**Abstract.** X-ray CT is increasingly being adopted in manufacturing as a non destructive inspection tool. Traditionally, industrial workflows follow a two step procedure of reconstruction followed by segmentation. Such workflows suffer from two main problems: (1) The reconstruction typically requires thousands of projections leading to increased data acquisition times. (2) The application of the segmentation process a posteriori is dependent on the quality of the original reconstruction and often does not preserve data fidelity. We present a fast iterative X-ray CT method which simultaneously reconstructs and segments an image from a limited number of projections called Fourier Null Space Regularization (FNSR). The novelty of the approach is in the explicit updating of the image null space with values derived from a regularized image from the previous iteration, thus compensating for any missing projections and effectively regularizing the reconstruction. The speed of the method is achieved by directly applying the Fourier Slice Theorem where the Non-Uniform Fast Fourier Transform (NUFFT) is used to compute the frequency spectrum of the projections at their positions in the image k-space. At each iteration a segmented image is computed which is used to populate the null values of the image k-space effectively steering the reconstruction towards a binary solution. The effectiveness of the method to generate accurate reconstructions is demonstrated and benchmarked against other iterative reconstruction techniques using a series of numerical examples. Finally, FNSR is validated using industrial X-ray CT data where accurate reconstructions were achieved with 18 or more projections, a significant reduction from the 5000 needed by filtered back projection.

## 1. Introduction

X-ray CT is becoming an increasingly common method of non destructively assessing and quantifying material and dimensional properties of industrial components e.g., [1, 2]. Traditionally, industrial X-ray CT workflow consists of a reconstruction followed by image segmentation [1]. Once a segmented image is generated it can be used to assess the specimen for flaws, material properties, quality control and dimensional analysis. However, these workflows typically suffer from time consuming acquisition and a final segmented image which is dependent on the quality of the original reconstruction.

Industrial X-ray CT reconstruction is typically computed using filtered back projection (FBP) or equivalent [3, 4]. The main advantage of FBP methods are its computational speed and low memory requirements. However, FBP methods require hundreds or thousands of projections, each evenly distributed for an accurate reconstruction [3, 4]. These large datasets lead to increased acquisition times particularly in aerospace applications where superalloys are routinely used and long exposure times, on the order of seconds, are necessary to achieve adequate signal-to-noise ratios (SNR). Inevitably these long acquisition times leads to manufacturing bottlenecks which require additional X-ray CT capacity to be purchased or a reduction in the exposure times of the individual X-rays projections, degrading image quality. Additionally, the workflow suffers from the a posteriori application of the segmentation process which is dependent on the quality of the reconstruction and often does not preserve X-ray projection fidelity in the final image e.g.,[5].

An alternative to this two stage workflow is the simultaneous reconstruction and segmentation (SRS) of the image for which a number of methods have been developed. One such approach is to use prior information as a regularization term in the reconstruction [6]. Such priors include sparsity in the gradient of the image which can be exploited by Total Variation (TV) regularization [7, 8], or by assignment of pixels to a given class, using knowledge about the number of materials present [9, 10]. Alternatively, level-set segmentation methods can be incorporated into the reconstruction as shape based priors [5, 11, 12]. Typically the SRS methods are applied to datasets acquired using a full set of projections, which would not lead to reduced data acquisition times.

Binary or discrete tomography deals with image reconstruction from a small number of projections where the pixels are known to be limited to one or a number of distinct values [13, 14]. Unlike conventional tomography where the projections have continuous amplitudes that are related to the distance a raypath travels through an object, in binary tomography the projections are made up of discrete integer sums where only the number of pixels within each material traversed by a raypath is needed. Discrete tomographic problems have been shown to be highly ill posed, are highly unstable in the presence of noise [15] and difficult and complex to solve exactly [13, 14, 16]. The computational difficulty and in particular the highly unstable nature of the problem in the presence of noise means discrete tomography methods cannot be applied successfully to experimental data. However, a number of discrete tomographic methods have been

specifically developed to either provide approximate solutions or to handle experimental projection data; examples of such methods include greedy algorithms [17], Monte Carlo based optimization methods [18, 19, 20] network flow methods [21] and iterative hybrid approaches that alternate between a continuous reconstruction using algebraic reconstruction and a discrete reconstruction [22, 23, 24, 25].

Despite significant improvements in computational power and the increasing application of graphics cards to tomographic problems [26], improvements to the resolution of the X-ray detectors and subsequent image resolution continue to make SRS and discrete tomographic methods computationally expensive. The computational expense of these methods renders FBP methods popular due to their speed and small computational footprint.

We introduce a new fast iterative Fourier based CT reconstruction method called Fourier Null Space Regularization (FNSR). The novelty of the approach is in its explicit inclusion of regularization into the null space to compensate for any missing projections. The method achieves its speed by directly applying the Fourier Slice Theorem to compute values for the image k-space corresponding to the projection data. A threshold image is computed at each iteration which is used to populate the reconstruction k-space where no values are available. The population of this null-space is used to regularize and steer the reconstruction towards a binary solution. Numerical experiments are conducted using different binary phantoms to benchmark the computational speed and reconstruction quality of FNSR against other algebraic reconstruction methods as a function of the number of projections. Finally, the method is validated using experimental X-ray data from a turbine blade.

## 2. Fourier Null Space Regularization (FNSR)

In this section we describe the FNSR method which builds upon the Fourier slice theorem and uses null space regularization to steer the solution towards a desired reconstruction.

### 2.1. Fourier slice theorem and back projection

The Radon transform relates the X-ray projection data to a line integral through an object  $f(x, y)$ , at an angle  $\theta$  to the  $x$  axis with an offset from the centre of rotation  $t$  [3, 4]. The Radon transform is defined as

$$\begin{aligned} \mathcal{R}f \equiv p(\theta, t) &= \int_{(\theta, t)} f(x, y) dS \\ &= \int \int f(x, y) \delta(x \cos \theta + y \sin \theta - t) dx dy, \end{aligned} \quad (1)$$

where  $t = x \cos \theta + y \sin \theta$  and  $\delta$  is the Dirac delta function. The projection or sinogram dataset are subsequently a collection of line integrals taken at different offsets and angular rotations [3, 4].

75 The main objective of CT is to recover the image  $f(x, y)$  from the sinogram data by  
 76 computing the inverse of the Radon transform ( $\mathcal{R}^{-1}p$ ). A cornerstone in the calculation  
 77 of  $\mathcal{R}^{-1}p$  is the Fourier slice theorem (FST) which relates the 1D Fourier transform  
 78 of the projection data at an angle  $\theta$  to the corresponding slice through the 2D Fourier  
 79 transform of the image of interest [3, 4]. Therefore, the recovery of the object is obtained  
 80 by performing a Fourier transform of the sinogram slices which are used to populate the  
 81 corresponding 2D spatial frequency positions. This is then followed by an inverse 2D  
 82 Fourier transform to give the final image in cartesian coordinates.

83 The implementation of the FST requires the frequency domain of the projection  
 84 data to be interpolated from a polar to a cartesian grid in order to compute the inverse  
 85 2D transform. Generally the direct implementation of the FST is avoided due to the  
 86 significant errors introduced during the polar to cartesian grid interpolation in the spatial  
 87 frequency domain [3]. An alternative formulation of the CT problem, and by far the  
 88 most widely used is filtered back projection where the sinograms are filtered, then back  
 89 projected (smeared) through the image. This filtering acts to remove the amplification  
 90 of particular spatial frequency components introduced by the back projection stage.  
 91 Provided there are sufficient projections with an even angular sampling the filtered back  
 92 projection method yields an accurate image of the object [3, 4]. Recent development  
 93 of the non-uniform sampled FFT (NUFFT) [27] [28] has allowed for the accurate  
 94 application of the FST with similar computational overheads to the standard 1D and  
 95 2D FFT, with results equal to the back projection methods [29] [30].

