Abstract: An unstructured mesh tidal model of the west coast of Britain, covering the Celtic Sea and Irish Sea is used to compare tidal distributions computed with finite element (F.E.) and finite volume (F.V.) models. Both models cover an identical region, use the same mesh, and have topography and tidal boundary forcing from a finite difference model that can reproduce the tides in the region. By this means solutions from both models can be compared without any bias towards one model or another. Two dimensional calculations show that for a given friction coefficient there is more damping in the F.V. model than the F.E. model. As bottom friction coefficient is reduced the two models show comparable changes in tidal distributions. In terms of mesh resolution, calculations show that for the M2 tide the mesh is sufficiently fine to yield an accurate solution over the whole domain. However in terms of higher harmonics of the tide, in particular the M6 component, its small scale variability in near shore regions which is comparable to the mesh of the model, suggests that the mesh resolution is insufficient in the near coastal regions. Even with a finer mesh in these areas, without detailed bottom topography and a spatial varying friction depending on bed types and bed forms, which is not available, model skill would probably not be improved. In addition in the near shore region, as shown in the literature, the solution is sensitive to the form of the wetting/drying algorithm used in the model. Calculations with a three dimensional version of the F.V. model show that for a given value of  $k$ , damping is reduced compared to the two dimensional version due to the differences in bed stress formulation, with the three dimensional model yielding an accurate tidal distribution over the region.

Detailed Response to Reviewer's comments on paper D-10-150 "A model study of tidal distributions in the Celtic...." by Davies et al.

### General Response

Comments such as "this paper is very interesting, clear and well organised" and "merits publication... minor corrections" (Ref 1) are much appreciated. In addition that Ref 2, finds the objective of the paper "interesting" is good to read.

In revising the paper we have taken account of both sets of reviewers comments.

### Detailed Response to Ref 1.

- (1) Tables of M4/M2 amplitude ratio and where possible M6/M2 ratio for sites where M6 exceeds 5cm, have now been added and discussed.
- (2) P4, L35, FVCOM, spelled out.
- (3) P5, L33, typing corrected.
- (4) Where possible annotation on cotidal charts improved.

### Detailed Response to Ref 2.

- (1) Description of models slightly enhanced. As a detailed description is given in published papers, these are cited, as we do not wish to repeat information. In addition since a functional form of the solution is given over each finite element or finite volume this can be used to interpolate solutions (e.g. water elevations) to any location. This point made in text.
- (2) It is made clear that the staircase representation of the coastline only relates to a certain class of finite difference model.
- (3) The  $k=0.003$  calculations are mentioned "early on".
- (4) Possibility of lack of mesh resolution influencing solution of higher harmonics is discussed in context of the fact that this could also be influenced by "wetting and drying". Additional references added.
- (5) Abstract rephrased to suggest this, rather than claim that it has been shown. Similar in text.
- (6) Elaborated to show that in the near short region the amplitude of the higher harmonics changes very rapidly from one mesh element to another. A sure sign of a lack of spatial convergence. The confusion between temporal convergence, where iteration ensures that a converged solution does occur and spatial convergence is now clarified.
- (7) The realistic nature of these coefficients is confirmed by reference to published observed bottom friction coefficients that occur in the region.

### Summary

Paper revised taking account of all reviewers comments. Our thanks to reviewers and editor for comments and time taken to review the paper.

2 Abstract  
3  
4

5 An unstructured mesh tidal model of the west coast of Britain, covering the Celtic Sea and  
6  
7 Irish Sea is used to compare tidal distributions computed with finite element (F.E.) and finite volume  
8  
9 (F.V.) models. Both models cover an identical region, use the same mesh, and have topography and  
10  
11 tidal boundary forcing from a finite difference model that can reproduce the tides in the region. By  
12  
13 this means solutions from both models can be compared without any bias towards one model or  
14  
15 another. Two dimensional calculations show that for a given friction coefficient there is more  
16  
17 damping in the F.V. model than the F.E. model. As bottom friction coefficient is reduced the two  
18  
19 models show comparable changes in tidal distributions. In terms of mesh resolution, calculations  
20  
21 show that for the  $M_2$  tide the mesh is sufficiently fine to yield an accurate solution over the whole  
22  
23 domain. However in terms of higher harmonics of the tide, in particular the  $M_6$  component, its small  
24  
25 scale variability in near shore regions which is comparable to the mesh of the model, suggests that the  
26  
27 mesh resolution is insufficient in the near coastal regions. Even with a finer mesh in these areas,  
28  
29 without detailed bottom topography and a spatial varying friction depending on bed types and bed  
30  
31 forms, which is not available, model skill would probably not be improved. In addition in the near  
32  
33 shore region, as shown in the literature, the solution is sensitive to the form of the wetting/drying  
34  
35 algorithm used in the model. Calculations with a three dimensional version of the F.V. model show  
36  
37 that for a given value of  $k$ , damping is reduced compared to the two dimensional version due to the  
38  
39 differences in bed stress formulation, with the three dimensional model yielding an accurate tidal  
40  
41 distribution over the region.

1  
2 1. Introduction  
3

4 To date the most common approach used in oceanography to model tidal distributions in a region  
5 has been the application of uniform grid finite difference methods. Initial calculations were restricted  
6 by lack of computational power to coarse grid limited area models, such as the west coast of Britain  
7 model of Davies and Jones (1992) (hereafter DJ92) which had a grid resolution of the order of 7km.  
8 Subsequently the domain of such models was expanded to the whole of the Northwest European  
9 Continental Shelf (Kwong et al., 1997, Davies and Kwong 2000), although the grid resolution  
10 remained coarse at the order of 10km. With such coarse grids it was not possible to accurately include  
11 the near shore regions where “wetting and drying” occurred over a tidal cycle and important non-  
12 linear processes lead to the generation of higher harmonics of the tide. To overcome these difficulties  
13 higher resolution limited area models were developed such as the 1km eastern Irish Sea model of  
14 Jones and Davies (1996)(hereafter JD96). Although in the eastern Irish Sea this model could resolve  
15 the near shore region where “wetting and drying” occurred and non-linear effects gave rise to higher  
16 harmonics of the tide, the limited geographical extent of the model meant that these higher harmonics  
17 had to be specified along the open boundaries of the model. Hence the distribution of these higher  
18 harmonics was determined by both model dynamics and the open boundary condition. Consequently  
19 the ability of the model to generate higher harmonics could not be tested independently of the open  
20 boundary conditions. An alternative approach is to nest a higher resolution finite difference model  
21 within one of coarser resolution. However, the false reflection at the interface between the models of  
22 waves that can be resolved on the fine grid but not the coarse grid, is a major deficiency of this  
23 approach. In addition as shown by Aldridge and Davies (1993), the “stair-case” nature of the coastal  
24 boundary in the majority of conventional finite difference models (the exception being those that use a  
25 boundary fitted coordinate) produced “spurious solutions” in a near coastal boundary layer of the  
26 order of three to four grid boxes wide.

