(Ga_{1-x}Fe_x)Sb is one of the promising ferromagnetic semiconductors for spintronic device applications because its Curie temperature (T_C) is above 300 K when the Fe concentration x is equal to or higher than ~ 0.20 . However, the origin of the high T_C in (Ga,Fe)Sb remains to be elucidated. To address this issue, we use resonant photoemission spectroscopy (RPES) and first-principles calculations to investigate the x dependence of the Fe 3d states in (Ga_{1-x}Fe_x)Sb ($x = 0.05, 0.15, \text{ and } 0.25$) thin films. The observed Fe 2*p*-3*d* RPES spectra reveal that the Fe-3*d* impurity band (IB) crossing the Fermi level becomes broader with increasing x , which is qualitatively consistent with the picture of double-exchange interaction. Comparison between the obtained Fe-3*d* partial density of states and the first-principles calculations suggests that the Fe-3*d* IB originates from the minority-spin (\downarrow) e states. The results indicate that enhancement of the double-exchange interaction between e_{\downarrow} electrons with increasing x is the origin of the high T_C in (Ga,Fe)Sb.

I. INTRODUCTION

Ferromagnetic semiconductors (FMSs) are alloy semiconductors which show both semiconducting and ferromagnetic properties. In III–V FMSs, cation sites (group III sites) are partially replaced by a sizable amount of magnetic impurities such as Mn and Fe ions. The ferromagnetism of FMSs is considered to be caused by the magnetic interaction between the doped magnetic ions mediated by the spin of the carriers. This ferromagnetism is called carrier-induced ferromagnetism [1]. In order to explain the ferromagnetism of FMSs, two models in which ferromagnetic interaction is mediated by itinerant carriers (band conduction) [2,3] and localized carriers (hopping conduction) [4,5] have been proposed so far. The former and the latter are called the Zener's *p*-*d* exchange model and the impurity band (IB) model [6], respectively. Here, the characteristic difference between these models is caused by the position of the 3*d* impurity band relative to the Fermi level in the valence-band structure.

The Mn-doped III–V FMSs, such as (In,Mn)As [7–10] and (Ga,Mn)As [11–13], have been intensively studied as prototypical FMSs for more than twenty years. Nevertheless, they have some issues to be solved for device applications, that is the Mn-doped FMSs show low Curie temperature (T_C) below room temperature [14,15] and have only *p*-type carriers. Recently, Fe-doped III–V FMSs such as *n*-type (In,Fe)As [16–18], *n*-type (In,Fe)Sb [19–21], and *p*-type (Ga,Fe)Sb [22–24] have been successfully grown by molecular beam epitaxy (MBE). Since the doped Fe ions in the III–V semiconductors are expected to substitute for the cation (In³⁺ or Ga³⁺) sites as Fe³⁺ and conducting carriers can be introduced by donor/acceptor doping, off-stoichiometry, and defects, one can independently control the concentrations of Fe ions and carriers in Fe-doped FMSs. Furthermore, the highest T_C values reported so far in (In_{0.65}Fe_{0.35})Sb (385 K) [21] and (Ga_{0.8}Fe_{0.2})Sb (> 400 K) [25] are well above room temperature. Considering these advantages, Fe-based FMSs are more promising materials for practical semiconductor spintronics devices operating at room temperature. However, the origin of the high T_C has not been unveiled yet. Since the electronic structures of Fe-doped FMSs with T_C higher than room temperature have not been fully clarified, understanding the origin

of the high- T_C ferromagnetism from the electronic structure point of view is indispensable for the design and realization of functional FMSs.

As for (Ga,Fe)Sb, some experimental [26–28] and theoretical [29–31] studies on its electronic structure were performed to understand the mechanism of the carrier-induced ferromagnetism. The local electronic structure, magnetic properties of Fe ions, and the valence-band (VB) structure were investigated by x-ray absorption spectroscopy (XAS), x-ray magnetic circular dichroism (XMCD), and resonant photoemission spectroscopy (RPES) [26]. From these experiments, it was found that Fe ions in (Ga,Fe)Sb take the $3d$ [6] configuration, which has both itinerant and correlated nature of $3d$ electrons, and there is a finite Fe partial density of states (PDOS) at the Fermi level (E_F). The Fe PDOS at E_F is consistent with the IB model and the itinerant nature of $3d$ electrons is attributed to the p - d exchange interaction through the finite sp - d hybridization. Hence these results suggest that both the double-exchange interaction and the p - d exchange interaction contribute to the ferromagnetism. We have recently studied the electronic states of (Ga_{0.95},Fe_{0.05})Sb in the vicinity of E_F by soft x-ray angle-resolved photoemission spectroscopy (SX-ARPES) [27]. This study indicates that the electronic structure of (Ga_{0.95},Fe_{0.05})Sb is consistent with the IB model and the origin of its ferromagnetism is the double-exchange interaction. The first-principles calculations for (Ga,Fe)Sb [29–31] well reproduce the observed electronic structure. The Fe-concentration dependence of the VB of (Ga,Fe)Sb has been studied by infrared (IR) magnetic circular dichroism (MCD) [28]. The IR-MCD results can be explained by the IB model and suggest that E_F gradually move upwards with the increase of the Fe concentration. However, the origin of the high T_C in (Ga,Fe)Sb is still poorly understood, since the electronic structure of the heavily Fe-doped (Ga,Fe)Sb has never been directly observed so far. In this paper, we reveal the Fe-concentration (x) dependence of the Fe $3d$ states of (Ga_{1- x} ,Fe _{x})Sb with $x = 0.05, 0.15,$ and 0.25 by RPES measurements. Systematic analyses of the Fe $2p$ - $3d$ RPES spectra indicate that the Fe $3d$ states near E_F play a key role to induce the high- T_C ferromagnetism.