## 96 2.2. Null space regularization

97 Consider the linear operation  $\mathcal{L}$  which acts on an image  $x$  to generate some data  $d$ , which  
 98 may be written as  $\mathcal{L}x = d$ . In X-ray CT, the linear operator is  $\mathcal{L}$  is the Radon transform.  
 99 The goal of an inverse problem is to recover the image thus effectively undoing the  
 100 operator  $\mathcal{L}$ . In general,  $\mathcal{L}$  is non invertible, so an iterative approach is required to  
 101 obtain a solution [31] [32]. Additionally,  $\mathcal{L}$  is typically ill conditioned which means  
 102 that an infinite number of null space images  $\mathcal{L}x_n = 0$  exist to which  $\mathcal{L}$  is effectively  
 103 insensitive to. The insensitivity of the operator  $\mathcal{L}$  to the null space means that any  
 104 recovered image which matches the data will consist of a combination of the true and  
 105 null space images. Therefore, any solution to the inverse problem is non-unique where  
 106 multiple images exist which match the measured data.

107 It is initially assumed that the values of the null space are zero. The addition of  
 108 regularization terms allow for the null space to be updated towards more representative  
 109 values, thus reducing the effects of non-uniqueness on the solution [31] [32]. The type  
 110 and amount of regularization allows for certain preferential solutions to selected based on  
 111 some prior assumptions e.g., smooth or edge preserving solutions [6], [7],[31], [32]. The  
 112 generation of the null space values by regularization may be achieved either implicitly  
 113 or explicitly. In the former both the data and the regularization terms are fitted and  
 114 no consideration is given to the null space terms. In the explicit case the null space

115 and measurable components are separated via some appropriate transform with the  
 116 measurable terms matched with the data whilst the null space components are updated  
 117 based on a regularized reconstruction.

118 Deal and Nolet [33] used a ‘null space shuttle’ to seismic tomographic problems  
 119 where a non-linear filter is estimated and applied as a post processing step and only  
 120 modifies components of the null space. Huthwaite *et al.*, [34] and Shi and Huthwaite [35]  
 121 applied an iterative null space regularization method to limited view ultrasonic imaging,  
 122 applying a threshold to the image from the previous iteration. This threshold image is  
 123 used to generate synthetic data for the missing viewing angles which are incorporated  
 124 with the measured data to perform the next iteration of the procedure. In this sense  
 125 the threshold image is focusing the data onto the higher contrast areas of the image,  
 126 attempting to minimise the lower contrast smearing artefacts which appear both in  
 127 subsampled and limited angle of view problems.

128 Here, we apply a similar strategy to [34] and [35], but specifically tailored it to  
 129 limited data X-ray CT. Below we review the theory used by [34] and [35] for ultrasonic  
 130 imaging. As stated previously the main objective of any imaging approach is to  
 131 reconstruct an image  $x$ , from a set of measurements  $d$  by undoing the linear operator  
 132  $\mathcal{L}$ . However,  $\mathcal{L}$  is not invertible in general, since there are multiple sets of  $x$  which can  
 133 produce the same data  $d$ . We define a corresponding imaging operator  $\mathcal{I}$  which can  
 134 therefore only generate  $x'$ , an approximation of  $x$ ,

$$135 \quad x' = \mathcal{I}(d). \quad (2)$$

136 We define an operator  $\mathcal{R}$  which maps an image into a regularised image

$$137 \quad x_{reg} = \mathcal{R}(x). \quad (3)$$

138 We do not, at this point, make any assumptions other than that  $\mathcal{I}$  and  $\mathcal{L}$  are linear.  
 139 The focus of this paper is to generate images when data is limited, which means that  $d$   
 140 is not known in its entirety. We therefore split this into two data sets:

$$141 \quad d = \left\{ \begin{array}{c} d_m \\ d_u \end{array} \right\}, \quad (4)$$

142 where  $d_m$  is the known, measured, data, and  $d_u$  is a hypothetical, unmeasurable data  
 143 set which completes the ideal, full data set. The value of splitting the data in this way  
 144 is that we can target a solution which matches  $d_m$  while using regularisation to estimate  
 145  $d_u$ . This is achieved through iteration.

146 An initial image is generated by setting the unknown components  $d_u$  to zero, and  
 147 combining these with  $d_m$  as in (4) to obtain the full-view data set at the first iteration

$$148 \quad d^{(1)} = \left\{ \begin{array}{c} d_m \\ 0 \end{array} \right\}. \quad (5)$$

149 where we use the superscript ( $k$ ) to indicate the value of a variable at iteration  $k$ . The  
 150 image is then approximated from this data set as

$$151 \quad x^{(1)} = \mathcal{I} (d^{(1)}) . \quad (6)$$

152 The point of regularisation is to steer an image towards the true solution, based on  
 153 some prior knowledge; the operator can be applied such that  $x_{reg}^{(n)}$  should be a better  
 154 representation of the true object than  $x^{(n)}$

$$155 \quad x_{reg}^{(1)} = \mathcal{R} (x^{(1)}) . \quad (7)$$

156 This regularisation improvement, encoded within  $x_{reg}^{(1)}$ , needs to be combined with our  
 157 measured data set  $d_m$  to provide an improved estimate for the unknown values at the  
 158 next iteration. To do this, we use the forward model to generate a complete data set  
 159 from  $x_{reg}^{(1)}$

$$160 \quad d_{reg}^{(1)} = \mathcal{L} (x_{reg}^{(1)}) . \quad (8)$$

161 As before, the components of  $d_{reg}^{(1)}$  can be subdivided into two sets depending on  
 162 whether or not they can be measured from the original limited view array

$$163 \quad d_{reg}^{(1)} = \left\{ \begin{array}{c} d_{reg,m}^{(1)} \\ d_{reg,u}^{(1)} \end{array} \right\} . \quad (9)$$

164 This subdivision enables us to identify two components. In general,  $d_{reg,m}^{(1)} \neq d_m$ ,  
 165 i.e. the regularisation will have moved the measured components away from the true  
 166 values. However, we seek a solution where these components do match. The unknown  
 167 components  $d_{reg,u}^{(1)}$  have also been adjusted from the zero values they were set to before,  
 168 which is caused by the regularisation. We wish to maintain this behaviour. Therefore,  
 169 we seek a solution where the data for the next iteration is

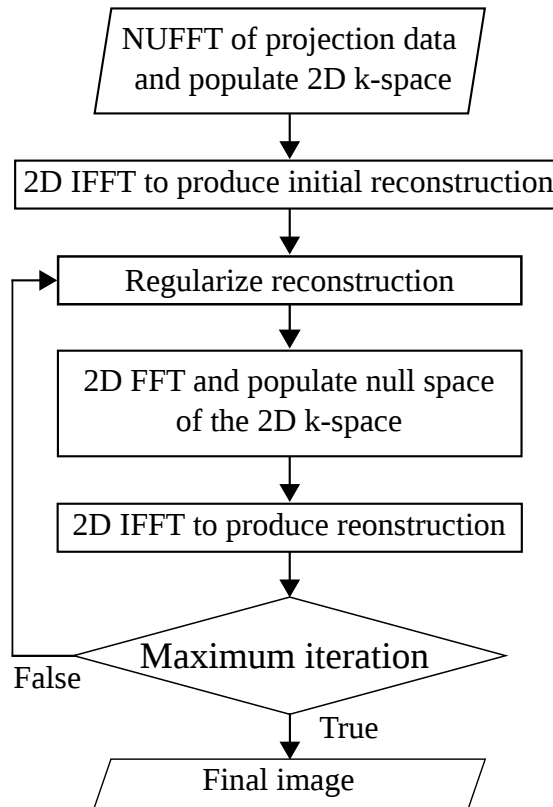

$$170 \quad d^{(2)} = \left\{ \begin{array}{c} d_m \\ d_{reg,u}^{(1)} \end{array} \right\} . \quad (10)$$

171 We have outlined the process for the first iteration; these steps can be repeatedly applied  
 172 until convergence is achieved. As highlighted, the steps up to this point are as given in  
 173 [34].