54

55 An alternative approach to the application of finite differences is to use an unstructured mesh, and  
56 solve the resulting equations by applying the finite element method. The application of this technique  
57 in oceanography has recently been reviewed by Jones (2002), Walters (2005), and Greenberg et al.  
58  
59  
60  
61  
62  
63  
64  
65

1 (2005, 2007), and consequently details will not be presented here. Some recent applications to tidal  
2 problems are given in e.g. Foreman et al. (1993, 1995), Fortunato et al. (1997), Ip et al. (1998),  
3  
4 Legrand et al. (2006, 2007), Levasseur (2007), Lynch et al. (1993, 2004) and Walters (1992). A  
5  
6 comparison of the performance of finite difference and finite element models for reproducing the  $M_2$   
7  
8 tide and its higher harmonics in the English Channel was performed by Werner (1995). However, as  
9  
10 the model domain was limited higher harmonics were included in the open boundary condition. Also  
11  
12 there were no significant “wetting and drying” areas in the region which as shown by Greenberg et al.  
13  
14 (2005), Jones et al. (2008), Chen et al. (2008) and Karna et al. (2011) significantly influence tidal  
15  
16 distributions in shallow regions. In addition because of the limited domain of the model the  $M_2$  tidal  
17  
18 solution was constrained by the open boundary. Consequently a detailed comparison of the  
19  
20 performance of finite difference and finite element solutions in such conditions was not possible.  
21  
22  
23

24 In this paper the tidal distribution over a much larger domain is considered, namely the west coast  
25  
26 of Britain which was first examined by DJ92 using a finite difference approach. In this case the model  
27  
28 open boundaries are well removed (Fig 1a) from the region of interest, namely the eastern Irish Sea  
29  
30 (Fig 1b) where “wetting and drying” occurs and higher harmonics are generated. Consequently only  
31  
32 the  $M_2$  tide along the open boundary is used to force the model, and higher harmonics which are  
33  
34 important in the eastern Irish Sea are generated by the model. By this means it is possible to compare  
35  
36 the performance of a finite volume (F.V.) model, based on FVCOM (Finite Volume Coastal Ocean  
37  
38 Model) and a finite element (F.E.) model namely TELEMAC in a shallow nearshore region, namely  
39  
40 the eastern Irish Sea, which is well removed from the region of boundary forcing (Fig 1a). In addition  
41  
42 by using an identical domain, boundary forcing and topography to that used earlier by DJ92 in a finite  
43  
44 difference model, the tidal solution is not biased towards either the F.V. or the F.E. approach.  
45  
46  
47  
48

49 The objective of the paper is to compare tidal solutions computed with a F.V. model based on  
50  
51 FVCOM (Chen et al 2003, 2007, Huang et al 2008), with those derived from a F.E. model namely  
52  
53 TELEMAC (e.g. Hervouet, 2002, Jones and Davies 2005, 2007, 2010, Malcherek 2000, Nicolle and  
54  
55 Karpytchev 2007), under identical conditions of boundary forcing and bottom topography. The form  
56  
57 of the hydrodynamic equations and brief details of the models, with references to the literature for  
58  
59 more extensive technical details is presented in the next section. Tidal solutions and comparisons with  
60  
61  
62  
63  
64  
65

1 observations are presented subsequently, with a conclusions section summarising the main findings  
2 from the study.

## 3 4 2. Hydrodynamic equations and model formulations. 5

6 As the primary aim of the paper is a comparison of tidal elevations computed with finite volume  
7 and finite element models, then the majority of the calculations were performed with two dimensional  
8 vertically integrated models. To be consistent with earlier finite difference calculations, the bottom  
9 friction coefficient  $k$  was initially set at a constant value of  $k=0.003$ , although subsequently this was  
10 reduced to  $k=0.0025$  (Table 1). However as shown by Aldridge and Davies (1993), and Davies and  
11 Lawrence (1995)(see their Fig 2) bed types and bed forms vary significantly over the eastern Irish  
12 Sea, and to examine the sensitivity to bottom friction coefficient, the F.V. model was also run with  $k$   
13 set at half this value, namely  $k=0.00125$ . This range of friction coefficients is physically justified and  
14 corresponds to the range of bed types found in the Irish Sea that vary from gravel (high  $k$  value) to  
15 mud (low  $k$  value) (see Davies and Lawrence 1995). In addition to see to what extent tidal elevation is  
16 sensitive to three dimensional effects, the F.V. model was run in three dimensions with 21 sigma  
17 levels in the vertical. In this case  $k$  was determined from  
18  
19  
20  
21  
22  
23  
24  
25  
26  
27

$$32 \quad k = \max \left\{ 0.0025, \left[ \frac{K}{\ln(Z_r/Z_0)} \right]^2 \right\} \quad (1)$$

