## 1 **Abstract**

2 This paper assesses changes in the macrophyte community of Loch Leven over a  
3 period of 100 years. Evidence is presented that shows that these changes are associ-  
4 ated with both eutrophication, and subsequent recovery from eutrophication following  
5 reductions in anthropogenic nutrient inputs to the loch. This study uses macrophyte  
6 survey data from 1907, 1966, 1972, 1975, 1986, 1993, 1999 and 2008. In each of  
7 these surveys, except for that conducted in 1907, the loch was divided into 19 sectors,  
8 each with at least one transect, ranging from the shallowest to the deepest occurrence  
9 of macrophytes. From these data, a range of indicators of recovery were considered at  
10 a whole lake scale: the relative abundance of taxa, taxa richness and evenness and  
11 maximum growing depth. All of these metrics showed an improvement since 1972.  
12 Species richness, measured at the scale of survey sector and individual samples also  
13 appears to have increased in recent years. All of these measures, coupled with  
14 ordination of presence/absence composition data from all survey years, indicate that  
15 the macrophyte community in the loch is recovering towards the state recorded in  
16 1907.

## 17 **Introduction**

18 Loch Leven has been a focus for ecological and water quality research since the late  
19 1960s. During this period there have been problems with eutrophication caused by  
20 industrial, agricultural, and sewage effluent, with nutrient inputs reaching a peak in  
21 the 1980s (May et al., submitted). A decline in the abundance, diversity and maximum  
22 growing depth of macrophytes reflected the resultant deterioration in water quality  
23 (Jupp et al., 1974). Since then, external inputs of phosphorus to the loch have been  
24 reduced (May et al., submitted) and, over the past decade, there appears to have been

1 a significant reduction in phosphorus concentration in the loch water (Carvalho et al.,  
2 submitted; Ferguson et al., 2008).

3 Macrophytes are generally considered good indicators of water quality, particularly in  
4 relation to eutrophication pressures (Penning et al., 2008a; Penning et al., 2008b;  
5 Schaumburg et al., 2004; Søndergaard et al., 2005). They play a key physical  
6 structuring role in shallow lakes providing important habitat for invertebrates, fish and  
7 birds (Jeppesen et al., 1998; Warfe & Barmuta, 2006). The US EPA Lake and  
8 Reservoir Bioassessment and Biocriteria protocols comment: “Macrophytes respond  
9 more slowly to environmental changes than do phytoplankton or zooplankton and  
10 might be better integrators of overall environmental conditions. This would allow a  
11 single sampling event per year, during the time of maximum abundance of  
12 macrophytes.” (US Environmental Protection Agency, 1998). It is, therefore, timely to  
13 examine the changes in the macrophyte community of Loch Leven, over both the  
14 eutrophication and recovery period, and to put these changes into context of the  
15 historical past (West, 1910).

16 Although earlier records exist for individual species, aquatic macrophytes were first  
17 surveyed systematically at Loch Leven by West in 1907 (West, 1910), as part of the  
18 bathymetric survey of Scottish Lochs (Murray & Pullar, 1910). Data from the 1907  
19 survey form a historical baseline against which more recent data can be compared,  
20 including surveys of Jupp et al. (1974), Britton (1975), Robson (1986), Murphy and  
21 Milligan (1993), and Griffin and Milligan (1999). This paper compares these data  
22 with macrophyte data collected in 2008 to examine whether changes in macrophyte  
23 communities provide evidence for a continuing recovery of Loch Leven from  
24 eutrophication. This paper examines the following specific questions; (1) do long-

1 term changes in the species composition of aquatic plants reflect the well documented  
2 eutrophication and subsequent recovery from eutrophication in Loch Leven, and (2)  
3 has the aquatic plant community returned to a state comparable with that observed in  
4 1907?