174 In X-ray CT reconstruction, the FST, introduced in Section 2.1, provides the means  
 175 to transform between the image space (in which regularisation can be applied) and the  
 176 data space (in which data can be combined and replaced). It is powerful in that it is fast,  
 177 which is critically important when iterating, and it is invertible, relying only on the 2D  
 178 FFT and its inverse, avoiding the solution drifting from the true data. This is the key  
 179 contribution of the FNSR, and it should be noted that it is general for any regularisation  
 180 approach allowing both binary and non-binary x-ray images to be recovered.

181 FNSR is applied as follows and summarised in Figure 1: (1) take the NUFFT of  
 182 the projection data and populate the corresponding 2D k-space locations. The initial

183 image is estimated by taking the inverse 2D FFT. (2) regularisation is applied, (3) the  
 184 2D FFT takes the image into k-space, (4) the measured components are corrected to  
 185 their true components and (5) the latest image is generated by the inverse 2D FFT.  
 186 This is then iterated from point (2).

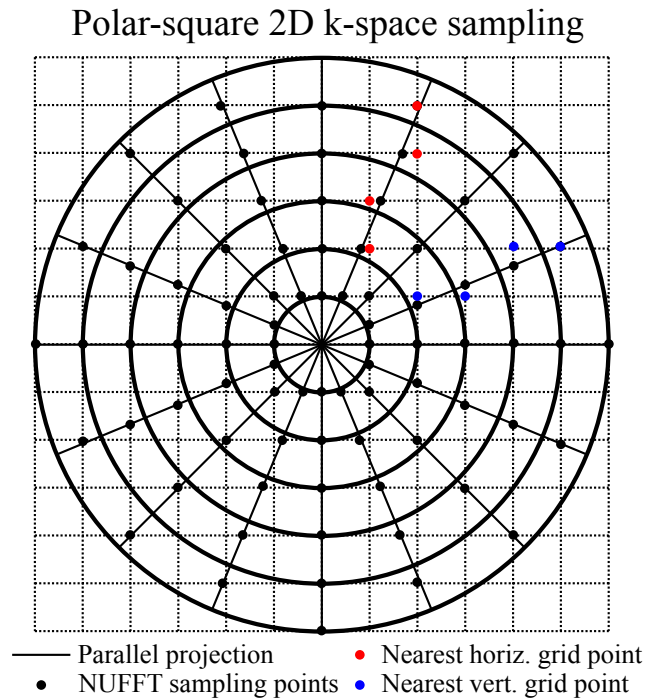

**Figure 1.** Summary workflow of the FNSR algorithm.

### 187 2.3. Data k-space stencil

188 Fundamental to the FNSR algorithm is the population of the data and null components  
 189 of the image k-space. The FST is used to populate the 2D image k-space using the FFT  
 190 of the projection data [3, 4]. Typically, the direct calculation of the FST is avoided  
 191 due to significant interpolation errors associated with converting the projection data  
 192 from a polar to cartesian grid. However, these interpolation errors are mitigated by  
 193 sampling the 2D image k-space using a series of concentric squares [36], [37] and using  
 194 the NUFFT to obtain exact horizontal or vertical grid point values (Figure. 2). This  
 195 sampling scheme reduces the interpolation to a single dimension with results comparable  
 196 to FBP [36].

197 The concentric sampling and data k-space estimation are computed as follows:

- 198 (i) Data are divided in two; sub-horizontal projection  $\theta \in [-45^\circ, 45^\circ)$  and sub-vertical  
 199 projection  $\theta \in [45^\circ, 135^\circ)$  where  $\theta$  is the angle of projection taken counter clockwise  
 200 from the horizontal.

**Figure 2.** Illustration of the k-space sampling using a polar and concentric square grid. The radial lines are the parallel projections the circles show the sampling positions obtained by Fourier Transforming the projection data. The black dots are the sampling positions we wish to obtain using the NUFFT. The red and blue dots show the location of the nearest vertical or horizontal grid point to each NUFFT sample.

- 201 (ii) Compute the 1D NUFFT of the projection data using the method of Greengard and  
 202 Lee [28] with a desired output sampling interval of  $\Delta k_p = \frac{\Delta k_x}{\cos \theta}$  for sub-horizontal  
 203 and  $\Delta k_p = \frac{\Delta k_y}{\sin \theta}$  for sub-vertical projections where  $\Delta k_x$  and  $\Delta k_y$  are the horizontal  
 204 and vertical sampling rate of the 2D k-space. These points correspond to the black  
 205 dots along the radial lines in Figure 2.
- 206 (iii) 1D linear interpolation of the computed k-space values along vertical lines for sub-  
 207 horizontal projections ( $\theta \in [-45^\circ, 45^\circ)$ , red dots Figure 2) and along horizontal  
 208 lines for the sub-vertical projections ( $\theta \in [45^\circ, 135^\circ)$  blue dots Figure 2).

209 This k-space, where the data have been interpolated onto the nearest horizontal  
 210 or vertical grid space (red and blue dots in Figure 2) is called the data k-space  $X_{data}$   
 211 and corresponds to  $d_m$  in (4). Following, that we define a binary k-space stencil  $X_{stencil}$   
 212 which is used to define the null space of the current system where the  $j^{th}$  pixel is defined  
 213 as:

$$214 \quad X_{stencil}^j = \begin{cases} 1 & |X_{data}^j| = 0 \\ 0 & \text{otherwise} \end{cases} . \quad (11)$$

215 By performing a point-by-point multiplication of this stencil with the FFT of the  
 216 regularized image  $X_{reg}$  we eliminate the data component  $d_m$  in the k-space leaving

217 only components belonging to  $d_{reg,m}^{(k)}$ . A combined dataset (10) is estimated by adding  
 218 the  $X_{data}$  to the newly formed regularised k-space.

### 219 3. Binary FNSR algorithm

220 In this section we describe regularization scheme when combined with FNSR generates  
 221 binary reconstructions of X-ray CT data. We begin by describing the binary steering  
 222 approach of Censor [22] followed by a brief description on the implementation of the  
 223 algorithm. A summary of the algorithm is given by the pseudo-code in Algorithm 1.

#### 224 3.1. Binary regularization

225 The binary regularization scheme used is a binary steering approach which incrementally  
 226 steers each iteration towards a discrete image [22]. Any iterative reconstruction may be  
 227 written as

$$228 \quad x^{k+1} = x^k + c(x^k, d), \quad (12)$$

229 where  $x$  is the image vector,  $d$  is the data,  $c$  is the correction function which updates  
 230 the image, and  $k$  is the iteration number. The binary steering step is applied to the  
 231  $k^{th}$  iterate of the image vector  $x_k$  and is used as the input to the correction function.  
 232 The method relies on three sequences of real numbers,  $\alpha = \{\alpha_k\}_{k \geq 0}$  which defines the  
 233 lower segmentation value,  $\beta = \{\beta_k\}_{k \geq 0}$  which defines the upper segmentation value, and  
 234  $\tau = \{\tau_k\}_{k \geq 0}$  which defines the final image threshold. The three sequences of numbers  
 235 satisfy the conditions  $0 \leq \alpha_k < \tau_k < \beta_k \leq 1$ ,  $\alpha_k < \alpha_{k+1}$  and  $\beta_{k+1} < \beta_k$ . Typically  $\tau$  is  
 236 usually fixed at 0.5 with  $\alpha$  and  $\beta$  defined as  $\alpha_k = \frac{k}{K}\tau$  and  $\beta_k = 1 - \alpha_k$ , where  $K$  is the  
 237 total number of iterations. At the  $k^{th}$  iterate  $\alpha$  and  $\beta$  are applied to the  $j^{th}$  pixel of the  
 238 image  $x^k$  to define the binarised image  $\tilde{x}^k$  as [22],

$$239 \quad \tilde{x}_j^k = \mathcal{B}(x^k) = \begin{cases} 0 & \text{if } x_j^k \leq \alpha_k \\ 1 & \text{if } x_j^k \geq \beta_k \\ x_j^k & \text{otherwise} \end{cases}, \quad (13)$$

240 However, practically the image pixels values are equal to the radiographic  
 241 attenuation coefficient of the imaged object their values may not binary (i.e, 0 or 1).  
 242 In order to apply the binarisation step the image is normalized between 0 and 1 using  
 243 linear normalization which for the  $j^{th}$  pixel is given by:

$$244 \quad \hat{x}_j^k = x_j^k \frac{1}{\max(x^k)}, \quad (14)$$

245 where  $\max(x^k)$  is the maximum image pixel amplitude of the  $k^{th}$  iteration. The  
 246 normalized image is subsequently binarised using (13).

