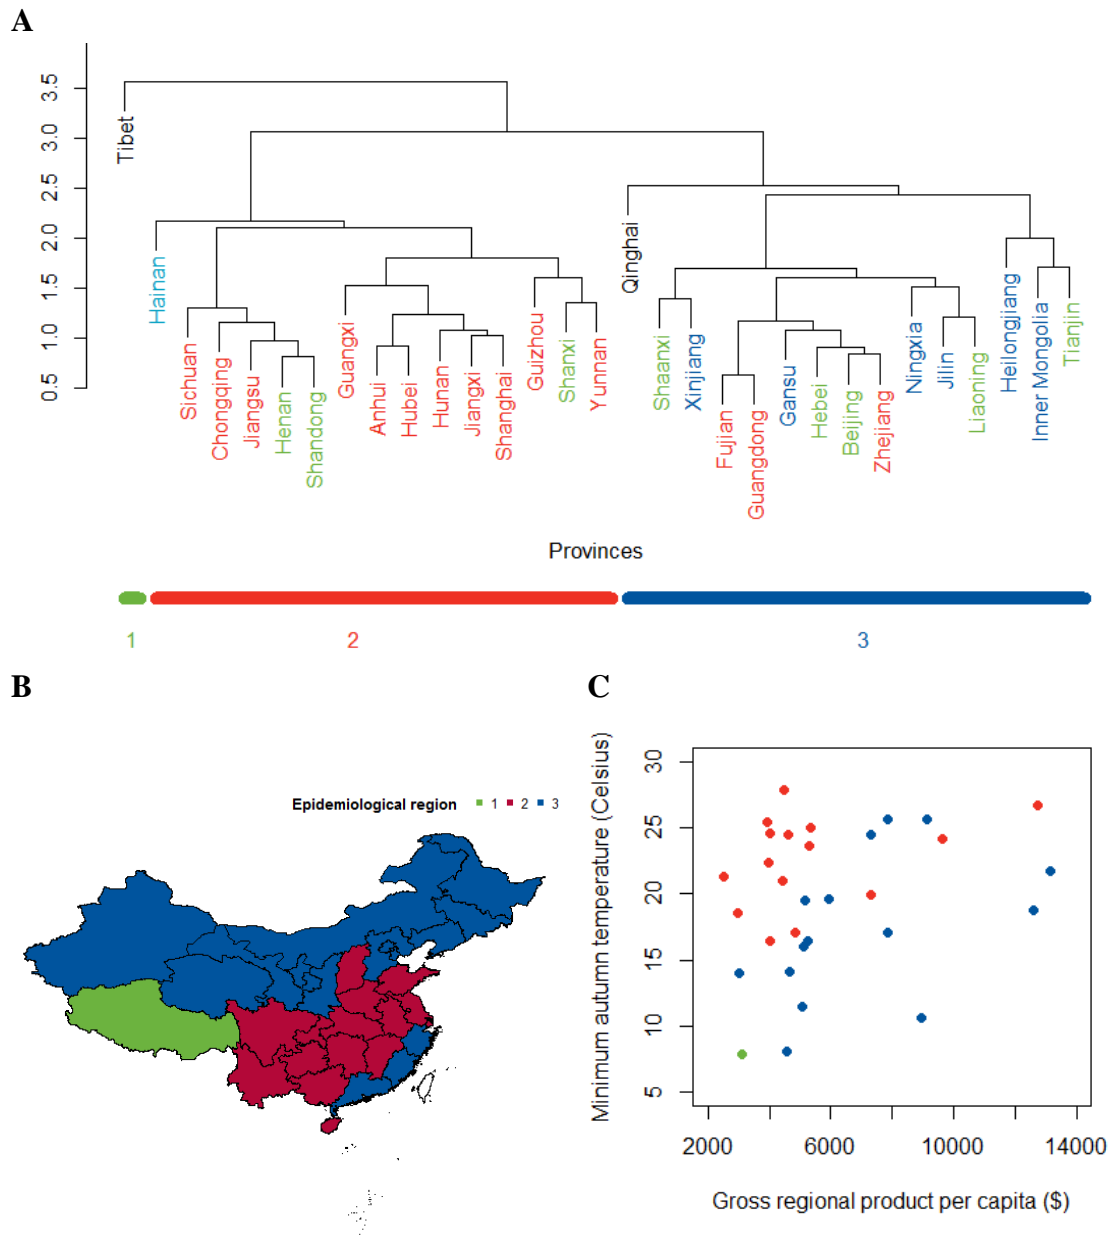

Ratio semi-annual component vs longitude

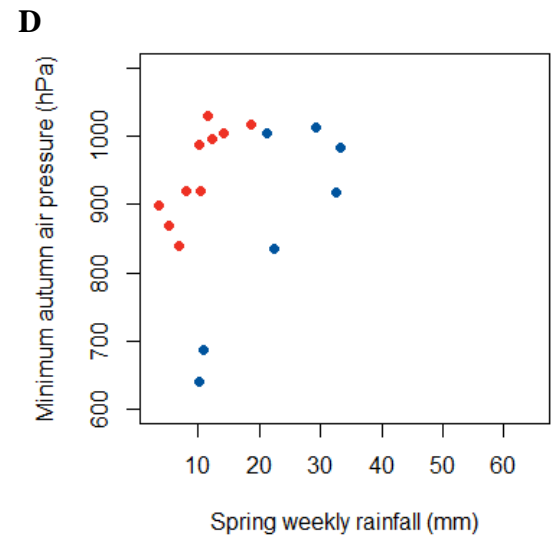

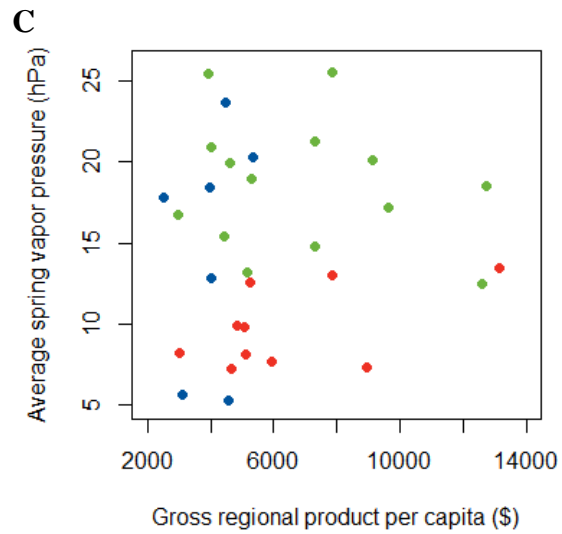

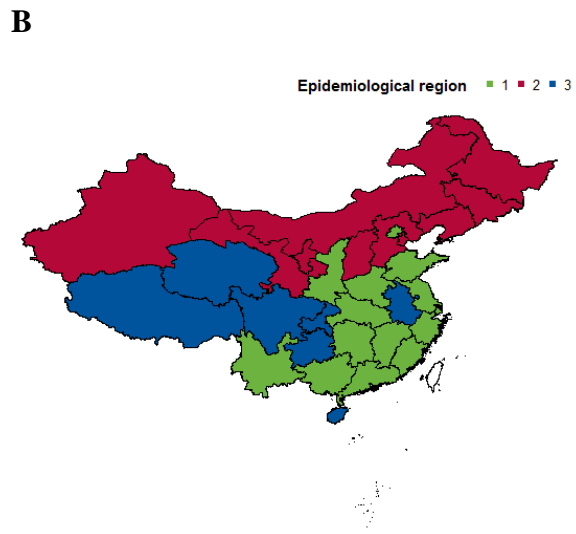

Appendix Figure 8. Importance of semiannual seasonality of EV71, CV-A16 and other enterovirus

Importance of the semiannual periodicity, measured by the ratio of the amplitude of the semiannual cycle to the sum of the amplitudes of annual and semiannual cycles. EV71=enterovirus 71. CV-A16=Coxsackievirus A16.