II. EXPERIMENT

(Ga_{1- x} ,Fe _{x})Sb thin films ($x = 0.05, 0.15,$ and 0.25) with a thickness of 30 nm were grown on p -type GaAs(001) substrates by MBE, where the growth condition was the same as the previous research [22,23]. The surface of the films was covered by a thin amorphous Sb capping layer to avoid surface contamination. The sample structure is, from top to bottom, Sb capping layer 1–2 nm/(Ga_{1- x} ,Fe _{x})Sb, 30 nm/GaSb, 100 nm/AlSb, 100 nm/AlAs, 10 nm/GaAs, 100 nm/ p -GaAs substrate. Since the thickness of the capping layer was comparable with the mean free path or escape depth (1–2 nm) of photoelectrons in the soft x-ray region, we were able to measure photoemission signals without removing the capping layer [32]. During the MBE growth, the excellent crystallinity of the samples was confirmed by reflection high-energy electron diffraction. The values of T_C of (Ga_{1- x} ,Fe _{x})Sb with $x = 0.05, 0.15,$ and 0.25 , which were estimated by MCD [22–24], are about 40, 125, and above 300 K, respectively.

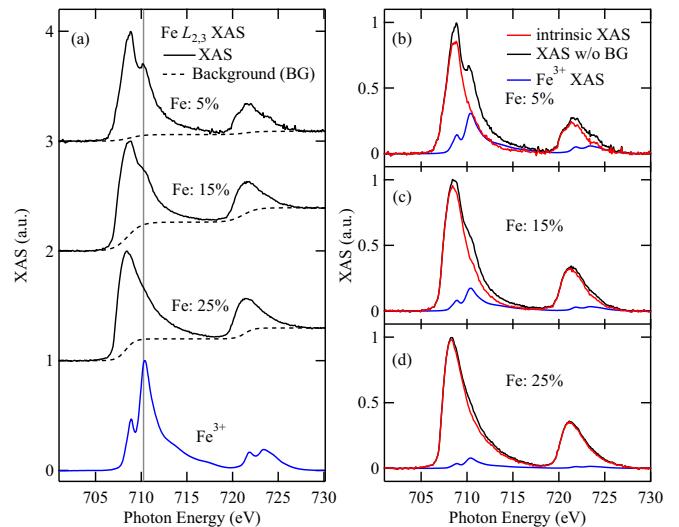

FIG. 1. XAS spectra at the Fe $L_{2,3}$ absorption edge. (a) XAS spectra of (Ga_{1- x} ,Fe _{x})Sb ($x = 0.05, 0.15,$ and 0.25) (black curves) and Fe³⁺ (blue curve) [36]. Black dashed curves represent the backgrounds. Gray vertical line denotes peak position of the Fe³⁺. (b)–(d) Decomposition analysis for the XAS spectra. Intrinsic and extrinsic Fe³⁺ components are separately shown by red and blue curves, respectively. Here, the black curves are the XAS spectra without background in Fig. 1(a).

The RPES experiments were performed at beamline BL23SU of SPring-8. The measurements were conducted under an ultrahigh vacuum below 1.3×10^{-8} Pa at a temperature of 30 K. The photon energy ($h\nu$) of the incident beam was varied from 690 to 740 eV and circular polarization was used for the measurements. The total energy resolution including the thermal broadening was between 100 and 160 meV depending on $h\nu$. The E_F position of RPES spectra has been corrected by the Fermi edge of an Au foil in electrical contact with the samples. Fe $L_{2,3}$ x-ray absorption spectroscopy (XAS) spectra were measured in the total-electron-yield mode.

First-principles calculations were performed on a $3 \times 3 \times 3$ GaSb supercell with one substitutional Fe atom, namely, (Ga₂₆,Fe₁)Sb₂₇ (3.7% Fe), using the full-potential augmented-plane-wave method as implemented in the WIEN2K code [33]. The experimental lattice constant of 6.085 Å, estimated from Vegard’s law in Ref. [23], was used for the calculation, and lattice relaxation was not taken into account. For the exchange-correlation potential, the generalized gradient approximation (GGA) of Perdew-Burke-Ernzerhof parametrization [34] was employed with/without the empirical Hubbard U (GGA+ U) [35] accounting for the on-site Coulomb correlation of Fe $3d$ electrons. Spin-orbit interaction was also included. The Brillouin-zone integration was performed on a $4 \times 4 \times 4$ k -point mesh.