33 where  $K$ = Von Karman's constant with  $Z_r$ = reference height and  $Z_0$  bed roughness. As both models  
34 are fully non linear (see Hervouet, 2002, Malcherek, 2000, Jones and Davies 2010, for details of  
35 TELEMAC, and Chen et al 2003, 2007 for details of FVCOM), and contain "wetting and drying"  
36 (see for example Chen et al (2008) and Karna et al (2011) for a detailed discussion of "wetting and  
37 drying" and references to algorithms for implement it), which occurs when the total water depth falls  
38 below 0.05m, then they contain all the necessary physics for generating higher harmonics of the tide  
39 in shallow water. As the physics of higher harmonic generation is given in Davies 1986, Filloux and  
40 Snyder 1979, Heaps 1978, Inoue and Garret 2007, LeProvost 1991, Walters and Werner 1991, Jones  
41 and Davies 2010, it will not be discussed here. In all calculations (Table 1), solutions were generated  
42 from initial conditions of zero elevation and motion at  $t=0$ , by integrating over seven tidal cycles and  
43 harmonically analysing the final cycle for the  $M_2$ ,  $M_4$  and  $M_6$  tides. At closed boundaries, the normal

1 component of velocity was zero, and the horizontal gradient normal to the coast of alongshore  
2 velocity was set to zero. This gave a perfect lateral slip condition.  
3

4 The model domain, water depths and tidal open boundary condition were the same in all  
5 calculations and were taken from the finite difference model of DJ92. The unstructured mesh used in  
6 the calculations (Grid G3AX, Fig 2) was generated using a mesh refinement based on water depth  
7 such that the ratio between element size and  $(gh)^{1/2}$  was constant, with  $g$  acceleration due to gravity and  
8  $h$  water depth. This gave a maximum element size of order 5km in deep water and 0.5km for near  
9 shore elements.  
10

### 11 3. Numerical solution using the F.E. and F.V. models. 12

13 As the TELEMAC finite element code has been used extensively and is well documented (see for  
14 example Jones and Davies (2010) and references therein) details will not be presented here. In  
15 addition, as details of the F.V. code formulation are given in Chen et al (2003, 2007), they will not be  
16 repeated here. Both models use time integration methods that ensure an accurate converged solution  
17 in the time domain. However accuracy in the spatial domain is determined by the specified mesh  
18 resolution which is fixed and does not vary with time. Consequently although the mesh may be  
19 sufficiently fine to represent the large scale spatial variability of the  $M_2$  tide it may be insufficient to  
20 accurately resolve short wavelength higher harmonics such as  $M_6$  which are generated in coastal  
21 regions (see later discussion). An extensive comparison with observations at a number of coastal and  
22 offshore positions (see Fig 1c for locations) for the  $M_2$ ,  $M_4$  and  $M_6$  tidal elevation amplitude and phase  
23 in the eastern Irish Sea is given in Tables 2, 3 and 4. By applying the functional form of the elements  
24 used in both approaches, values can be interpolated from element nodes where they are computed to  
25 any spatial location in order to compare with observations (see Chen et al (2003) and references in  
26 Jones and Davies (2010) for more details). The accuracy of the two models for a range of friction  
27 coefficients is presented here in terms of the comparisons with observations given in these tables.  
28

#### 29 3.1 The F.E. model with $k=0.003$ (Calc 1 (F.E.)). 30

31 In an initial calculation (Table 1, Calc 1 (F.E.)), tides were computed using the F.E. model. As a  
32 detailed discussion of cotidal distributions in the Irish and Celtic Seas is given elsewhere (eg. DJ96,  
33  
34  
35  
36  
37  
38

64  
65

1 Davies (1986), George (1980), Robinson (1979), Jones (1983)) only the major features are presented  
2 here, where the main focus is an intercomparison of F.E. and F.V. solutions and the influence of  
3 bottom friction upon these. The  $M_2$  cotidal chart derived from the F.E. model (Fig 3a), shows a  
4 degenerate amphidromic point off the south-east coast of Ireland, with tidal amplitudes increasing  
5 rapidly in the shallow water of the eastern Irish Sea, and within the Bristol Channel. The overall  
6 distribution of the tidal amplitude and phase in the Irish and Celtic Seas is in good agreement with  
7 observations, and Irish Sea cotidal charts derived by Robinson (1979) based on observations. In the  
8 northern part of the model, namely within the North Channel of the Irish Sea, the rapidly changing  
9 tidal distribution associated with a second degenerate amphidromic point (Fig 3a), is reproduced with  
10 a comparable accuracy to that found in limited area high-resolution models of this region (Davies et  
11 al. 2001). A detailed comparison with measurements at coastal and off-shore gauges in the eastern  
12 Irish Sea (Table 2) shows that on average there is good agreement between model and observations,  
13 although at some locations computed amplitude and phase are overestimated by 10cm and  $5^\circ$ .  
14  
15  
16

20  
21  
22  
23  
24  
25  
26  
27  
28

29 The largest errors between model and observations occur at locations that are adjacent to  
30 large regions of shallow water, e.g. Hilbre, Conwy, the three tide gauges Y,Z and AA in close  
31 proximity to each other and located near Barrow (Fig 1c), and at Morecambe (BB) and Fleetwood  
32 (CC). As shown by Jones et al (2009) although the mesh has high resolution in these areas, namely a  
33 mesh length of order 500m, this is not sufficient to accurately resolve the  $M_2$  tidal variations that  
34 occur over very short distances (less than 500m) in these coastal regions. This lack of resolution  
35 suggests that in order to improve the accuracy of the  $M_2$  tide in these regions, a higher mesh  
36 resolution is required. However without a more detailed and accurate set of bathymetry and a spatially  
37 varying friction coefficient reflecting bed types and bed forms, any improvement could be small. In  
38 addition the form of the “wetting/drying” algorithm will also influence the solution in the near shore  
39 region (see for example the discussion in Karna et al. (2011). However, since the primary aim here is  
40 to examine differences in the F.E. and F.V. calculations, using identical meshes, boundary forcing and  
41 water depth, this lack of high resolution in near coastal regions is not significant.