247 Next an intermediary image  $y^{k+1} = x^k + c(\tilde{x}^k, d)$  is computed by applying the  
 248 correction function  $c$  to the binarised image  $\tilde{x}^k$ . The intermediate image  $y^{k+1}$  may  
 249 result in the amplitudes of previously binarised pixels  $x^k$  significantly changing resulting

in pixel ‘conflict’ [22] which can lead to the unstable binarisation and reconstructions. A pixel is defined as being in conflict when the intermediate image  $y^{k+1}$  crosses the image threshold  $\tau$  i.e., if  $x^k \leq \alpha_k$  and  $y^{k+1} \geq \tau$  or if  $x^k \geq \beta_k$  and  $y^{k+1} \leq \tau$ . To resolve pixel conflict and allow for the smooth and stable binarisation of the image a conflict resolution function  $\mathcal{C}$  is defined as:

$$x_j^{k+1} = \mathcal{C}(y^{k+1}, x^k) = \begin{cases} \tau - \epsilon & \text{if } x_j^k \leq \alpha_k \text{ and } y_j^{k+1} \geq \tau \\ \tau + \epsilon & \text{if } x_j^k \geq \beta_k \text{ and } y_j^{k+1} \leq \tau \\ y_j^{k+1} & \text{otherwise} \end{cases} \quad (15)$$

where  $\epsilon$  is a small constant greater than 0 which ensures that each pixel falls the correct side of the threshold value  $\tau$ .

*3.1.1. Implementation* First, a binary image is generated from the previous iteration using (13) and (14). Next, the 2D FFT of the binarised image is computed and used to regularize the reconstruction. Differences in the amplitudes of the binarised image  $\tilde{x}^k$  and the data derived image  $x$  must be accounted for prior to regularization. This is achieved by computing the modified inverse of 14 where  $\max(x^k)$  is replaced by the median of all pixels which were identified with values greater than the threshold  $\beta$  (median ( $\{x_j^k \mid \tilde{x}_j^N = 1\}$ )). The median was used instead of the maximum to reduce the effects of any spuriously large pixel amplitude values on the regularization. Following the rescaling the 2D FFT of the image is computed to give the the binarised k-space  $X_b$ .

Next, the k-space of the binarised image,  $X_b$  is projected on to the null space of the current reconstruction by performing element by element multiplication with the stencil  $X_{stencil}$ . Following the calculation of the regularized reconstruction  $y^k$  any conflicts associated with changes in pixel assignment are resolved using (15) where the terms  $\alpha, \beta, \tau$  and  $\epsilon$  are scaled according to the inverse of (13).

By binarising the image, information about sharp contrast objects will be introduced into the image null space via the FFT. The effect of taking the 2D FFT of an image with sharp edges in the image domain is a sinc function centred at 0 frequency in the k-space. The effect of any spurious ringing on the reconstruction will be limited for two main reasons (1) The majority of the information relating to an image is contained at low spatial frequencies in the k-space, which is adequately sampled even with a few projections due to the polar nature of the sampling geometry – considering two points at the same radius separated by a particular angle, the cartesian separation distance will be small when the radius is small. Therefore, at low spatial frequency the 2D k-space is dominated by the data. (2) The Fourier transform is linear and as such its inverse will reproduce the original sharp edges of the image.

Of greater concern to the quality of the reconstruction is the potential presence of high frequency noise in the image i.e., single pixel holes in an object. To alleviate this the final stage of the algorithm is a smoothing operation which is used to enforce coherency between adjacent pixels and further mitigate the mislabeling of pixels from

288 the binarisation phase. From a practical perspective the smoothing is justified by the  
 289 fact that the imaged objects are homogeneous with any flaws or voids expected to be  
 290 made up of more than tens of pixels.

## 291 4. Numerical Examples

292 A series of numerical experiments were conducted to assess the capability of the proposed  
 293 algorithm to accurately reconstruct five different phantoms. The tests assess the  
 294 FNSR sensitivity to iteration number, filter size and the convergence behaviour of the  
 295 method. Finally a comparison is made between FNSR and the algebraic reconstruction  
 296 method's capability to reconstruct an object using a limited number of projections. The  
 297 projections are computed for a parallel beam geometry using (1) with each projection  
 298 spaced evenly between 0 and 180°.

299 The quality of the reconstruction is assessed by comparing the percentage of  
 300 mislabeled pixels and the root mean squared (RMS) of the difference between the  
 301 phantom and reconstruction. The mislabeling of the  $j^{th}$  pixel is defined as

$$302 \quad x_m^j = \begin{cases} 1 & |x_t^j - x_r^j| > 0.5, \\ 0 & \text{otherwise} \end{cases} \quad (16)$$

303 where  $x_t$  is the true image and  $x_r$  is the reconstruction. Throughout the experiments  
 304 the final segmentation threshold  $\tau = 0.5$  and the conflict resolution parameter  $\epsilon = 10^{-4}$

**Figure 3.** Phantoms used for the numerical simulations. (a) Phantom 1. (b) Phantom 2. (c) Phantom 3. (d) Phantom 4. (e) Phantom 5.

#### 305 4.1. Phantoms

306 The numerical experiments are based on five binary representative phantoms (Figure  
 307 3), where Phantoms 2 and 4 were taken from [25] whilst phantom 5 was generated using  
 308 the XDesign software package [38]. The trivial process of using the same forward model  
 309 in the inversion as used to generate the simulated data is known as an ‘inverse crime’  
 310 and should be avoided [32]. Within CT imaging, inverse crimes are typically avoided by  
 311 using continuous or high resolution phantom data to generate the projections that can  
 312 then be used for the desired reconstruction at a lower resolution. Here, the projection  
 313 data were computed using phantoms with pixel resolutions of  $1024 \times 1024$  for phantom  
 314 1,  $4096 \times 4096$  for phantoms 2-4 and  $2048 \times 2048$  for phantom 5 and a desired image  
 315 reconstruction of  $512 \times 512$ . The projection data were interpolated so that each detector  
 316 pixel corresponded to the length of the pixels in the output image. For comparisons  
 317 with the reconstructed data the phantoms were downsampled to  $512 \times 512$  pixels.

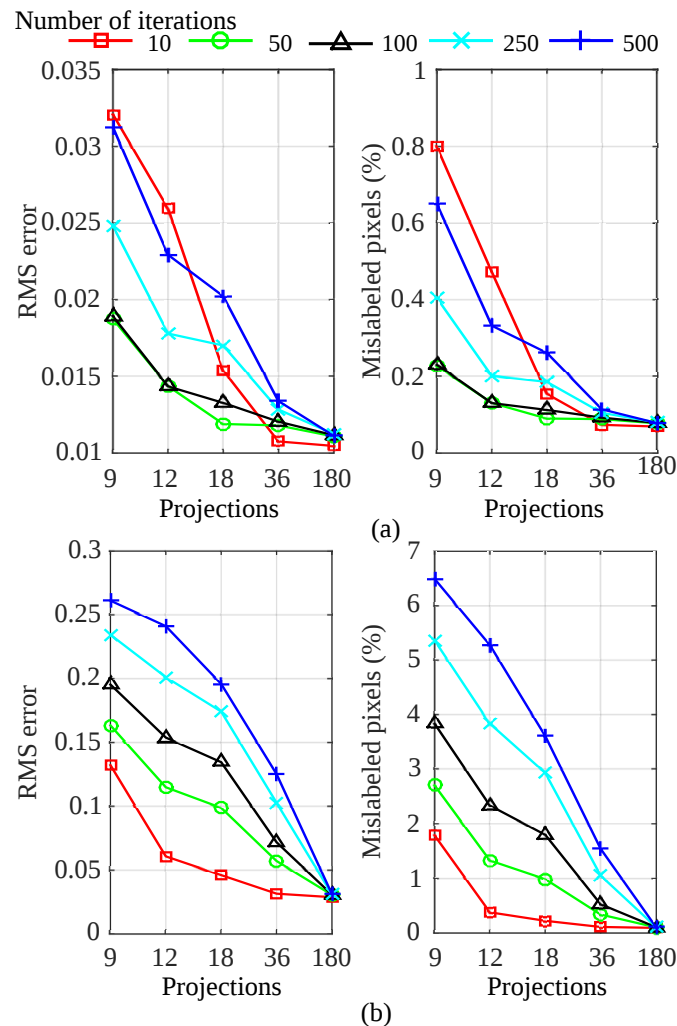

#### 318 4.2. Effect of number of iterations

319 A key factor of the performance of the FNSR algorithm is the total number of iterations,  
 320 since this controls the rate of binarisation and the null space thresholding. The effect  
 321 of the number of iterations on the quality of reconstruction as a function of the number  
 322 of projections is tested here. For this test no filtering was applied to the results at the  
 323 end of each iteration.