III. RESULTS AND DISCUSSION

A. XAS spectra at the Fe $L_{2,3}$ absorption edge

Figure 1(a) shows XAS spectra at the Fe $L_{2,3}$ absorption edge of (Ga_{1- x} ,Fe _{x})Sb ($x = 0.05, 0.15,$ and 0.25) (black curves), where the black dashed curves represent the

background components. Here, the Fe $L_{2,3}$ XAS spectrum of α -Fe₂O₃ is also shown as a reference spectrum of Fe³⁺ (blue curve) [36]. Besides the main peak at \sim 708 eV, there is a shoulder structure at \sim 710 eV in the XAS spectra of (Ga,Fe)Sb. The previous XMCD and RPES studies [26] showed that the shoulder component can be attributed to Fe³⁺ oxides (such as α -Fe₂O₃) and is not related to the ferromagnetism in (Ga_{1-x},Fe_x)Sb. The oxidized components in the present capped (Ga,Fe)Sb samples are less than that in a previous uncapped (Ga,Fe)Sb thin film [26], suggesting that the surface of our samples is well protected by the amorphous Sb capping layer from oxidation.

To extract the intrinsic components of (Ga,Fe)Sb, the Fe $L_{2,3}$ XAS spectra have been decomposed using the Fe³⁺ reference spectrum. Figures 1(b)–1(d) show the decomposition analysis for the XAS spectra of (Ga_{1-x},Fe_x)Sb. Here, the red, black, and blue curves represent intrinsic XAS spectra of (Ga,Fe)Sb, raw XAS spectra, and the reference spectra of Fe³⁺, respectively. The intrinsic XAS spectra are obtained by eliminating the Fe-oxide component from the raw XAS spectra. Comparing these intrinsic spectra, the line shapes of the spectra are nearly identical to each other irrespective of x . This result indicates that the valence states (local electronic structure) of Fe ions are independent of x in (Ga,Fe)Sb.

B. RPES: Comparison between on- and off-resonance spectra

According to the previous SX-ARPES result [27], the electronic state of Fe 3d in the vicinity of E_F plays a key role in the ferromagnetism based on the double-exchange interaction, which originates from the exchange of electrons between Fe ions through Sb ions. First-principles calculations suggest that the IB broadens with increasing the concentration of magnetic impurities in the case of double-exchange interaction due to kinetic energy gain [37,38]. Thus, the VB structure of (Ga,Fe)Sb is expected to depend on x . To characterize the x dependence of the Fe-3d PDOS in the VB structure, we have conducted RPES measurements on the (Ga_{1-x},Fe_x)Sb ($x = 0.05, 0.15, \text{ and } 0.25$) thin films and analyzed the spectra in detail. The resonant enhancement of the photoemission intensity measured at $h\nu = 708$ eV should reflect the energy position of the ferromagnetic component of Fe 3d states in (Ga_{1-x},Fe_x)Sb, because Fe L_3 XMCD has a prominent peak at $h\nu = 708$ eV, the intensity of which as a function of magnetic field shows a ferromagnetic behavior [26]. Figure 2(a) shows the RPES spectra of the (Ga_{1-x},Fe_x)Sb thin films taken at $h\nu = 708$ eV (on resonance) and $h\nu = 704$ eV (off resonance), respectively. These spectra are normalized to the intensity of incident x rays. To extract the resonant behavior, the off-resonance spectra are subtracted from the on-resonance ones. Figure 2(b) shows the differences between the on- and off-resonance spectra. Depending on x , spectral differences appear at around E_F (black dashed arrows) and binding energy (E_B) of 1.6 eV (black solid arrows). That is, the intensity at around E_F increases and the peak at around 1.6 eV becomes vague with increasing x .

The previous RPES study of (Ga,Fe)Sb [26] demonstrated that the difference spectra are composed of symmetric and asymmetric Gaussian components originating from the Fe-3d PDOS and Auger peak, respectively. In the previous RPES

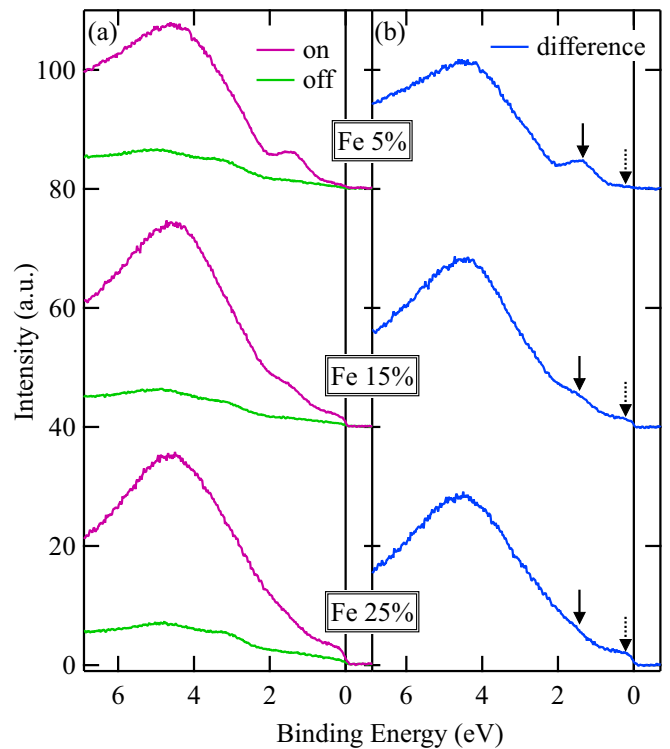

FIG. 2. RPES spectra of (Ga_{1-x},Fe_x)Sb (a) On(off)-resonant spectra of $x = 0.05, 0.15, \text{ and } 0.25$ taken at $h\nu = 708$ eV (704 eV). Purple (green) curves represent on(off)-resonant spectra. (b) The difference spectra (blue curves), which are differences between the on- and off-resonant spectra.