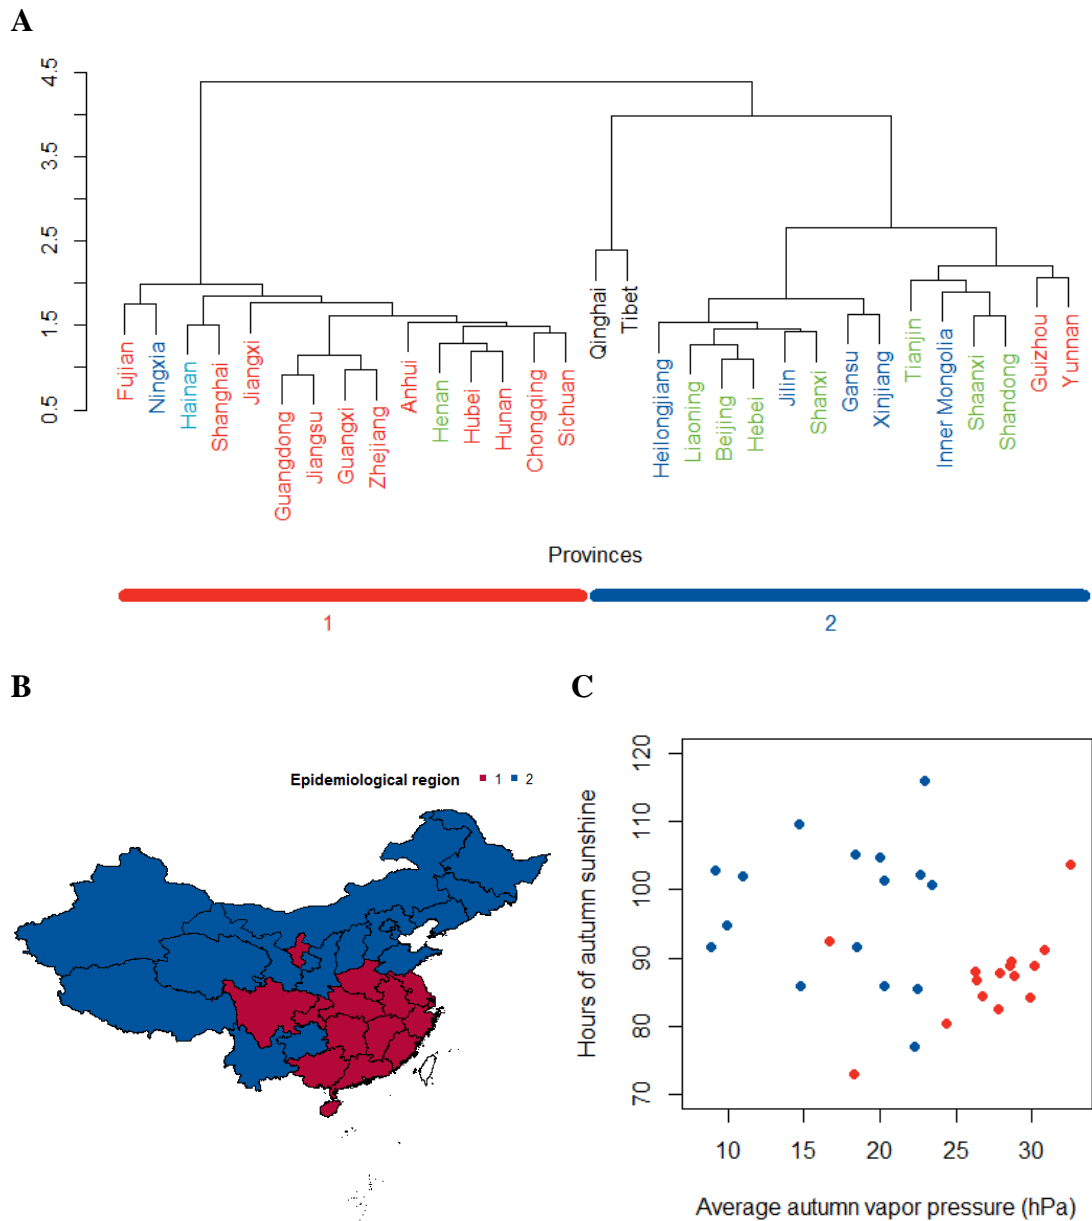

Appendix Figure 9. EV71 epidemiological regions and predictors

(A) Identified epidemiological regions based on hierarchical clustering, using the Euclidian distance between weekly standardized EV71 time series. Provinces are color-coded by climatic region (see legends of appendix figure 1). (B) Map of the three epidemiological regions identified in panel A. (C) Predictors of the two main clusters identified in panel A, based on stepwise discriminant analysis.

Appendix Figure 10. CV-A16 epidemiological regions and predictors

(A) Identified epidemiological regions based on hierarchical clustering, using the Euclidian distance between weekly standardized CV-A16 time series. Provinces are color-coded by climatic region (see legends of appendix figure 1). (B) Map of the three epidemiological regions identified in panel A. (C) Climate predictors of the two main clusters identified in panel A, based on stepwise discriminant analysis. (D) Climate predictors of the two sub-clusters identified in panel A, based on stepwise discriminant analysis.

Appendix Figure 11. Other enteroviruses epidemiological regions and predictors

(A) Identified epidemiological regions based on hierarchical clustering, using the Euclidian distance between weekly standardized other enterovirus time series. Provinces are color-coded by climatic region (black: cold-temperate, blue: mid-temperate, green: warm temperate, orange: subtropical, red: tropical). (B) Map of the three epidemiological regions identified in panel A. (C) Climate predictors of the two main clusters identified in panel A, based on stepwise discriminant analysis.