65

1 The  $M_4$  cotidal chart (Fig 3b), shows the  $M_4$  tidal amplitude increasing over the Celtic Sea  
2 from zero at the open boundary to a maximum of 10cm in the southern part of the Irish Sea.  
3  
4 Subsequently the  $M_4$  amplitude decreases to a minimum to the west of the Isle of Man (Fig 3b). A  
5  
6 rapid increase in the shallow coastal regions of the eastern Irish Sea is evident. This spatial  
7  
8 distribution is found in observations and shelf wide finite difference models (Davies and Kwong  
9  
10 2000). Comparisons with a high resolution (1km) finite difference limited area eastern Irish Sea  
11  
12 model (JD96), showed that the  $M_4$  distribution computed with the present model was of comparable  
13  
14 accuracy. The high accuracy obtained by JD96, was in part due to the specification of the  $M_4$  tide  
15  
16 along the open boundary of that model, which only covered the eastern Irish Sea. The fact that the  
17  
18 present model with no  $M_4$  input and covering a large area can reproduce this  $M_4$  distribution suggests  
19  
20 that the present model contains the necessary physics to reproduce the  $M_4$  tide in the region. As for  
21  
22 the  $M_2$  tide, it is evident from Table 3, that at a number of coastal locations there are significant errors  
23  
24 in the  $M_4$  tide computed with the model. This is in part, as discussed for the  $M_2$  tide, due to a lack of  
25  
26 mesh resolution. In addition in some shallow coastal regions (e.g. Barrow RI) there is extensive  
27  
28 “wetting and drying” which removes energy from the  $M_2$  tide, the amplitude of which is decreased  
29  
30 compared to observations due to excessive energy going into the  $M_4$  tide arising from the “wetting  
31  
32 and drying”. With a finer mesh and more accurate depth distribution the region of “wetting and  
33  
34 drying” would change, with an associated change in energy transfer from  $M_2$  to  $M_4$ . In a detailed study  
35  
36 of tide-surge interaction involving the spatial distribution of non-linear terms in coastal regions, Xing  
37  
38 et al (2010) showed that on the present mesh there was significant spatial variability in coastal regions  
39  
40 from one node to another.

41  
42  
43  
44  
45  
46  
47  
48 A rapid increase in  $M_6$  tidal amplitude (Fig 3c) occurs in shallow water in the Liverpool Bay  
49  
50 region and in the Cumbrian coastal area as water is particularly shallow here, and there is significant  
51  
52 “wetting and drying” which leads to a local increase in  $M_6$ . Point by point comparisons (Table 4)  
53  
54 show that at a number of shallow water locations e.g. Barrow, Birkenhead, Hilbre, Barrow HP, the  
55  
56 computed amplitude exceeds the observed. In these regions there is very rapid spatial variability from  
57  
58 one node to another, suggesting that the model mesh is too coarse. In addition the depth distribution  
59  
60  
61  
62  
63  
64  
65

1 used in the model is not sufficiently accurate to resolve local near coastal variations in water depth  
2 that determine the exact location of “wetting and drying” regions and the detailed distribution of the  
3  
4  $M_6$  tide. A close examination of tidal distributions in particular the higher harmonics namely  $M_4$  and  
5  
6  $M_6$  in regions such as the Solway estuary and Morecambe Bay (Fig 3b(ii) and 3c(ii)) clearly shows  
7  
8 significant small scale variability, suggesting that more detailed coastal resolution is required, with an  
9  
10 associated enhancement of the mesh, in order to resolve this variability. However, as shown by  
11  
12 Aldridge and Davies (1993) and Davies and Lawrence (1995) there is significant spatial variation in  
13  
14 bed types and bed forms over the Irish Sea, giving rise to spatial variability in the bottom friction  
15  
16 coefficient that must be taken into account in any detailed simulation of tides or surges in near shore  
17  
18 regions (e.g. Nicolle and Karpytchev 2007). Since, as stated previously the objective of the present  
19  
20 paper is a comparison of F.E. and F.V. models the use of a constant friction coefficient is justified.  
21  
22 However, the sensitivity of the various solutions to changes in the value of  $k$  will also be considered  
23  
24 later.  
25  
26  
27

### 28 29 30 3.2 The F.V. model with $k=0.003$ (Calc 1 (F.V.))

31  
32  
33 In a subsequent calculation (Calc 1 (F.V.)) the tidal distribution over the region was computed  
34  
35 with the F.V. model and  $k=0.003$ . The computed  $M_2$ ,  $M_4$  and  $M_6$  cotidal charts show similar  
36  
37 distributions to those found with the F.E. model. Although there is no significant difference in the  
38  
39 distribution of co-amplitude and co-phase lines in the region of the northern and southern boundaries  
40  
41 the location of the amphidromic point in the North Channel is slightly different to that found in the  
42  
43 F.E. model. In addition the position of the degenerate amphidromic point off the east coast of Ireland  
44  
45 has moved farther north. This has the effect of decreasing  $M_2$  amplitudes in the region to the north and  
46  
47 south of the Isle of Man, namely the western boundary of the eastern Irish Sea by the order of over  
48  
49 40cm (see difference plots Fig 4a(i)(ii)). A consequence of this is that tidal amplitudes in the shallow  
50  
51 coastal region of eastern Irish Sea computed with the F.V. model are of the order of 35cm to 40cm  
52  
53 lower than those computed with the F.E. model (see difference plots Fig 4a(i)(ii)) and found in  
54  
55 observations (Table 2). This suggests that in shallow coastal regions the  $M_2$  tide computed with the  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1 F.V. model is more heavily damped than that computed with the F.E. model, although there is little  
2 difference in phase.  
3

4  
5 For the  $M_4$  component, its distribution in the eastern Irish Sea (see difference plots Fig 4b (i)(ii))  
6 is comparable to that found with the F.E. model, although its magnitude at coastal gauges (Table 3) is  
7 reduced compared to the F.E. model, due to the reduction in the  $M_2$  tide in the F.V. model compared  
8 to the F.E. model. Although its magnitude is reduced, it shows a similar spatial distribution of high  
9 and low values at coastal ports, as found in the observations and the F.E. solution. For example (Table  
10 3), computed high (over 25cm)  $M_4$  amplitudes at Barrow, Birkenhead, Hilbre, Liverpool, New  
11 Brighton, Creetown, Conwy, Barrow (RI, HP), Morecambe, Fleetwood, with computed low (under  
12 10cm) at Douglas, Wylfa Head, Amlwch and STD Irish Sea occur in both solutions (Table 3). This  
13 suggests comparable  $M_4$  amplitude distributions, although quantitatively those computed with the  
14 F.V. model are below those computed with the F.E. model. In terms of phase differences between the  
15 solutions, at coastal gauges there are significant differences, and no clear pattern in the distribution of  
16 these differences. However, at off shore gauges (Q, R, S, T, U, V) there are only slight (on average of  
17 order  $4^\circ$ ) differences in the phase computed with the two models. This suggests that tidal distributions  
18 at off shore gauges can be accurately resolved, whereas at coastal gauges, further resolution is  
19 required in order for the small scale tidal variations to be resolved. However, the significant difference  
20 in the  $M_2$  tidal amplitudes in shallow regions between the F.E. and F.V models does suggest  
21 differences in their damping characteristics.