study, there were two symmetric components around $E_B = 1.7$ and 10.3 eV and an asymmetric Auger component around $E_B = 4.0$ eV. To identify these components in the present study, the difference spectra are fitted by a linear combination of the exponentially modified Gaussian for the asymmetric Auger component, which do not represent the Fe-3d electronic states, and Gaussian functions for the symmetric component, as shown in Figs. 3(a)–3(c). These fittings are conducted except for the range in the vicinity of E_F (-0.14 – 1.2 eV). The symmetric components around $E_B = 1.6$ eV and $E_B = 2.6$ eV are denoted by α and γ , respectively. No peak around $E_B = 2.6$ eV has been observed in the chemically etched (Ga,Fe)Sb [26]. Since the γ component is not resonantly enhanced at $h\nu = 710$ eV, which corresponds to the main peak of the Fe³⁺ XAS spectrum, the γ component does not originate from the oxidized Fe³⁺ ions. Red curves shown in Figs. 3(d)–3(f) represent the spectra after subtracting the fitted asymmetric Gaussian component from the difference spectra, which reflect the PDOS of Fe 3d electrons. The difference between the Fe-PDOS spectra and the $\alpha + \gamma$ spectra corresponds to the Fe-3d IB in the vicinity of E_F observed with SX-ARPES [27], as shown by blue filled areas in Figs. 3(d)–3(f).

C. Fe concentration dependence of Fe-3d PDOS

The peak position and the width of the α component depend on x . To elucidate the x dependence of the α and γ

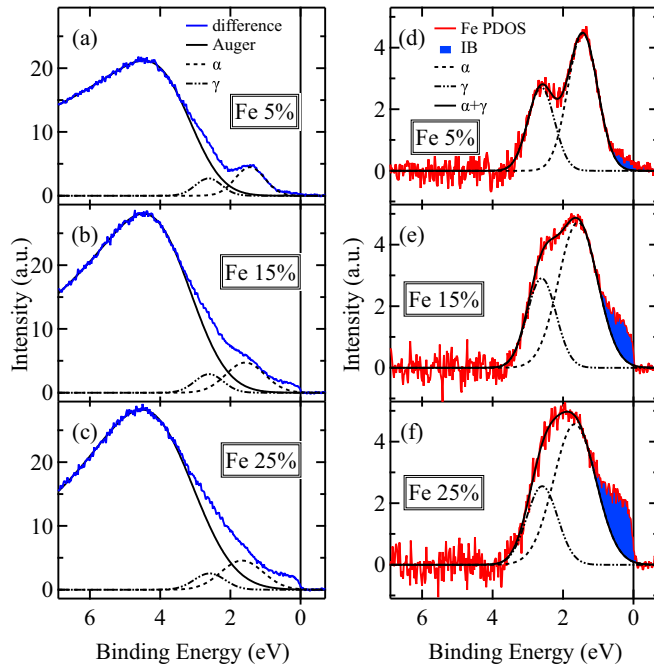

FIG. 3. Decomposition analysis of the RPES spectra of the $(\text{Ga}_{1-x},\text{Fe}_x)\text{Sb}$ thin films. (a)–(c) Subtraction of the Auger component from the spectra shown in Figs. 2(d)–2(f), respectively. Solid black, dashed, dash-dotted, and blue solid curves are Auger components fitted by using asymmetric Gaussian function, fitting components of two Gaussian functions for α and γ components, and the difference spectra. These fittings are conducted except for the range in the vicinity of E_F (fitting range: $1.2 \text{ eV} < E_B < 7.0 \text{ eV}$). (d)–(f) Fe-PDOS spectra (red curves) are obtained by subtracting the Auger components from the difference spectra (blue curves). Here, dashed, points-dashed, and solid black curves represent fitted α , γ , and $\alpha + \gamma$ components, respectively. The blue filled areas represent the Fe-3d IB component.

components quantitatively, the values of peak positions (PPs) and full width at half maximum (FWHM) of α and γ for $(\text{Ga}_{1-x},\text{Fe}_x)\text{Sb}$ are compared. The values of FWHM represent the broadening of the states. Figure 4(a) shows the PP of the α (red markers) and γ (blue markers) components relative to that of $(\text{Ga}_{0.95},\text{Fe}_{0.05})\text{Sb}$ as a function of x . The value of PP of the α component increases with increasing x as shown in Fig. 4(a). In contrast, the PP of the γ component seems independent of x . Figure 4(b) shows the FWHM of the α and γ components. While the value of FWHM of the γ component is nearly identical irrespective of x within the experimental accuracy, that of the α component increases with increasing x . Both the PP and FWHM of the γ components are independent of x , indicating that the γ is an extrinsic component. As described above, the γ component is different from the Fe^{3+} oxides, and therefore, the γ component likely originates from some kinds of extrinsic precipitates between the surface of the $(\text{Ga}_{1-x},\text{Fe}_x)\text{Sb}$ films and the capping layers. On the other hand, the PP and FWHM of the α component systematically changes with x , reflecting the change of the intrinsic Fe-3d PDOS with x in $(\text{Ga}_{1-x},\text{Fe}_x)\text{Sb}$.