## 5 **Methods**

### 6 *Site description*

7 Loch Leven is a shallow lake (mean depth of 3.9 m and maximum depth about 25 m),  
8 with a surface area of 13.3 km<sup>2</sup>. It is located near the town of Kinross, in the central  
9 lowlands of Scotland, UK. The structure and physical environment of the loch are  
10 described in detail by Smith (1974). Further details about the catchment, nutrient  
11 inputs, and historical alterations can be found in [May & Spears \(submitted\)](#) and [May](#)  
12 [et al. \(submitted\)](#).

### 13 *Data selection*

14 To assess long-term, community-wide changes in the macrophyte community,  
15 datasets of taxonomic occurrence were selected on the basis of comparability and  
16 completeness. As a result, many historical records that did not form part of a  
17 comprehensive survey of the lake, including some of those described by Jupp et al.  
18 (1974), were excluded. Sources of the data used in this study are shown in Table 1.  
19 Apart from Jupp et al. (1974), most of these are unpublished reports. Palaeobotanical  
20 data were also available for Loch Leven (Salgado et al., 2010).

21 The survey conducted in 1907 (West, 1910) is the earliest comprehensive dataset for  
22 macrophytes at Loch Leven. Although the survey gives information on which plants  
23 were found, in contrast to the other studies, no measures of abundance were recorded

1 and the sampling method is unknown. For this reason, these data were only suitable  
2 for use in assessing change in terms of presence/absence of species.

### 3 *Sampling methods*

4 Taxonomic occurrence data were used only from surveys for which the sampling  
5 methods were generally consistent. The main differences between surveys were the  
6 total number of samples taken (see Table 1), the length of drag when sampling, and  
7 the size and shape of sampling rake used.

8 All of the surveys (apart from 1907) were conducted along pre-determined transects  
9 using a boat. Since 1986, the lake has been divided into 'sectors' that have been  
10 sampled consistently in terms of transect and sampling locations. For all data  
11 collected since 1986, it has been possible to assign a sector to each sample, which has  
12 allowed analysis of diversity across a range of spatial scales.

13 Samples of the aquatic vegetation (post 1907) were obtained at intervals along these  
14 transects using a double headed rake. The rake was constructed from two garden rake  
15 heads joined back-to back with wire mesh attached to the faces of the rake heads.  
16 Although the basic design of the sampling rake remained constant in most of the  
17 surveys, some aspects of the design changed from survey to survey. For example,  
18 Jupp et al. (1974) explained that, in the 1972 survey, drag-rakes varied between  
19 transects in their weight (1240 to 1923 g), width (19 to 28.7 cm), prong length (14 to  
20 19 cm), number of prongs per side (8 to 12), prong shape (straight to strongly curved),  
21 and screen mesh size (1 to 2.5 cm). These details are not always given in subsequent  
22 surveys.

1 In the earlier modern surveys (1966, 1972 and 1974), the boat was kept in constant  
2 motion and the sampling rake was allowed to drag along the bottom for between 50  
3 and 100 m (Jupp et al., 1974). In 1986 sampling distances of between 5 and 129 m  
4 were used (Robson, 1990). In all the surveys since then, drag distances of only 2 m  
5 have been used (Griffin & Milligan, 1999; Murphy & Milligan, 1993; this study).

6 A bathyscope was also used to observe underwater plants in some of the surveys. The  
7 taxa seen through the bathyscope were given equal consideration to those sampled  
8 with the rake. In many of the surveys, a measure of abundance, either a weighting or  
9 some semi-quantitative measure, was given to either individual taxa or the sample as a  
10 whole. These measures of abundance have not been used as part of the analyses  
11 presented here because it was judged that these measured were not compatible  
12 between surveys. At the sample level (either bathyscope or rake), only presence/  
13 absence data have been used for this study.