37  
38  
39  
40  
41  
42  
43

44 For the  $M_6$  tide, the F.V. model shows a similar spatial distribution to that found with the F.E.  
45 model, namely a decrease in amplitude from the region to the north-east of the Isle of Man, to a  
46 minimum to the east of the Isle of Man, and a rapid increase moving south of this and into Liverpool  
47 Bay. However, despite this agreement, difference plots (Fig 4c (i)(ii)) and Table 4, show on average a  
48 reduced  $M_6$  amplitude computed with the F.V. model compared to the F.E. model. This is certainly  
49 due to the differences found in the  $M_2$  tidal amplitude in the eastern Irish Sea region computed with  
50 these models. As with the F.E. model there is significant spatial variability in the phase computed  
51 with the two models in coastal areas, although more consistent phases are found at offshore gauges.

1 This again emphasises the need to refine the mesh in shallow regions in order to accurately resolve the  
2 higher harmonics.  
3

#### 4. Influence of bottom friction upon tidal distributions.

4  
5  
6  
7 In the previous section it was evident from Tables 2,3 and 4, that the F.E. model with  $k=0.0030$   
8 could accurately reproduce the  $M_2$  tide in the region. However, with this value of friction coefficient  
9 the F.V. model had a tendency to underestimate the  $M_2$  tide which had consequences for the other  
10 tidal constituents. In this series of calculations  $k$  is reduced to 0.0025 to see how this influences the  
11 tidal solutions.  
12  
13  
14  
15  
16  
17

##### 4.1 The F.E. model with $k=0.0025$ (Calc 2 (F.E.))

18  
19  
20  
21 Although the distribution of the co-amplitude and co-phase lines (not shown) computed with the  
22 F.E. model with  $k=0.0025$  is comparable to that found previously (Fig 3a (i)(ii)), the effect of  
23 reducing the bottom friction coefficient is to increase the  $M_2$  amplitude above that found in the  
24 observations (see Table 2). This arises because of a decrease in energy dissipation through bottom  
25 friction. It is evident from Table 2, that the phase of the tide is not appreciably influenced. This  
26 increase in  $M_2$  tidal amplitude is accompanied by an increase in amplitude of the  $M_4$  and  $M_6$  tide in  
27 the eastern Irish Sea (see Tables 3 and 4).  
28

32  
33  
34  
35

##### 4.2 The F.V. model with $k=0.0025$ (Calc 2 (F.V.)).

36  
37  
38  
39 In the case of the F.V. model, as with the F.E. model reducing  $k$  leads to an increase in tidal  
40 amplitude (see Tables 2,3,4). This produces a change in the location of the tidal amphidrome in the  
41 North Channel and off the east coast of Ireland, and an increase in the  $M_2$  amplitude computed with  
42 the F.V. model. However, it is evident compare Figs 5a (i)(ii) and Fig 3a(i)(ii) that the F.V. model  
43 even with  $k$  reduced to 0.0025, still underpredicts that computed with the F.E. model ( $k=0.003$ ) and  
44 found in observations (Calc 2, F.V.)(Tables 2,3,4). It is evident from Table 2, that at offshore gauges  
45 (Q,R,S,T,U,V) the  $M_2$  tidal amplitude computed with the F.E. model ( $k=0.0030$ ) tended to be  
46 overestimated by the order of 15cm. In the calculation with the F.V. model ( $k=0.0025$ )Calc 2(F.V.)  
47 the amplitude of the  $M_2$  tide is underestimated by a comparable amount, even though bottom friction  
48 is substantially less. In the case of the F.E. model ( $k=0.0030$ )(Calc1(F.E.)) the fact that the model  
49

64  
65

1 overestimates the tide at off shore gauges by 15cm, appears to be corrected for by enhanced  
2 dissipation in shallow water resulting in an accurate simulation of  $M_2$  tidal amplitude at coastal  
3 locations such as Birkenhead, Heysham and Liverpool (G.D.) (Table 2). On the other hand for the  
4 F.V. model (Calc 2(F.V.)) ( $k=0.0025$ ), the error of order -15cm, at off shore gauges, leads to an  
5 enhanced error at Birkenhead (-38cm), Heysham (-26cm), and Liverpool G.D. (-33cm) (Table 2, Calc  
6 2 (F.V.)). This suggests that the F.V. code over-damps the  $M_2$  tide in both deep and shallow water. In  
7 the case of the F.E. code, there is too little damping in deep water, with the overdamping in shallow  
8 water, to a certain extent correcting for it.

64  
65  
These differences in the  $M_2$  solution computed with the F.E. and F.V. model are reflected in the  
 $M_4$  and  $M_6$  solutions in Tables 3 and 4, and eastern Irish Sea co-tidal charts (Figs 5 (b) and (c)). In  
terms of the  $M_4$  tide it is evident from Table 3 (comparison of Calc 1 (F.E.) ( $k=0.0030$ ) and Calc 2  
(F.V.) ( $k=0.0025$ )) that the reduced  $M_2$  tidal elevation in the F.V. calculation leads on average to a  
reduction in the  $M_4$  tidal amplitude compared to the F.E. calculation, producing better agreement with  
observations at a number of ports (e.g. Hilbre, Liverpool, New Brighton). In terms of phase  
differences between the two solutions, on average these are of the order of  $10^\circ$ . In addition,  
comparison of co-tidal charts (Fig 3b(ii)(F.E.  $k=0.003$ ), and Fig 5b (F.V.  $k=0.0025$ )) shows a reduced  
 $M_4$  in the eastern Irish sea with the F.V. model even when  $k=0.0025$ .