324 Figure 4 shows the RMS and the percentage number of mislabeled pixels for  
 325 Phantoms 1 and 3 for different number of iterations. In both examples it can be seen  
 326 that fewer iterations, generally 50 or below, produce results with the lowest number of  
 327 misidentified pixels and RMS error. However, the two phantoms have distinctly different  
 328 error trajectories. In the case of Phantom 1 the optimum number of iterations are  
 329 dependent on the number of available projections; for example at 180 and 36 projections  
 330 10 iterations marginally produce the most accurate reconstructions but for fewer than 36  
 331 projections the image quality rapidly decreases. On average, 50 iterations produces the  
 332 reconstructions with the lowest number of mislabeled pixels and RMS error. However,  
 333 for Phantom 3 the error trajectories are distinct with 10 iterations producing the best  
 334 reconstruction in all cases in Figure 4.

335 The variability in the reconstruction quality as a function of iteration is seen in  
 336 Figure 5. Where an increasing number of iterations are used, leading to a finer set  
 337 of binarisation thresholds, the images exhibit ‘noise’ in the form of mislabeled pixels.  
 338 These mislabeled pixels and associated image noise are particularly prevalent at low  
 339 numbers of projections. The mislabeling of pixels tends to occur during the final set of  
 340 iterations where pixels with amplitudes close to the final segmentation threshold  $\tau$  are  
 341 set incorrectly.

342 Two main factors contribute to the mislabeling of pixels at higher iterations. The  
 343 first is the influence of the null space regularization on the FNSR reconstruction which is  
 344 dependent on the both the shape of the imaged object and relative size of the data and  
 345 null spaces. This explains the variability in error trajectories between both phantoms  
 346 in Fig 4. In general, as the size of the null space increases it exerts a greater influence  
 347 on the solution and, as such, a pixel which has been labeled by the binarisation process

**Figure 4.** Comparison of the effect of different number of iterations on the final RMS error and misidentified pixels of (a) Phantom 1 and (b) Phantom 3 using a limited number of projections.

**Figure 5.** Comparison of the effect of different number of iterations on RMS error and misidentified pixels of (a) Phantom 1 and (b) Phantom 3 using 18 projections.

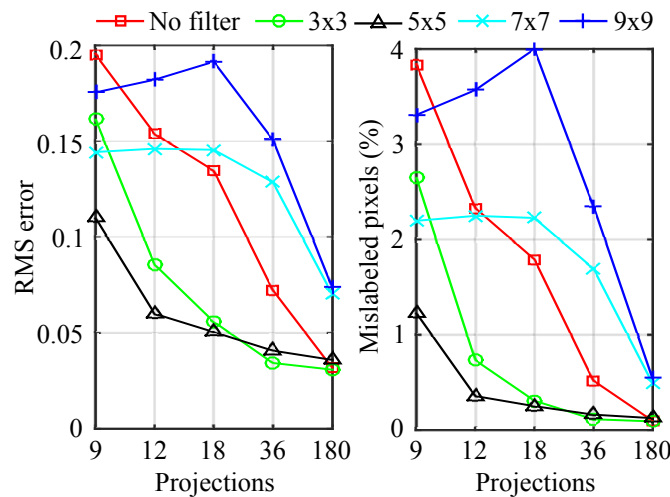

348 tends to remain with this designation in subsequent iterations.

349 The second influence on the solution is the conflict resolution phase (15) which  
 350 stabilizes reconstruction by inhibiting significant change in pixel labels particularly close  
 351 to  $\tau$ . In addition, other non binarised pixels will now exhibit large changes in amplitude  
 352 to compensate for the mislabeling of other pixels thus enhancing the effect. To combat  
 353 these effects the number of iterations should be as low as possible to produce an accurate  
 354 reconstruction whilst also reflecting the expected pixel amplitude variability for each  
 355 iteration. In addition a filtering operation is applied at each iteration to regularize the  
 356 solution, which is discussed next.

### 357 4.3. Filter regularization

358 In the previous section it was seen that some regularization was necessary in order to  
 359 prevent the mislabeling of pixels and the generation of noise in the image (Figure 5). We  
 360 select a 2D median filter as a method of regularizing the image and test how the window  
 361 size affects the quality of the reconstruction. The median filter was selected because of  
 362 its ability to minimise 'salt and pepper' type noise, which is how these errors typically  
 363 manifest themselves, while avoiding blurring edges. All experiments were conducted  
 364 using 50 iterations.

365 Figure 6 shows the RMS error and the percentage number of mislabeled pixels of  
 366 Phantom 5 with varying filter size. From the two graphs it can clearly be seen that  
 367 the addition of a small filter improves the reconstruction for a decreasing number of  
 368 projections whilst larger filters degrade the image. The effect of the different filters for  
 369 18 projections is seen in Figure 7. We can see that the  $3 \times 3$  filter reduces the number  
 370 mislabeled pixels whilst preserving the edges of the internal features of the object. The  
 371 larger filter windows  $7 \times 7$  and  $9 \times 9$  remove all mislabeled pixels at the expense of  
 372 rounding the edges and removal of the internal features of the object. From both the

**Figure 6.** Comparison of the effects of different median filter lengths on the RMS error and misidentified pixels of Phantom 5 using a limited number of projections and FNSR.

373 graph (Figure 6) and image comparison (Figure 7) the  $5 \times 5$  median filter produces the  
 374 best result by removing the noise associated with the mislabeled pixels whilst preserving  
 375 the edges of the internal features of the object.

376 The optimal filter size is dependent on the effect of the number of iterations on the  
 377 reconstruction, which itself is a function of the number of projections (Figure 4). In  
 378 general the best results are obtained when the lowest number of iterations and smallest  
 379 filter size are used.

**Figure 7.** Comparison of the effects of different median filter lengths on the reconstruction of Phantom 5 both with 18 projections.

#### 380 4.4. Evaluation of reconstruction algorithms

381 A number of iterative algorithms have been developed over the years to solve the inverse  
 382 problem  $d = Ax$ , where  $d$  are the data,  $A$  is the model or projection matrix which links  
 383 the data to the image  $x$  e.g., [3, 4, 31, 32]. Algebraic reconstruction techniques (ART) are  
 384 a family of reconstruction methods which have been routinely applied to X-ray CT and  
 385 efficiently solve the inverse problem in a least squares sense using a series of forward and  
 386 back projections [3, 4, 31, 32]. Here, we test the quality and speed of the proposed FNSR  
 387 algorithm against a number of ART algorithms using a limited number of projections.

388 All tests were performed on a desktop workstation (32 Intel Xeon E502690 processor,  
389 2.90GHz CPU, 8 cores and 256 GB RAM) using MATLAB 15.