#### 14 *Taxa aggregation and exclusion*

15 Occurrence records for some taxa were aggregated. This was either because they had  
16 been previously aggregated in some of the surveys used, or because it was judged  
17 that, in some surveys, these taxa may have been confused due to their similarity.  
18 These aggregates included *Potamogeton filiformis* / *P. pectinatus*, all *Chara* species,  
19 all *Tolypella* and *Nitella* species, *Potamogeton berchtoldii* / *P. pusillus*, all *Ranun-*  
20 *culus* taxa, and *Myriophyllum alterniflorum* / *M. spicatum*.

21 Some taxa were excluded from the analyses because they did not seem to have been  
22 recorded in a consistent manner. This group includes all lemnids (free-floating plants),  
23 bryophytes, algae other than charophytes, the floating-leaved *Nymphaea alba*, and

1 emergent vegetation. This left submerged vascular plants, with some aggregations,  
2 and charophytes. A total of 18 taxa were included in the analyses (Table 2).

### 3 *Indicators of recovery*

4 A number of measures were used to examine temporal and spatial changes within the  
5 macrophyte community. The simplest of these was loch-wide richness, which was  
6 calculated as the total number of taxa (as defined above) found in any single survey.

7 Evenness was calculated using Simpson's index ( $E_{1/D}$ ), calculated according to  
8 Magurran (2004, pp. 115-116). This measure can take values of between 0 and 1,  
9 where an evenness of 1 implies equal numbers of individuals of all taxa in the  
10 population, and an evenness of 0 implies only one taxon. Evenness was calculated for  
11 all survey years except 1907, for which no quantitative data were available.

12 Species counts at smaller spatial scales were examined by comparing the means,  
13 medians, and 10<sup>th</sup>, 25<sup>th</sup>, 75<sup>th</sup> and 90<sup>th</sup> percentiles of the number of taxa found in a  
14 single sample for years when the sampling method was considered to be equivalent,  
15 i.e. when there had been equal sampling effort per sample. These were the years 1993,  
16 1999 and 2008. Similarly, the same statistics were compared for the number of taxa  
17 found in a survey sector for years when it was considered that the likelihood of  
18 finding all taxa in a sector was equivalent, i.e. there had been equal sampling effort  
19 per sector. These were the years 1986, 1993, 1999 and 2008.

20 A Euclidean multi-dimensional scaling (MDS) analysis was conducted using the R  
21 software package (R Development Core Team, 2008). This indirect gradient analysis  
22 produces a two-dimensional ordination of compositional change over the survey  
23 period. Presence/absence data from all surveys were used for this analysis.

## 1 *Maximum growing depth*

2 The maximum depth to which macrophytes grow in Loch Leven is discussed in an  
3 historical context by May & Carvalho (submitted). Data from this paper were  
4 combined with the observation of deepest submerged plants from the 2008 survey, to  
5 examine the patterns of change in maximum growing depth over time.

## 6 **Results**

### 7 *Long-term variation in macrophyte community composition*

8 There has been considerable variation in both the taxa present and their relative  
9 abundances, as shown by the surveys presented in this paper. Of the 18 taxa studied,  
10 three *Potamogeton* species were found in 1907 and have not been recorded since (*P.*  
11 *gramineus*, *P. lucens*, and the hybrid of *P. gramineus* x *lucens*, also known as *P. x*  
12 *zizii*). Another *Potamogeton* species, *P. obtusifolius*, was recorded in 1907 and 1972,  
13 but has not been found since. *Potamogeton praelongus* and *Ranunculus* spp. were  
14 observed in 2008, but had not been seen since 1907. Similarly *Potamogeton*  
15 *berchtoldii/pusillus* was recorded in 1907, then seen rarely in 1975 and 1993, before  
16 returning in some abundance in 1999 and 2008. Only two of the 18 taxa were not  
17 found in 1907. These were *Potamogeton crispus*, which was observed consistently  
18 from 1966 to 1993, but not since, and *Zannichellia palustris*, which has been found in  
19 every survey since 1966, but appears to be declining in the last two surveys.