For the  $M_6$  tide point values (Table 4) and comparison of Figs 3c(ii) and 5c show that the  
amplitude computed with the F.V. model (Calc 2 (F.V.),  $k=0.0025$ ) is smaller than that computed  
with the F.E. model (Calc 1 (F.E.),  $k=0.0030$ ), reflecting differences in the  $M_2$  solution between the  
two models. As discussed previously in connection with Calc 1, F.E. and F.V. intercomparisons, there  
is no clear pattern in the phase difference between the two solutions. These comparisons do however  
clearly show that even when the bottom friction coefficient is reduced in the F.V. model below that  
used in the F.E. model, the computed tidal amplitude is below the observed. This suggests that there is  
more damping in the F.V. model than the F.E. model.

1  
2 In order to further examine the differences between observations and the various model results it  
3 is valuable to compute (Tables 5 and 6) the ratio of the amplitudes of the  $M_4$  and  $M_6$  tides to the  $M_2$   
4 tide for locations where the amplitude exceeds 5cm. This value was chosen because amplitudes below  
5 5cm may be more prone to significant errors. Such a comparison is useful in that it indicates the  
6 extent to which energy is transferred from the fundamental to its higher harmonics.  
7  
8  
9

10  
11 Comparing results computed with  $k=0.0030$  (Tables 5 and 6) for the F.E. and F.V. models (Calcs  
12 1(F.E.) and 1(F.V.)) it is evident that on average, the  $M_4/M_2$  ratio, computed with the F.V. model is  
13 less than that determined with the F.E. model, reflecting the reduced  $M_2$  amplitude computed with the  
14 F.V. compared to F.E. model. However, in general both models show a similar variation in this ratio  
15 from one port to another, reflecting that they both produce a significant  $M_4$  tide in regions where  
16 observations show a large  $M_4$  tide.  
17  
18  
19  
20  
21  
22  
23  
24  
25

26 Although, as shown previously decreasing the value of bottom friction (Calcs 2 (F.E.) and  
27 2(F.V.)) leads to an increase in  $M_2$  amplitude in both models, the ratio of  $M_4$  to  $M_2$  on average  
28 decreases slightly due to the fact that the  $M_4$  amplitude is not appreciably influenced by this decrease  
29 in friction (Table 3).  
30  
31  
32  
33  
34  
35

36 For the  $M_6$  tidal constituent computed with  $k=0.003$  (Calcs 1) both models show similar  $M_6$  to  $M_2$   
37 ratios (Table 6), with the F.V. model on average having a lower value due to the reduced  $M_2$  tide  
38 computed with this model. When the bottom friction coefficient is reduced (Calcs2) both models  
39 show that on average this ratio increases slightly due to the increase in the  $M_2$  tide giving a larger  $M_6$   
40 tide as more energy is transferred to it.  
41  
42  
43  
44  
45  
46  
47

48 These similar spatial variations in  $M_4$  and  $M_6$  ratios, and changes with bottom friction suggest that  
49 both models exhibit a similar conversion of  $M_2$  energy into its higher harmonics, despite some  
50 differences in  $M_2$  amplitude.  
51  
52  
53  
54

55 4.3. The F.V. model with  $k=0.00125$  (Calc 3 (F.V.))  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1 Halving the value of bottom friction in the F.V. model to  $k=0.00125$ , (Calc (3)(F.V.)) causes  
2 the amphidromic point off the east coast of Ireland to move off shore and farther to the north (Fig  
3 6a(i)). This is consistent with tidal calculations of Davies and Aldridge (1993), who found that as  
4 bottom friction in a three dimensional spectral model of the Irish Sea was reduced this amphidromic  
5 point had a tendency to move to the east. The effect of this change in position of the amphidrome is to  
6 increase the tidal amplitude in the region to the north and south of the Isle of Man by the order of  
7 20cm (Fig 6a (i)(ii)) compared to the F.V. solution with  $k=0.0025$  (Fig 5a(ii)). This enhanced coastal  
8 amplitudes to a similar extent, as can be seen from Table 2 (compare Calc 2 (F.V.)( $k=0.0025$ )) and  
9 Calc 3 (F.V.)( $k=0.00125$ ). The effect of this change in  $k$ , upon phase was small (of the order of  $3^\circ$ ).  
10 Despite this reduction in  $k$ ,  $M_2$  amplitude at coastal gauges remained below those computed with the  
11 F.E. model with  $k=0.003$ , as shown in Table 2 (compare Calcs 1(F.E.) and 3 (F.V.)).

16  
17  
18  
19  
20  
21  
22  
23  
24

25 This reduction in  $k$  did not appreciably influence the  $M_4$  tide in the eastern Irish Sea computed  
26 with the F.V. model ( $k=0.00125$ ) compared with the earlier F.V. solution ( $k=0.0025$ )(see Table 3 and  
27 Fig 6b compared with 5b). In addition, away from the near shore region the F.V. model  $M_4$  tidal  
28 distribution computed with  $k=0.00125$  was comparable to that found in the F.E. model with  $k=0.003$   
29 (compare Fig 3b(ii) and 6b) although in the near shore region there were some differences. Also there  
30 were some changes in phase at coastal gauges which on average were reduced by about  $20^\circ$ , although  
31 this varied from location to location. As found previously, the F.V. model tended to underestimate the  
32  $M_4$  amplitude compared to the F.E. model ( $k=0.0030$ ) in near shore regions (compare Figs 3b(ii) and  
33 6b). For the  $M_6$  component of the tide the distribution in the eastern Irish Sea (Fig 6c) was appreciably  
34 different to that found with the F.V. model ( $k=0.0025$ ) (Fig 5c) and that computed with the F.E.  
35 model ( $k=0.003$ )(Fig 3c(ii)). In essence  $M_6$  tidal amplitudes in the northern part of the region had  
36 increased with a slight decrease in the Liverpool Bay area and off the north coast of Wales. Since the  
37 quadratic friction term is a major source of the  $M_6$  tide, it is evident that the value of  $k$  can influence  
38 its distribution in the eastern Irish Sea, and at coastal locations (compare Calcs 2 (F.V.) and Calc 3  
39 (F.V.) in Table 4).