The IR-MCD study on $(\text{Ga}_{1-x},\text{Fe}_x)\text{Sb}$ [28] has demonstrated that the sp bands move to the high- E_B direction with

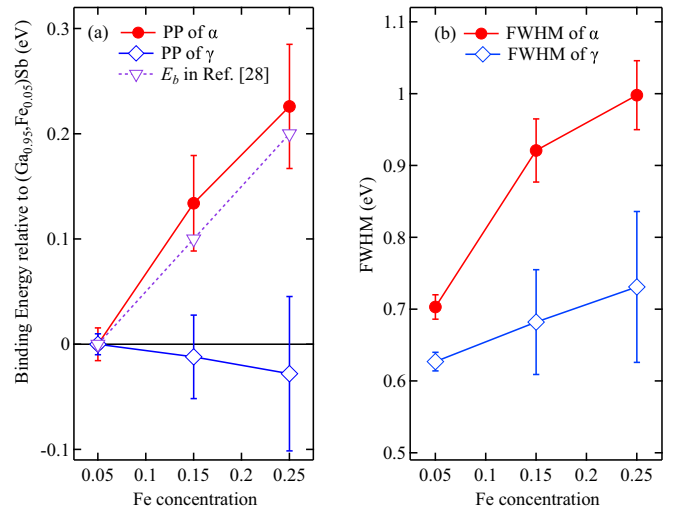

FIG. 4. Peak position (PP) and FWHM of the α and γ components. (a) Binding energy of PP relative to that of $(\text{Ga}_{0.95},\text{Fe}_{0.05})\text{Sb}$ of the α (red markers) and γ (blue markers). Here, E_b is the distance between E_F and the VB at the L point (purple markers). (c) FWHM of the α and γ components. Red and blue points/lines denote the α and γ components, respectively.

the increase of x because the E_F moves upwards. The shifts of the sp bands relative to those of $(\text{Ga}_{0.95},\text{Fe}_{0.05})\text{Sb}$ estimated from the IR-MCD results are plotted in Fig. 4(a) (purple markers). Figure 4(a) shows that the x dependence of the PP of the α component follows the same trend as that of the sp bands. This result indicates that the shift of the α component with increasing x corresponds to the chemical potential (E_F) shift in $(\text{Ga},\text{Fe})\text{Sb}$.

The x dependence of the Fe-3d IB near E_F is different from that of the α component. Figure 5(a) shows the intrinsic Fe-3d PDOS with different x . It should be noted here that the shifts of the Fe-3d-IB tail (solid blue arrows) with increasing x are larger than the peak shifts of the α component (black dashed arrows). This indicates that the Fe-3d IB broadens with increasing x since the difference of the shifts is not explained by the chemical potential shift. The broadening of the Fe-3d IB is also suggested in the IR-MCD study of $(\text{Ga},\text{Fe})\text{Sb}$ [28]. The broadening of the IB with the increase of magnetic impurities is also predicted by first-principles calculations for $(\text{Ga},\text{Mn})\text{N}$ [38], where the Mn-3d IB crosses E_F as in the case of Fe-3d IB in $(\text{Ga},\text{Fe})\text{Sb}$. This broadening of the Fe-3d IB with increasing x observed in $(\text{Ga},\text{Fe})\text{Sb}$ is qualitatively consistent with the picture of double-exchange interaction [38–40]. Therefore, this result indicates that the origin of ferromagnetism in $(\text{Ga},\text{Fe})\text{Sb}$ is double-exchange interaction irrespective of x . Although the width of IB is presumably proportional to square root of x Refs. [37,38], it is difficult to elucidate the x dependence of the bandwidth in $(\text{Ga},\text{Fe})\text{Sb}$ experimentally since the occupation and the bandwidth of the IB simultaneously change with x .

D. Discussion

Based on the experimental findings, let us discuss the x dependence of the Fe-3d electronic states and its effect on the