### 20 *Long-term variation in indices of diversity*

21 At the whole lake scale, the values of all of the indicators of diversity examined were  
22 greater in 2008 than in any of the previous years, apart from 1907. Taxon richness  
23 was highest in 1907 (16 taxa), and lowest in 1966 (7 taxa) (Figure 1a). Taxa richness

1 was 11 in 1972 and 1975, then 8, 10 and 9 in 1986, 1993 and 1999 respectively, and  
2 13 in 2008. Evenness was lowest in 1966 (0.15) and highest in 2008 (0.53), and was  
3 generally constant between 1972 (0.37) and 1999 (0.34) (Figure 1b).

4 At the more local scale, there appeared to be some increases in taxon richness. The  
5 taxa count per sample increased from a mean of ~1.5 in 1993 to ~2.2 in 2008  
6 (Figure 2). Similarly, mean taxa count per survey sector increased from ~3.5 in 1993  
7 to ~6 in 2008 (Figure 3).

8 In the multi-dimensional scaling analysis (Figure 4), 69% of variability in species  
9 composition was explained by the first two ordination axes with the first ( $E = 9.7$ ,  
10 variability = 46%) explaining twice as much as the second ( $E = 4.8$ , variabi-  
11 lity = 23%). The first axis appears to be consistent with the diversity indicators  
12 generally representing a recovery from degradation, as suggested by the fact that the  
13 earliest modern samples are furthest away from the 1907 point, and the 2008 survey  
14 was closest to it.

#### 15 *Maximum growing depth*

16 Maximum depth of colonisation, as reported by May & Carvalho (submitted),  
17 declined from 1907 (4.6 m) to the early 1970s (1.5 m), then exhibited some  
18 improvement in the late 1970s and 1980s (2.4 m in 1979), and a dramatic  
19 improvement between 1990 (1.8 m) and the present day (4.3 m in 2008). These data  
20 are shown in Figure 5.

1

## 2 **Discussion**

3 The aquatic plant community at Loch Leven has clearly undergone large changes  
4 since 1907. By all measures presented in this study, there has been a decline between  
5 the early 1900s, and the 1970s and 1980s, followed by a recovery which appeared to  
6 be continuing in 2008. This is consistent with similar patterns observed in water  
7 quality and other biota, as reported by [Carvalho et al., submitted](#); [Gunn et al.,](#)  
8 [submitted](#); [May et al., submitted](#); [Spears et al., submitted](#)). Changes in species  
9 richness over time show this pattern most simply; of the 18 taxa considered in this  
10 study, the highest number (16) were found in 1907, while eight or less were found in  
11 the 1966, 1986 and 1993 surveys. In the most recent survey, in 2008, the situation  
12 improved, with 13 taxa being recorded.

13 The increases in taxonomic evenness, richness per sample and richness per sector  
14 recorded over the last three comparable surveys seem to indicate that smaller-scale  
15 diversity (i.e. at the sector and sample scales) has increased, at least since the early  
16 1990s. This supports the interpretation of increasing richness at a whole lake scale and  
17 is consistent with improving water quality conditions. In particular, improvements in  
18 the late spring/early summer light climate ([Carvalho et al., submitted](#)) are likely to  
19 open up a much wider range of ecological niches within a transect or sector, in terms  
20 of both light requirements and substrate available for growth ([Sand-Jensen et al.,](#)  
21 [2008](#); [Vestergaard & Sand-Jensen, 2000](#)). Increasing light availability may also  
22 protect plants from the limitations imposed by both wave action and grazing by  
23 waterfowl ([Jupp & Spence, 1977](#)).