61  
62  
63  
64  
65

1 This series of calculations clearly shows that even when  $k$  is reduced in the F.V. calculation,  
2 to such a degree that the amphidromic point off the east coast of Ireland moves to the east, the model  
3 still slightly underpredicts the  $M_2$  tide in the eastern Irish Sea compared to the observed. In addition  
4 this significant reduction in  $k$ , changes the  $M_6$  tidal distribution in the region. Since bottom friction  
5 plays an important role in  $M_6$  generation, and to examine to what extent three dimensional effects  
6 influence tidal elevations, a three dimensional F.V. calculation was performed.  
7  
8  
9  
10  
11  
12  
13

14 5. Three dimensional F.V. model with minimum  $k=0.0025$  (Calc 4(F.V.)).  
15  
16

17 In order to determine three dimensional effects the F.V. model was run with 21 sigma levels and  
18 bottom friction formulation given by equation (1). Consequently over the deeper water region  
19 ( $h>60\text{m}$ )  $k=0.0025$ , however in shallow water where the value of  $Z_r$  is small, and the bottom boundary  
20 layer can be resolved, then  $k$  is determined by the values of  $Z_r$  and  $Z_0$  (taken as  $0.001\text{m}$ ), and is larger  
21 than  $0.0025$ .  
22  
23  
24  
25  
26  
27  
28

29 The computed  $M_2$  co-tidal chart determined with the three dimensional model, (Fig 7a(i)(ii))  
30 shows a similar distribution to that determined with the F.V. model with  $k=0.00125$ . Although the  
31 bottom friction coefficient in the three dimensional model has a minimum value of  $0.0025$ , and is  
32 higher in shallow water, the bed stress is determined by the bottom current rather than the depth mean  
33 current. Consequently the bed stress will be smaller than in a two dimensional model with an  
34 equivalent value of  $k$ . This is the reason why the cotidal chart computed with the three dimensional  
35 model corresponds more closely to that computed with the two dimensional model with  $k=0.00125$   
36 than  $k=0.0025$ . Similarly in the eastern Irish Sea the position of the  $220\text{cm}$  co-amplitude lines (Fig  
37 7a(ii)) occur at similar locations to those found in the two dimensional F.V. model ( $k=0.00125$ ).  
38 However, the location of the  $240\text{cm}$  co-amplitude line is slightly different, with the  $310^\circ$  co-phase line  
39 showing the effect of enhanced bottom friction in the three dimensional model in the eastern Irish Sea.

54 A port by port comparison (Table 2, Calc 3 (F.V.) and Calc 4 (F.V., 3D)) reveals a reduction of  
55 about  $3\text{cm}$  and small phase change of a few degrees between the two solutions, with the three  
56  
57

1 dimensional F.V. model also underpredicting the tide compared to the F.E. model ( $k=0.003$ ) and  
2 observations, despite the reduced friction coefficient over the majority of the region.  
3

4  
5 For the  $M_4$  tide in the eastern Irish Sea (Fig 7b), in the region of the Isle of Man there are no  
6 appreciable differences in the 2D and 3D solutions (compare Fig 6b and 8b). However, in the coastal  
7 region of the eastern Irish Sea, the  $M_4$  amplitude in the 3D model exceeds that found in the 2D model  
8 and this is clearly seen in Table 3 (compare Calcs 3 and 4). In particular at ports such as Birkenhead,  
9 Hilbre, Liverpool and New Brighton, the  $M_4$  tidal amplitude from the 3D model exceeds that from the  
10 2D model by about 3cm. In terms of phase there are differences at these ports of the order of  $15^\circ$  to  
11  $20^\circ$ .  
12  
13  
14  
15  
16  
17  
18  
19  
20

21 For the  $M_6$  tide in the eastern Irish Sea, it is evident from a comparison of Figs 7c and 6c that its  
22 amplitude had been reduced in the northern part of the region from that found in the 2D model. This  
23 reduction in amplitude with an associated change in phase is evident in the coastal gauge comparisons  
24 (Table 4, Calcs 3 and 4).  
25

27  
28  
29  
30

31 This comparison between 2D and 3D versions of the F.V. model and the F.E. model, clearly  
32 shows that even when calculations are performed with the 3D model with a reduced value of  $k$   
33 compared to the F.E. model, the  $M_2$  tidal amplitude is underestimated. This confirms the results found  
34 with the earlier 2D versions of the models, namely that the damping in the F.V. model is significantly  
35 larger than that in the F.E. model.

## 43 6. Concluding Remarks 44

45  
46 An intercomparison of  $M_2$  tidal distributions and its higher harmonics over the Celtic and Irish  
47 Sea regions has been performed using a F.E. and F.V. model. The same irregular mesh, bottom  
48 topography and  $M_2$  tidal open boundary forcing was used in all calculations. By this means  
49 differences in F.E. and F.V. solutions could be attributed to differences in model formulation. By  
50 using the same model domain, topography and open boundary forcing as that employed in an accurate  
51 tidal finite difference model, there was no inherent bias towards the F.E. or F.V. models. Also the

64  
65

1 influence of changing bottom friction coefficient in each model could be determined. In addition in  
2 the case of the F.V. model comparisons between 2D and 3D models were made.  
3  
4