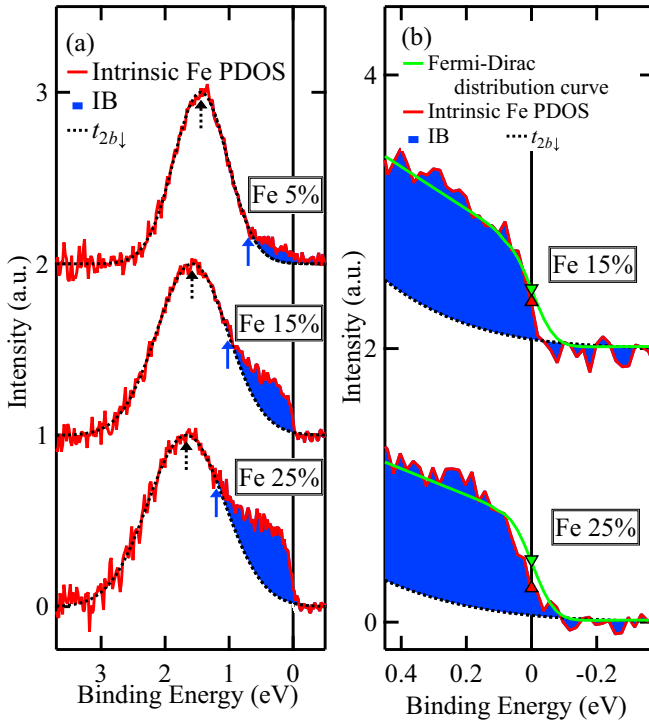

FIG. 5. Intrinsic Fe 3d PDOS of $(\text{Ga}_{1-x},\text{Fe}_x)\text{Sb}$. (a) Spectra with the extrinsic component subtracted from the spectra shown in Figs. 3(d)–3(f). Here, dashed and solid red curves represent fitted α , and intrinsic Fe 3d-PDOS components, respectively. The dashed black arrows denote the peak position of $t_{2b\downarrow}$. The blue solid arrows are a guide to the eyes tracing the tail of the Fe-3d IB. (b) Enlarged view of (a), where green curves represent the Fermi-Dirac distribution curves with backgrounds. Each curve is normalized so that the value at E_F of the Fermi-Dirac distribution curve is 0.5. Red and green triangles represent the points at E_F of the intrinsic Fe PDOS, and Fermi-Dirac distribution curves, respectively. The depletions of DOS at E_F are roughly estimated as 11% and 46% for $(\text{Ga}_{1-x},\text{Fe}_x)\text{Sb}$ with $x = 0.15$ and 0.25 , respectively.

ferromagnetism. From the observations described above, with the increase of x , the Fe 3d-IB component below E_F and the α peak become broader and the PP of α moves to the high- E_B direction.

To discuss the origin of the α component, the p - d hybridization should be taken into account. The strength of the p - d hybridization is significantly affected by the symmetry of d electrons in $(\text{Ga},\text{Fe})\text{Sb}$. The fivefold degenerate states of Fe 3d orbitals split into the twofold degenerate e states and the threefold degenerate t_2 states, because the Fe ions of $(\text{Ga},\text{Fe})\text{Sb}$ are in the tetrahedral crystal field. Because of the symmetries of the e and t_2 states, while the e states do not hybridize strongly with the ligand p bands, the t_2 states do hybridize strongly with these bands [41]. The p - d (t_2) hybridization leads to the antibonding (t_{2a}) and bonding (t_{2b}) states, which have both the Fe t_2 and the ligand Sb p characters.

Figure 6(a) shows the results of the first-principles calculations for spin-resolved density of states (DOS) of $(\text{Ga},\text{Fe})\text{Sb}$, where the total DOS, the PDOS of the Fe e states, and the PDOS of the t_2 states are plotted by gray area, and

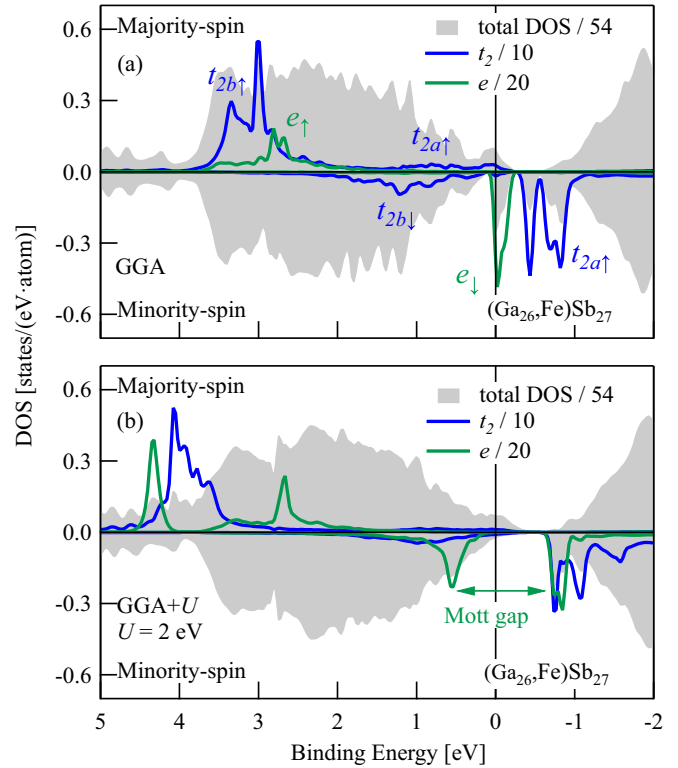

FIG. 6. Spin-resolved density of states (DOS) of a $(\text{Ga}_{26},\text{Fe})\text{Sb}_{27}$ supercell calculated using GGA (a) and GGA+U ($U = 2$ eV) (b) methods. The total DOS divided by the number of atoms in the supercell is plotted by gray area, the PDOS of the Fe e and t_2 orbitals are shown by green and blue curves, respectively.