390 The details of the ART algorithms tested are given below:

391 *4.4.1. Algebraic Reconstruction Technique (ART)* ART is an iterative reconstruction  
392 algorithm of form (12) where the data correction function is calculated by sweeping  
393 through each row of the matrix A and projecting the solution onto orthogonal  
394 hyperplanes e.g., [3, 4, 31]. A single iteration is completed when all rows of A have  
395 been swept through [3, 4, 31].

396 For the numerical experiments we set the total number of iterations to 100 which  
397 is sufficiently large to ensure that convergence has been achieved. Additionally, pixel  
398 amplitude positivity following each row iteration of the reconstruction is enforced. The  
399 inclusion of the positivity constraint yields better results than those without, particularly  
400 for limited data case e.g., [39].

401 *4.4.2. ART-TV* The TV reconstruction of Sidky *et al.*, was implemented [8]. This  
402 method is a two step approach which combines the ART algorithms with a TV  
403 minimization step. The first stage is a single iteration of ART where the positivity  
404 constraint is subsequently applied as opposed to after each individual row projection  
405 described above. The second stage of the algorithm is TV minimization using a fixed  
406 step,  $\gamma$ , and fixed iteration gradient descent approach. It should be noted that the  
407 gradient of the TV function with respect to each pixel is undefined, so a smooth  
408 approximation must be used where the amount of smoothing is controlled by the  
409 parameter  $\delta$  [8].

410 For the experiments a number of parameters must be set which were determined  
411 using trial and error process. We set  $\delta = 10^{-8}$  which is sufficiently small to stabilize the  
412 TV gradient without smearing any of the edges, the gradient descent has a fixed step  
413 length  $\gamma = 0.05$  for 200 iterations whilst the total number of iterations was set to 100  
414 which was sufficiently large for convergence.

415 *4.4.3. Discrete Algebraic Reconstruction Technique (DART)* DART is a practical  
416 discrete tomographic approach built upon the results of an ART approach [23]. The  
417 method relies on prior knowledge of the number of materials and their corresponding  
418 grey values to discretized an initial ART reconstruction. The method focuses on  
419 iteratively improving the boundaries between the segmented parts of the reconstruction  
420 which are known to be poorly resolved particularly when a limited number of projections  
421 are used [23]. At each iteration the edge pixels are identified along with a randomly  
422 selected subset of image pixels which are updated using the previous ART method [23].

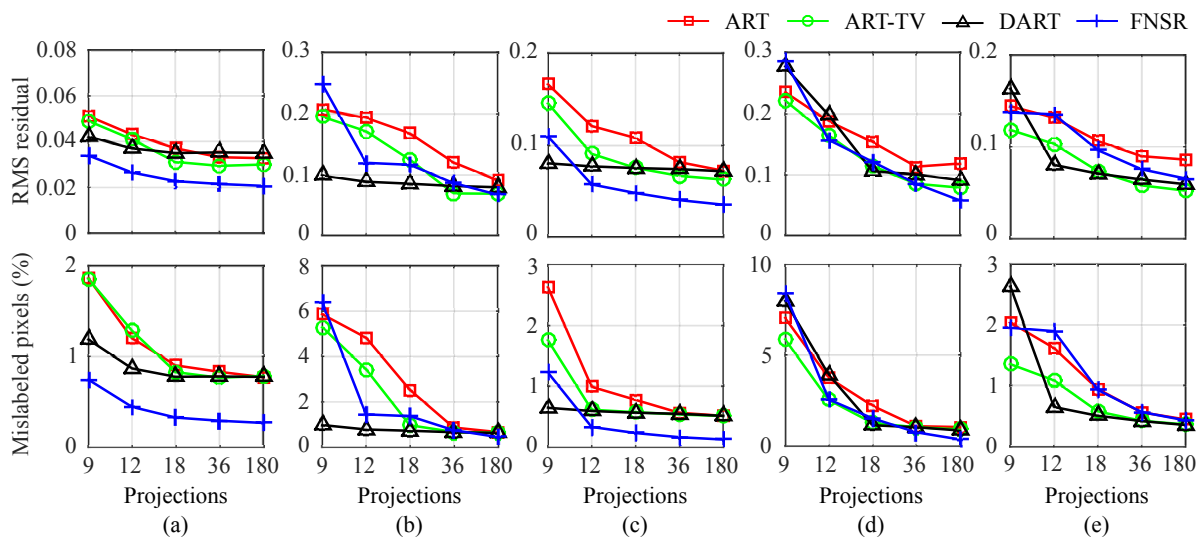

423 One of the major source of errors in the original DART algorithm was that the  
424 grey values of the pixels must be known a priori. In practice, true pixel grey values  
425 are affected by a number of factors, including the source energy, the spectrum of the  
426 source and whether any filters are used, and are therefore difficult to predict. The so

427 called Projection Distance Minimization (PDM) approach was developed to optimize  
 428 the grey values and segmentation threshold at each iteration [24]. PDM is a two  
 429 stage optimization approach which minimizes the least squares difference between the  
 430 measured projections and those calculated using the currently segmented image [24].  
 431 The first stage optimizes the segmentation thresholds followed by the pixel grey values  
 432 using the Nelder-Mead simplex algorithm [24].

433 For the numerical examples, the Simultaneous Iterative Reconstruction Technique  
 434 (SIRT) was used for the initial reconstruction with 500 iterations and positivity  
 435 constraints applied at each iteration. A total of 200 iterations were used for DART  
 436 and 100 iterations of SIRT for the edge update phase. At each DART iteration a PDM  
 437 update was computed for the image segmentation.

438 4.4.4. *FNSR* The number of iterations and size of the regularization filter were  
 439 determined following the results of Section 4.2 and Section 4.3. A total of 50 iterations  
 440 was deemed optimal with a regularization filter of  $3 \times 3$  in the case of Phantom 1 and  
 441  $5 \times 5$  for all other Phantoms (Figure 3).

**Figure 8.** RMS error and misidentified pixels of the reconstruction methods using a limited number of projections. (a) Phantom 1. (b) Phantom 2. (c) Phantom 3. (d) Phantom 4. (e) Phantom 5.

442 Figure 8 summarizes the RMS error and the percentage of mislabeled pixels as  
 443 a function of projections for all phantoms. The results show that FNSR consistently  
 444 produces more accurate reconstructions than the ART and ART-TV algorithms for all  
 445 projections. In the case of Phantoms 1 and 3 and for 36 projections or more FNSR  
 446 routinely outperforms DART. Table 1 provides an overview of the average ranking of  
 447 the various algorithms relative to one another as a function of the number of projections.  
 448 For 12 or more projections FNSR is ranked either 1<sup>st</sup> or 2<sup>nd</sup> within the algorithms tested  
 449 and falling to 3<sup>rd</sup> for 9 projections. These results suggest that FNSR required at least  
 450 12 projections or more in order to obtain an accurate reconstruction of the object.

**Table 1.** Rankings of the RMS and mislabeled pixels of the reconstructions using a limited number of projections averaged over all phantoms. The final column overall ranking of the reconstruction method. A score of 1 has the lowest RMS error/number of mislabeled pixels and 4 the highest.