1 These improvements in community measures are supported by recent increases in the  
2 maximum depth colonised by macrophytes. This measure was used as a target  
3 indicator by the Loch Leven Catchment Management Plan (LLCMP, 1999), with the  
4 target set at 4.5 m, close to the value found in 1907. This target appears to be nearly  
5 realised. Growing depths of 1.5 m in the early 1970s would have restricted substrate  
6 availability to predominantly more wave-disturbed and sandier sediments (Jupp &  
7 Spence, 1977; Spears & Jones, in preparation), whereas growing depths down to  
8 4.5 m allow additional species that are more usually associated with more stable, finer  
9 sediments. Additionally, the reductions in nutrient concentrations recorded (Carvalho  
10 et al., submitted), specifically the reduced SRP concentrations for most months of the  
11 year and enhanced nitrogen limitation in summer, may reduce epiphyte burdens on  
12 macrophyte leaves and allow slower growing, deep water macrophytes, such as *P.*  
13 *praelongus*, to compete alongside species such as *P. berchtoldii* / *P. pusillus* and  
14 *Chara globularis*, which can quickly develop large dense stands.

15 In the absence of comparable quantitative data, changes in survey methodologies can  
16 be used to infer a general increase in total aquatic plant biomass since 1966.  
17 Specifically, longer rake drags would have been used when submerged macrophytes  
18 were less abundant. In the earlier modern surveys (1966, 1972 and 1974), the boat  
19 was kept in constant motion and the sampling rake was allowed to drag along the  
20 bottom for between 50 and 100 m (Jupp et al., 1974). This strategy would have been  
21 impossible in dense vegetation. In 1986 sampling distances of between 5 m and 129 m  
22 were used (Robson, 1990). In all of the surveys since then, drag distances of only 2 m  
23 have been used (Griffin & Milligan, 1999; Murphy & Milligan, 1993; this study). In  
24 the most recent survey (2008), rake drags of longer than 5m would have been a very

1 ineffective means of retrieving a representative sample, as the rake was often full after  
2 a 2 m drag, and additional plant material would simply fall off.

3 It should also be noted that taxa richness and other measures of diversity used in this  
4 study are sensitive to sampling effort (Garrard et al., 2008; Wintle et al., 2004). This  
5 is of particular concern for rare taxa. It is unfortunate that sampling effort cannot be  
6 defined precisely here, due to the lack of information about methodologies for most of  
7 the survey data. However, it is clear that if there is a bias, then it is generally in favour  
8 of the earlier modern surveys, because in these surveys both the number of samples  
9 (Table 1), and the effort per sample (length of rake drag) were generally greater. This  
10 bias can only strengthen the conclusions made above regarding improvements in  
11 measures of aquatic plant diversity.

12 The results presented here clearly show that Loch Leven macrophyte community is  
13 becoming more diverse (both in terms of species richness and evenness) and also  
14 becoming more similar to the species recorded in 1907. Palaeobotanical studies of  
15 aquatic plant macrofossils at Loch Leven (Salgado et al., 2010), however, show that  
16 1907 was not an undisturbed baseline. In the 17<sup>th</sup> and 18<sup>th</sup> century even less  
17 competitive isoetids, such as *Isoetes lacustris* and *Lobelia dortmanna*, were abundant  
18 and by 1907 the loch was probably already altered not only by nutrients, but also by  
19 liming in the catchment (Salgado et al., 2010). Additional to the changes in land use  
20 and farming practices, there were substantial changes to the outflow and water level  
21 of the loch, which were made in the mid 1830s. These modifications lowered the  
22 water level by 1.4 m and converted 4.5 km<sup>2</sup> of aquatic habitat to farmland (May &  
23 Spears, submitted). This raises the question of what recovery target is appropriate.