blue curve, respectively. The Fe 3d PDOS of majority-spin (\uparrow) at around $E_B = 1.5$ eV is much smaller than that of minority-spin (\downarrow). Comparing with the observation and the calculation, the Fe PDOS measured at around $E_B = 1.5$ eV likely comes from the broad minority-spin states, suggesting that the α component corresponds to the $t_{2b\downarrow}$ state. As discussed above, the x dependence of the PP of $t_{2b\downarrow}$ is the same as that of the sp bands, as shown in Fig. 4(a). Since the Fe-3d IB is located near E_F , the Fe-3d IB are gradually occupied with the increase of x . Here, this Fe-3d IB near E_F is mainly the minority-spin state [27]. The gradual occupation of the Fe-3d IB by electrons is related to the broadening of the hybridized states with increasing x as shown in Fig. 4(b), the x dependence of the FWHM of the α indicates that the p - d (t_2) hybridized states broaden with increasing x . The calculation shown in Fig. 6(a) suggests that both the majority-spin $t_{2a\uparrow}$ and the minority-spin e_{\downarrow} states cross E_F . Considering the narrow bandwidth shown in Fig. 5(a), the Fe-3d IB likely originates from the minority-spin e_{\downarrow} state.

In the previous SX-ARPES measurements on $(\text{Ga}_{0.95},\text{Fe}_{0.05})\text{Sb}$ [27], the origin of the Fe-3d IB in the vicinity of E_F remained experimentally unclear, although it was expected that the Fe-3d IB consists of the e_{\downarrow} or $t_{2a\downarrow}$ states. To identify the origin of the IB state, we have elucidated the Fe-concentration dependence of the Fe-3d IB near E_F . Figure 5(b) shows the enlarged plot of the intrinsic Fe-3d PDOS

near E_F . Note that the slopes in the vicinity of E_F of the intrinsic Fe-PDOS spectra (Fe-3d IB) are slightly different from the Fermi-Dirac distribution curves (green curve). In particular, the distance between the red and green triangles at E_F becomes larger as x increases. The observation suggests either pseudogap or depletion of DOS near E_F possibly occurs in the Fe PDOS at E_F , where pseudogap means the decrease of DOS near E_F caused by gap opening. Additionally, the increase of the distance between the red and green triangles at E_F with the increase of x in Fig. 5(b) suggests that the decrease of the PDOS near E_F becomes large. The gap widths of $(\text{Ga}_{1-x}, \text{Fe}_x)\text{Sb}$ with $x = 0.15$ and 0.25 from E_F are smaller than ~ 50 and ~ 150 meV, respectively. These values are close to that of $(\text{Ga}, \text{Mn})\text{As}$ [42]. It is likely that this pseudogap or DOS depletion reflects the localized character of the Fe-3d state composing the Fe-3d IB. Since the e_\downarrow states are more localized than the hybridized $t_{2a,b}$ states, the Fe-3d IB predominantly consists of the e_\downarrow states. The $d-d$ Coulomb interaction and/or the degradation of the crystallinity with the increase of x are supposed to induce the pseudogap or depletion of DOS near E_F as discussed in the following. The pseudogap behavior is hardly seen in the calculation shown in Fig. 6(a). To qualitatively elucidate the effect of the Coulomb interaction U on the Fe-3d IB, first-principle calculations taking into account $U (= 2 \text{ eV})$ have been performed as shown in Fig. 6(b). The calculation with U suggests that the energy gap of the e_\downarrow states will open, while the delocalized $t_{2a\uparrow}$ states cross E_F even under the finite U . Actual U in $(\text{Ga}, \text{Fe})\text{Sb}$ is considerably smaller than the value (2 eV) assumed in the calculation shown in Fig. 6(b), because the gap is not fully opened in the observed spectra and the Fe 3d PDOS is approximately reproduced by the calculation without U shown in Fig. 6(a). When the e_\downarrow state is close to half filled with the increase of x , the effect of the Coulomb interaction will increase. Additionally, as for the deterioration of the crystal quality, a theoretical study of computational many-body methods for manganite $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ suggests that the pseudogap features appear at E_F when the system contains ferromagnetic cluster regions in an insulating background [43]. Since the Fe distribution in heavily Fe-doped $(\text{Ga}, \text{Fe})\text{Sb}$ is reportedly nonuniform [44], the inhomogeneity will lead to the pseudogap formation at E_F . Then, the observed pseudogap behavior likely reflects the effect of U on the e_\downarrow state and/or the nonuniform distribution of the Fe ions. It follows from these arguments that the Fe-3d IB in the vicinity of E_F originates from the e_\downarrow states.

Based on the findings, the x dependence of the Fe PDOS per Fe atom is schematically shown in Fig. 7. When x increases, the overlap between the majority-spin $t_{2a\uparrow}$ states and the Fe-3d IB states is expected to become larger due to the band broadening. This means that the Fe-3d IB states will be gradually occupied by electrons when x increases, as shown in Fig. 7. Since the minority-spin e_\downarrow is localized, the majority-spin $t_{2a\uparrow}$ predominantly contributes to the electrical conductivity. In contrast to the t_2 hybridized IB states related to the ferromagnetism in $(\text{Ga}, \text{Mn})\text{As}$, from the electronic structures shown in Fig. 7, the e_\downarrow electrons originating the Fe-3d IB would predominantly contribute to the ferromagnetism in $(\text{Ga}, \text{Fe})\text{Sb}$. The double-exchange interaction is considered to be stronger when the number of d electrons