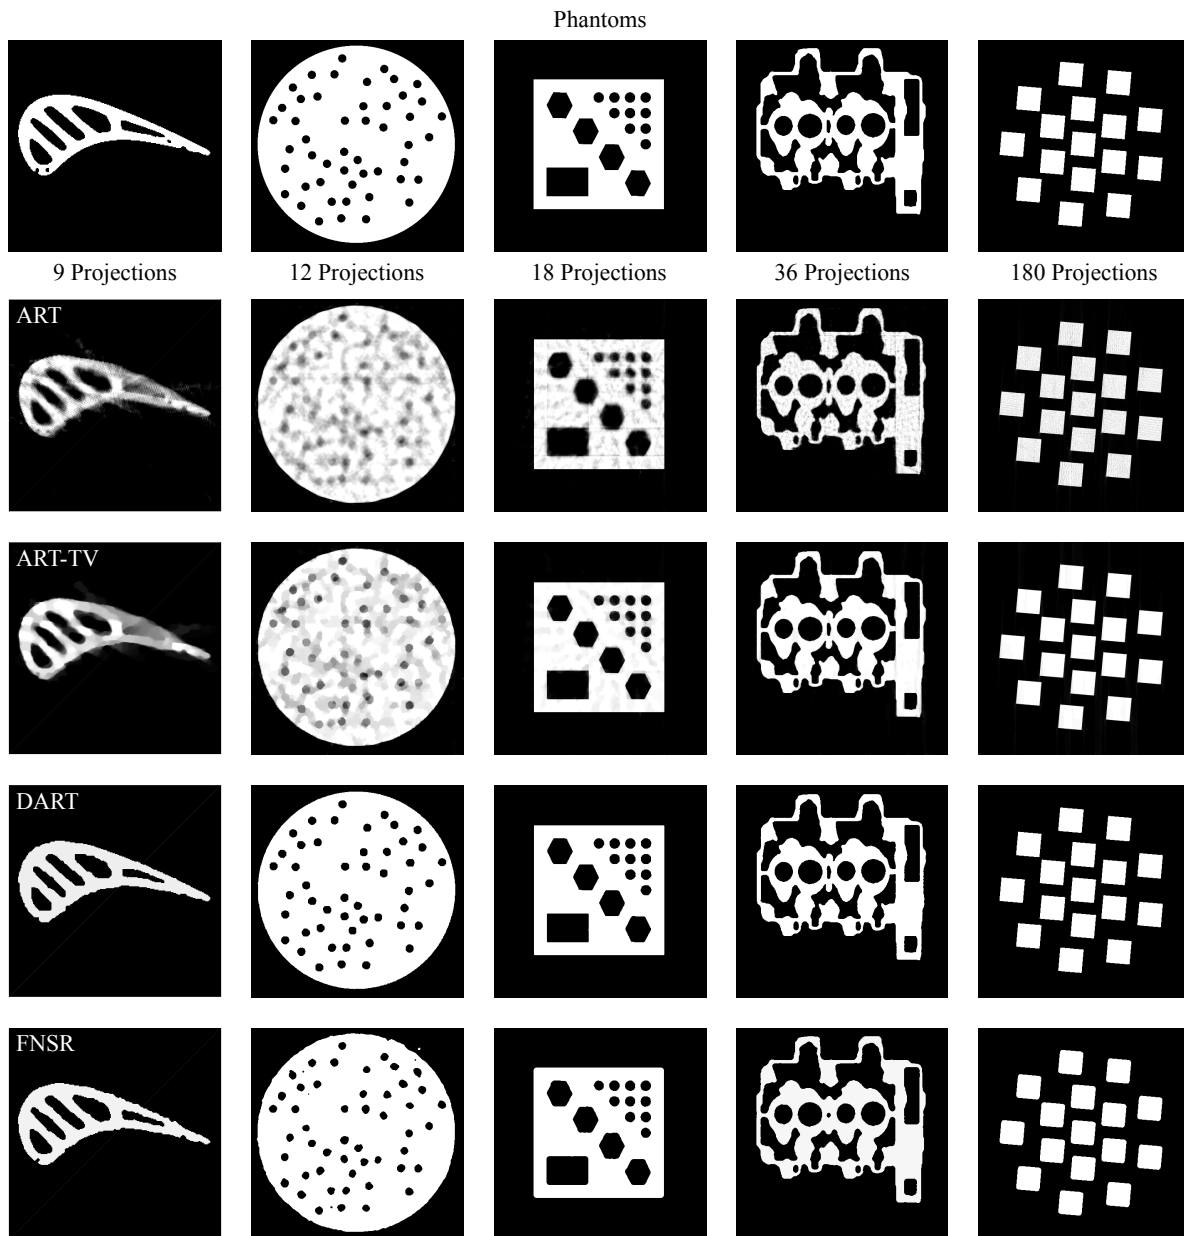

Method	RMS ranking					Average
	9 Projections	12 Projections	18 Projections	36 Projections	180 Projections	
ART	4	4	4	4	4	4
ART-TV	1	3	3	1	3	2
DART	2	2	1	3	2	3
FNSR	3	1	2	2	1	1

Method	Mislabeled pixel ranking					Average
	9 Projections	12 Projections	18 Projections	36 Projections	180 Projections	
ART	4	4	4	4	4	4
ART-TV	1	3	3	1	3	3
DART	2	1	1	3	2	1
FNSR	3	1	2	1	1	2

451 Examples of reconstructions as a function of the number of projections are seen  
 452 in Figure 9. The examples clearly show that the FNSR and DART reconstructions  
 453 produce similar results for Phantoms 1 and 2 with significantly less smearing than seen  
 454 in ART and ART-TV methods. In Phantom 4 some of the image details, particularly  
 455 the ellipsoid shape hole at the center of the image has been overly smoothed by the  
 456 regularizing filter. This smoothing may also be seen in the rounding of some of the  
 457 edges of Phantom 5. These images reiterate the importance of the trade off between  
 458 iteration number and filter size.

459 Figure 10 compares the run time of each algorithm as a function of the number  
 460 of projections for Phantom 3. All four algorithms scale approximately linearly as the  
 461 number of projections increase. In the case of the ART methods the run times increase  
 462 as a function of algorithm complexity. The run time of DART is significantly affected  
 463 by the PDM based segmentation with each iteration spending the majority of time in  
 464 Nelder-Mead simplex optimization [24]. FNSR is at least an order of magnitude faster  
 465 than the other methods with the 180 projection reconstruction having a similar run  
 466 time to an ART reconstruction with 9 projections.

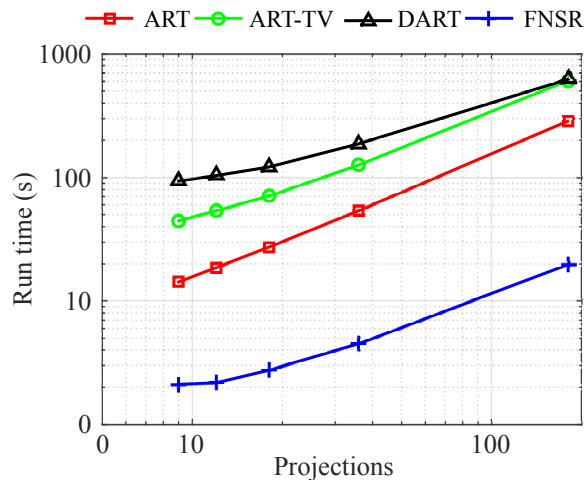

467 The main deviation between FNSR and DART occurs at 12 projections or fewer  
 468 (Figure 8 and Table 1). However, the reduction in run time of more than an order  
 469 of magnitude allows the FNSR method to allow for additional projection data to be  
 470 acquired without compromising processing speed, whilst improving the reconstruction  
 471 quality. Relative to DART and ART-TV based methods FNSR produces equivalent or  
 472 better quality reconstructions with a significantly reduced processing time.

**Figure 9.** Comparison of reconstructions using a limited number of projections (columns) for ART (row 2), ART-TV (row 3), DART (row 4) and FNSR (row 5)

#### 473 4.5. Convergence properties

474 The convergence behaviour of iterative methods is important to understand in order  
 475 to assess the quality and computational stability of the method. FNSR is a heuristic  
 476 reconstruction algorithm so a formal proof about the convergence conditions of the  
 477 algorithm cannot be provided. Thus far the numerical experiments have shown that  
 478 FNSR can accurately reconstruct a variety of phantoms with varying number of  
 479 projections (Section 4.4) but the result is dependent on the number of projections  
 480 (Section 4.2) and filter size (Section 4.3).

**Figure 10.** Comparison of the run times of the reconstruction methods using a limited number of projections for Phantom 3.

**Figure 11.** RMS error and mislabeled pixels of FNSR as a function of iteration using a limited number of projections. (a) Phantom 1. (b) Phantom 2. (c) Phantom 3. (d) Phantom 4. (e) Phantom 5.