1 Two of the main reasons that Loch Leven is so valued ecologically, are the  
2 internationally renowned over-wintering and breeding bird community (Quinn et al.,  
3 submitted) and the brown trout fishery (May & Spears, submitted). There are  
4 indications that both of these communities, and the benthic invertebrates that form a  
5 key part of their diet, have responded to attempts to restore water quality in the loch  
6 (Gunn et al., submitted; Quinn et al., submitted; Winfield et al., submitted). These  
7 broader recovery trends may be, in part, associated with the recovery observed in the  
8 macrophyte community. Increased abundance and diversity of plants could provide  
9 greater physical habitat structure for invertebrates (vandenBerg et al., 1997; Warfe &  
10 Barmuta, 2006), more productive and variable food sources for dabbling ducks and  
11 herbivorous birds, such as coot and swan (Moreno-Ostos et al., 2008; Perrow et al.,  
12 1997) and more physical habitat for fish feeding and breeding (Warfe & Barmuta,  
13 2006).

14 The comparison of multiple aquatic plant surveys has provided more evidence  
15 (additional to other papers in this special issue) that Loch Leven is currently  
16 undergoing recovery from eutrophication, at least since 1993. This is most evident  
17 when looking at species richness, at both the whole lake and smaller scales, and  
18 species evenness. The plant community has regained many, but not all, of the taxa that  
19 were present in 1907, so cannot yet be said to have returned to a state similar to that  
20 observed by West (1910). It is unlikely that the plant community will ever return to its  
21 pre-industrial state, due to changes in land use, and the regulation of the loch's outlet,  
22 which are likely never to be reversed.

1

## 2 **Acknowledgments**

3 The authors thank Bryan Spears and Linda May for substantial assistance with the  
4 preparation of the paper. Thanks are also due to all of the surveyors involved in the  
5 collection of the data on which this paper is based.

1 Table 2. List of taxa, which were used for analyses, found in Loch Leven in surveys  
2 included in this paper, including an indication of relative abundance where the  
3 information was available (an 'x' indicates that no abundance information was  
4 available). Abundance data are standardised point frequency, expressed as a  
5 percentage. All numbers have been rounded up to the nearest integer for clarity.

<b>Taxa</b>	<b>1907</b>	<b>1966</b>	<b>1972</b>	<b>1975</b>	<b>1986</b>	<b>1993</b>	<b>1999</b>	<b>2008</b>
<i>Chara</i> spp.	x	97	30	37	56	56	52	22
<i>Potamogeton berchtoldii</i> / <i>P.</i>								
<i>pusillus</i>	x			1		1	8	21
<i>Nitella</i> / <i>Tolypella</i>	x	1	13	28				19
<i>Callitriche hermaphroditica</i>	x		3	1	3	6	10	14
<i>Potamogeton perfoliatus</i>	x		1	1	6	7	7	7
<i>Potamogeton filiformis</i> / <i>P.</i>								
<i>pectinatus</i>	x	1	25	28	21	5	19	7
<i>Elodea canadensis</i>	x	2	1	2	2	6	1	6
<i>Zannichellia palustris</i>		1	30	5	13	21	2	5
<i>Eleocharis acicularis</i>	x			2		1	2	1
<i>Myriophyllum</i> spp.	x	1	1					1
<i>Potamogeton praelongus</i>	x							1
<i>Ranunculus</i> spp.	x							1

1 **Figures**

14 Figure 1. Counts of taxa (a) and evenness of taxa distribution (b) from all Loch Leven  
15 macrophyte surveys presented in this paper. The taxa are as described in the methods  
16 section.

1  
 2 Figure 2. Number of taxa found in each sample 1993, 1999 and 2008 expressed as  
 3 boxplots including 25<sup>th</sup> percentile, median, 75<sup>th</sup> percentile and 90<sup>th</sup> percentile. Note  
 4 that for 1993, the median was 1. Outliers (stars) and the mean are also shown (crossed  
 5 circle).

1  
 2 Figure 3. Number of taxa found in each survey sector of macrophyte surveys of Loch  
 3 Leven in 1986, 1993, 1999 and 2008 expressed as box plots, including 10<sup>th</sup> and 25<sup>th</sup>  
 4 percentiles, median, and 75<sup>th</sup> and 90<sup>th</sup> percentiles. Outliers (stars) and the mean are  
 5 also shown (crossed circle).