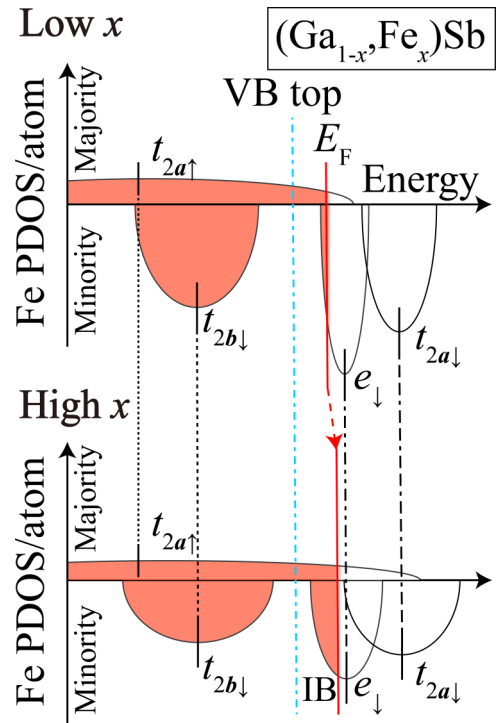

FIG. 7. Schematic energy diagram of Fe PDOS per Fe atom for the low (upper panel) and high (lower panel) Fe concentration.

mediating the interaction increases. The broadening of the e_\downarrow state accompanied by the electron occupation of the state with increasing x is consistent with the picture of double-exchange interaction. Since the d electrons are magnetically coupled through double-exchange interaction, the value of T_C is positively correlated with x in $(\text{Ga}, \text{Fe})\text{Sb}$ at least for $x < 0.25$. On the other hand, in the case of p -type FMS $(\text{Ga}, \text{Mn})\text{As}$, the Mn-3d IB in the vicinity of E_F originates from the $p-d$ hybridized states [45]. In $(\text{Ga}_{1-x}, \text{Mn}_x)\text{As}$, the $p-d$ exchange interaction increases with increasing hole-carrier concentration that is proportional to x , whereas the increase of x ($> 15\%$) will lead to disordering of the crystallinity and the sp band. As a consequence, the value of T_C will peak out when x increases in $(\text{Ga}, \text{Mn})\text{As}$. Therefore, from these arguments, the enhancement of double-exchange interaction in $(\text{Ga}, \text{Fe})\text{Sb}$ possibly results from the fact that the Fe-3d IB at E_F originates from the e_\downarrow states. The electron occupation of the e_\downarrow state increases with the increase of x , as shown in Fig. 7; this leads to the high T_C observed in heavily doped $(\text{Ga}_{1-x}, \text{Fe}_x)\text{Sb}$ thin films.

IV. SUMMARY

We have performed RPES measurements on $(\text{Ga}_{1-x}, \text{Fe}_x)\text{Sb}$ ($x = 0.05, 0.15, \text{ and } 0.25$) thin films to unveil the origin of the high- T_C ferromagnetism in $(\text{Ga}, \text{Fe})\text{Sb}$. The differences between the on- and off-resonance spectra can be decomposed into the intrinsic Fe 3d PDOS and extrinsic Fe components. The intrinsic Fe 3d PDOS are composed of the $p-d$ hybridized state (the α component) in VB and the Fe-3d IB located in the vicinity of E_F . The PP of α shifts to the high E_B direction with increasing x , indicating

that the chemical potential shift depending on x occurs in (Ga,Fe)Sb. The Fe-3d IB near E_F is gradually broadened with increasing x . This broadening is qualitatively consistent with the description of double-exchange interaction. The first-principles calculations reveal that the α and Fe-3d IB originate from the $t_{2b,\downarrow}$ and the e_{\downarrow} states, respectively. Based on the findings, it is concluded that the double-exchange interaction derived from the e_{\downarrow} electrons is the mechanism of the ferromagnetism in $(\text{Ga}_{1-x}\text{Fe}_x)\text{Sb}$ with $x \leq 0.25$, and the increase of the interaction with increasing the e_{\downarrow} electrons at E_F would be the origin of the high- T_C ferromagnetism in (Ga,Fe)Sb.

ACKNOWLEDGMENTS

The authors would like to thank K. Sato and H. Katayama-Yoshida for fruitful discussions. This work was supported by

Grants-in-Aid for Scientific Research (Grants No. 15H02109, No. 16H02095, No. 19K21961, No. 18H05345, and No. 23000010). L.D.A. acknowledge the support from PRESTO Program (JPMJPR19LB) of Japan Science and Technology Agency. This work was partially supported by the Spintronics Research Network of Japan (Spin-RNJ). This work was performed under the Shared Use Program of Japan Atomic Energy Agency (JAEA) Facilities (Proposals No. 2017B-E19 and No. 2019A-E15) supported by JAEA Advanced Characterization Nanotechnology Platform as a program of “Nanotechnology Platform” of the Ministry of Education, Culture, Sports, Science and Technology (MEXT) (Proposals No. A-17-AE-0038 and No. A-19-AE-0015). Supporting experiments at SPring-8 were approved by the Japan Synchrotron Radiation Research Institute (JASRI) Proposal Review Committee (Proposals No. 2017B3841 and No. 2019A2841).