5 Comparisons with a detailed set of  $M_2$  tidal elevation amplitudes in the eastern Irish Sea, showed  
6 that an accurate solution was obtained with the F.E. model with  $k=0.003$ . In the case of the F.V.  
7 model with the same  $k$  value, the solution yields  $M_2$  amplitudes below those found in the F.V. model  
8 and in observations. However, there were no major differences in phase between the models, which  
9 were in general in good agreement with measurement. For the  $M_4$  tide, the F.E. model had a slight  
10 bias to overestimate its amplitude, with significant differences between the observed and computed  
11 phase. In the case of the F.V. model, because the  $M_2$  tide was underestimated compared to the F.E.  
12 model, the  $M_4$  tide was also reduced, giving a slightly better agreement with observations. These  
13 differences in  $M_2$  and  $M_4$  amplitudes between the two models were reflected in the  $M_4$  to  $M_2$  ratio.  
14 However, both models had significant phase errors when compared to coastal gauges. In addition  
15 there were no systematic differences in either elevation or phase between the two models from one  
16 coastal location to another. A detailed examination of the two solutions in the eastern Irish Sea, away  
17 from the near shore region showed that they were comparable to each other. However in the near  
18 shore area, both solutions showed small scale variability in elevation and phase that was not  
19 consistent from one solution to another. This suggested that the mesh in this region was not  
20 sufficiently fine to accurately resolve the small scale spatial variability that occurs in the  $M_4$  tide. In a  
21 separate study of tide-surge interaction, Xing et al. (2010) found significant spatial variability in the  
22 non-linear terms from one node to another in the near shore region. This clearly shows that the non-  
23 linear terms which are important for  $M_4$  generation in the coastal region were not being accurately  
24 resolved on the present mesh in the coastal region, suggesting that a finer mesh was required in this  
25 area. In addition the “wetting and drying” algorithm can influence the tide in the near shore region  
26 particularly if the mesh is not sufficiently fine (Karna et al. 2011).

53

54 Comparison of the  $M_6$  tide computed with both models showed significant differences over the  
55 eastern Irish Sea, with amplitudes computed with the F.V. model below those found with the F.E.  
56 model. Since the  $M_6$  tide is primarily generated from the  $M_2$  tide through the quadratic friction term  
57  
58  
59  
60  
61

1 and to a certain extent from  $M_2$  and  $M_4$  interaction through the non-linear terms (see for example  
2 Jones and Davies (2010) and references therein for details), the fact that the  $M_2$  tide computed with  
3 the F.V. model was below that computed with the F.E. model meant that the  $M_6$  tide was appreciably  
4 less. In addition the short wavelength of the  $M_6$  tide meant that there was significant spatial variability  
5 over the eastern Irish Sea, suggesting that a further refinement of the mesh could be useful. In addition  
6 as shown in the non-linear interaction study of Xing et al. (2010) in the near shore region there is  
7 significant spatial variability from one node to another in the quadratic friction term, suggesting that  
8 as for the  $M_4$  tide a finer near shore mesh is required.  
9

10  
11  
12  
13  
14  
15  
16  
17  
18 Calculations with a reduced value of  $k$ , namely  $k=0.0025$ , showed that the F.E. model  
19 significantly overestimates the  $M_2$  tide, while the F.V. model consistently underestimates its value,  
20 although the phase of the tide was not appreciably influenced by this change in  $k$ . For the reasons  
21 discussed above, changes in the  $M_2$  tide are reflected in the  $M_4$  and  $M_6$  tidal distributions. A further  
22 reduction of  $k$  to  $k=0.00125$ , in the F.V. model gave rise to an offshore displacement of the  $M_2$   
23 amphidromic point off the east coast of Ireland, with an associated increase of the order of 20cm in  
24  $M_2$  tidal amplitude in the eastern Irish Sea, but little change in phase. Although amplitudes were still  
25 slightly lower than those computed with the F.E. model, on average they agreed with observations  
26 with a comparable accuracy to those found with the F.E. model and  $k=0.003$ . The  $M_4$  tide in the  
27 eastern Irish Sea was not substantially affected by this change in friction although the  $M_6$  tidal  
28 distribution did change, since this constituent is primarily generated by bottom friction.

44 Calculations with a three dimensional (3D) version of the F.V. model with a minimum friction  
45  $k=0.0025$ , and enhanced friction in shallow water, for the  $M_2$  tide gave a comparable solution to the  
46 two dimensional (2D) version with  $k=0.00125$ . In addition this solution was in good agreement with  
47 observations in the eastern Irish Sea. In terms of the  $M_4$  tide both calculations showed a similar  
48 distribution away from the coastal region, where the 3D version gave a slightly higher of order 2cm  
49 amplitude in the  $M_4$  tide, and on average a slightly better agreement with observations. For the  $M_6$   
50 tide the 2D and 3D models gave different distributions over the eastern Irish Sea reflecting differences  
51 in bottom friction formulation, namely in terms of the depth mean current in the 2D model and bottom

1 current in the 3D model. The significant spatial variability in both the observed and computed  $M_6$  tide  
2 suggested that on the present mesh the detailed model/data intercomparison presented in the Tables  
3 was rather inconclusive in terms of which model formulation was most accurate for the  $M_6$  tide. Even  
4 if the mesh in the eastern Irish Sea was refined to improve its ability to resolve small spatial scale  
5 variations in the tide, it would be necessary to obtain an enhanced representation of bottom  
6 topography, which is not currently available. Also in the near shore region the form of the  
7 “wetting/drying” algorithm used in the model will influence the near coastal tidal distribution. In  
8 addition as shown by Aldridge and Davies (1993) bed types and bed forms vary significantly in the  
9 area, and in any detailed model skill assessment it would be necessary to use a spatially varying  $k$   
10 reflecting this. As shown by Nicolle and Karpytchev (2007) such variations are important for tidal  
11 simulations in coastal regions although are currently not available over the whole domain presented  
12 here. However, despite this lack of a detailed knowledge of the spatial variability of  $k$ , and accurate  
13 near shore topography and an optimal “wetting/drying” condition, the calculations presented here  
14 show that for a given  $k$  there are differences in the tidal distributions computed with the F.E. and F.V.  
15 models, with the F.V. model having a larger dissipation than the F.E. model. In addition both models  
16 show similar changes to variations in  $k$ , with the 3D F.V. model giving an accurate representation of  
17 the tide with  $k=0.0025$  over the deep water part of the model, and increasing in coastal regions.