481 The convergence properties of FNSR were tested using Phantoms 1–5 by comparing  
 482 the RMS error and the number of mislabeled pixels as a function of iteration  
 483 for a varying number of projections. A total of 50 iterations were used and a  $3 \times 3$  size median  
 484 filter used for Phantom 1 and  $5 \times 5$  filter for all other phantoms. As shown in Figure  
 485 11 FNSR generally displays smooth convergence for RMS error and mislabeled pixels  
 486 although absolute convergence cannot be guaranteed. In all cases the RMS error and  
 487 number of mislabeled pixels slightly increased at the final iterations as the binarisation  
 488 sequence is completed. This slight increase is attributed to unlabeled pixels on the edge  
 489 of the object taking definitive values.

490 The iteration history of mislabeled pixels for Fig 11 (d) displays a significant  
 491 deviation from other convergence histories. This deviation can be attributed to the  
 492 use of the incorrect number of iterations and filter size for that particular phantom. In  
 493 this particular example the optimum number of iterations are 28 considering mislabeled  
 494 pixels and 33 for RMS error. The results of the incorrect number of iterations and  
 495 filter size can be seen in Figure 9 where the central ellipsoid hole is partially filled and  
 496 image edges have been overly smoothed. This example reiterates the importance of the

number of iterations in controlling the convergence of the reconstruction.

In the case of 180 projections we can see that the convergence history is flat with some deviation at the first and last iteration associated with the binarisation process (Figure 11). This type of behavior is not unexpected since there is sufficient data available to populate the 2D image k-space with the final result being effectively a binarised filtered back projection of the data.

## 5. Experimental Validation

Experimental X-ray CT data were acquired using a collimated 140 kV, 225  $\mu$ A source with a 4 mm copper filter and recorded on a linear array of 2048, 0.415mm long pixels with exposure times of 1s [39]. A total of 5000 projections with an even angular sampling of 0.72° through 360° were acquired. Using all of 5000 projections, a tomographic slice of the turbine blade was obtained using the industry standard FDK method, which was post processed to remove any beam hardening artefacts and segmented [39]. This image will be used as a reference to compare the FNSR reconstructions against.

Prior to applying FNSR the fan beam data were preprocessed to remove any beam hardening using an empirically defined amplitude correction curve [39]. The current implementation of the FNSR is applicable to parallel ray datasets and as such the projection data were resampled to generate a limited projection parallel ray datasets. The projections correspond to an evenly sampled dataset from 0° to 180° with the number of projections the same as that used in the previous numerical examples (9, 12, 18, 36 and 180). The fan beam data were subsampled to the desired number of projections and rebinned to generate a parallel ray dataset [3]. In the process of rebinning only data which correspond to the desired projection angles are retained which leads to an uneven sampling of the detector and subsequently the introduction of interpolation errors. We note that the NUFFT has been successfully and accurately applied to the transformation of fan to parallel beam data [29, 30] and could readily applied instead of rebinning and interpolation.

For the experimental reconstructions a total of 10 iterations was selected based on the results of the iterations test (Section 4.2) and a 3×3 regularization filter was used. Figure 12 shows the reconstruction of the experimental turbine blade dataset. It can clearly be seen that FNSR produces accurate images up to 18 projections, which is similar to results obtained by Jones and Huthwaite [39], who investigated the performance of different ART and TV methods for different industrial CT datasets. The RMS error and number of mislabeled pixels in the experimental data (Figure 13) are slightly higher than those observed for the numerical experiments on Phantom 1 using FNSR (Figure 8). For 18 or more projections the errors in the experimental reconstructions are comparable with those observed by the ART based reconstruction of numerical data (Figure 8). When fewer than 18 projections are used, the FNSR experimental based reconstruction and errors significantly deviate from those observed in the numerical examples.

**Figure 12.** FNSR reconstruction of experimental turbine blade data as a function of the number of parallel projections.

**Figure 13.** RMS and misidentified pixels between the reference image and FNSR as a function of the number of parallel projections.

537 The quality of the FNSR results are dependent on the number of iterations and the  
 538 regularization filter, both of which are affected by noise. Any noise in the projections  
 539 will introduce additional high frequencies into the image k-space thus degrading the  
 540 image. To alleviate this high frequency noise either additional preprocessing of the  
 541 projections are necessary, or an increase in the size of the FNSR regularization filter,  
 542 which will limit the method to accurately reconstruct the small features and object  
 543 edges. Additionally, beam hardening in the projection data can also limit FNSR and  
 544 other binary reconstruction methods in the production of accurate images.

545 The number of iterations and the size of the smoothing filter will vary depending  
 546 on the specific type of image regularisation used (Figure 1), the imaged object and the  
 547 SNR. In an environment where similar objects are to be imaged e.g., on a production  
 548 line the parameters would only need to be adjusted once. Based on the presented  
 549 examples where a binary regularisation approach was used (Sections 4.2 and 4.3) we  
 550 suggest setting the default reconstruction parameters to fewer than 50 iterations with a  
 551 median filter of  $3 \times 3$  or  $5 \times 5$  pixels.

## 552 6. Conclusions

553 We have presented a fast and accurate iterative reconstruction algorithm for X-ray  
 554 CT using a limited number of projections called Fourier Null Space Regularization  
 555 (FNSR). The method uses an innovative approach to regularize the reconstruction and

556 compensate for any missing projections by explicitly updating the image null space  
557 with values derived from a filtered image from the previous iteration. The speed of the  
558 method is achieved by directly applying the Fourier Slice Theorem using the NUFFT  
559 to compute the frequency spectrum of the projection data at their exact positions in  
560 the corresponding image k-space. Furthermore, the FNSR algorithm permits the use  
561 of any image regularization allowing both binary and non-binary x-ray images to be  
562 recovered. In line with many industrial X-ray CT applications we apply FNSR to  
563 binary tomographic reconstructions where a binary steering regularization method is  
564 used to drive the solution towards a discrete image.

565 The comparison of the reconstruction algorithms tested demonstrated that the  
566 FNSR method outperformed ART for all projections and produces comparable or  
567 better results to DART for 12 or more projections. The numerical experiments also  
568 highlight the significant reduction in computational time of more than an order of  
569 magnitude achieved by FNSR, relative to the other methods. The significant reduction  
570 in the computational processing time achieved by FNSR would permit more data to  
571 be acquired thus improving reconstruction quality without compromising acquisition or  
572 processing speeds.

573 The numerical experiments highlight the key role the number of iterations have in  
574 the accuracy of the reconstruction; too few and the reconstruction contains smearing  
575 artefacts from the lack of projections, whilst too many leads to fine ‘noise’ associated  
576 with the mislabeling of pixels close to the final segmentation threshold. The findings  
577 of the iteration test suggest that the number of iterations should be as low as possible,  
578 typically less than 50 and an additional regularizing filter should be included at the end  
579 of each iteration. A simple median filter with a window size of  $3 \times 3$  or  $5 \times 5$  was found to  
580 produce the best result in removing the noise associated with pixel mislabeling whilst  
581 preserving the edge and internal features of the object. Improvements to the overall  
582 FNSR algorithm could be made to the binarisation process by using spatially varying  
583 thresholding e.g., [40] and a more advanced filtering operation e.g., [41].

584 FNSR was validated using an industrial X-ray CT dataset of a turbine blade.  
585 The data were acquired in a fan beam configuration and resampled to generate a  
586 series of evenly spaced parallel ray datasets from  $0^\circ$  to  $180^\circ$ . FNSR produced accurate  
587 reconstructions for 18 or more projections with error estimates which are comparable to  
588 the numerical examples, confirming the applicability of the algorithm in practice. Future  
589 improvement for the practical application of the algorithm would be the extension of  
590 the method to non parallel ray acquisition geometries e.g., fan beam.

## 591 Acknowledgments

592 GAJ is funded by EPSRC RCNDE 3 (EP/L022125/1) and PH is funded by EPSRC  
593 Early Career Fellowship (EP/M020207/1). The authors would like to thank Rolls-Royce  
594 for providing the turbine blade and the Manufacturing Technology Centre for acquiring  
595 the turbine blade X-ray data. We would also like to thank 2 anonymous reviewers and

596 editorial board for their constructive comments and suggestions for the manuscript.
