Abstract

In 2012, the European Commission (EC) launched the Bioeconomy Strategy and Action Plan with the objective of establishing a resource efficient and competitive society that reconciles food security with the sustainable use of renewable resources. This report contributes to the plan by evaluating the macroeconomic impacts of bio-based applications in the EU. Such effects can only be evaluated with a computable general equilibrium model such as MAGNET.

Four bio-based applications are considered, namely biofuel (second generation), biochemicals, bioelectricity, and biogas (synthetic natural gas). This is done assuming that 1 EJ lignocellulose biomass is converted into fuel, chemicals, electricity and gas and that the final product replaces an equal amount of conventional (e.g. fossil energy) product (on energy basis). The results show that given the assumed efficiency of conversion technology, costs of conversion, biomass price and oil price, the production of second generation biofuel and biochemicals are the only competitive sectors compare to their conventional counterparts in the year 2030 for the EU. In the case of the fuel sectors, it represents a net GDP effect of 5.1 billion US\$ while biochemicals generates 6 billion US\$. A substantial part of this impact can be explained by the increase in wages, since the production of biomass is relatively labour intensive. The resulting increase in wages is transmitted to other sectors in the economy and increases production and consumption. Another important contributor is the lower oil and fuel price as a result of the substitution of oil based fuel production by bio-based fuel production, which in turn benefits the entire economy.

Executive summary

In 2012, the European Commission (EC) launched the Bioeconomy Strategy and Action Plan with the objective to establish a resource efficient and competitive society that reconciles food security with the sustainable use of renewable resources. The focus of the Action Plan is on 1) investing in research, innovation and skills; 2) reinforcing policy interaction and stakeholder engagement; and 3) enhancing markets and competitiveness in the bioeconomy.

To promote and monitor the development of the EU bioeconomy, the EC launched the Bioeconomy Information System Observatory project (BISO) aiming to set up a Bioeconomy Observatory. That observatory brings together relevant data sets and information sources, and uses various models and tools to provide a coherent basis for establishing baselines, monitoring, and scenario modelling for the bioeconomy. Moreover, the EC also started the Systems Analysis Tools Framework for the EU Bio-based Economy Strategy project (SAT-BBE) with the purpose to design an analysis toolbox useful to monitoring the evolution and impacts of the bioeconomy.

This report shall contribute to the Bioeconomy Strategy and Action Plan, and to the projects above as it aims to evaluate the macroeconomic impacts of bio-based applications in the EU. The macroeconomic effects of bio-based applications studied in this report are not only determined by the production costs, but also by the many indirect economic effects of these bio-based applications. Most of the indirect economic effects are caused by the interlinkages of the economy's sectors, mostly through the use of production factors (labour and capital) and intermediate inputs for bio-based production and by changes in prices, production, consumption and trade. Such effects can only be evaluated with economic models, such as MAGNET (Modular Applied GeNeral Equilibrium Tool) which is the global recursive dynamic computable general equilibrium model used in this study.

Four bio-based applications are considered in MAGNET for the EU only, namely biofuel (second generation), biochemicals, bioelectricity, and biogas (synthetic natural gas). This is done assuming that 1 EJ lignocellulose biomass is converted into fuel, chemicals, electricity and gas and that the final product replaces an equal amount of conventional (e.g. fossil energy) product (on energy basis). To evaluate the importance of the indirect economic effects two methods

are compared to calculate the net GDP effect. First, the expected change in production value is calculated based on the conversion efficiency and costs of bio-based and conventional applications, these results are reached without the use of a CGE model. The second method calculates the net GDP effect by using the CGE model MAGNET.

The impact of biomass applications on GDP in the EU (billion US\$).

	Direct cost calculations - Value of production	CGE GDP effect MAGNET	Multiplier effect
1 Fuel	+	+	>1
2 Chemicals	+	+	<1
3 Electricity	-	-	>1
4 Gas	-	-	>1

Source: Own and MAGNET calculations.

Given the assumed efficiency of conversion technology, costs of conversion, biomass price and oil price, the production of second generation biofuels and biochemicals are competitive sectors when compared to their conventional counterparts in the year 2030 for the EU, while the production of bio-based electricity and gas is not (Table above). Hence, replacing conventional fuels and chemicals by biofuels and biochemical will result in an increase in GDP. In the case of the fuel sector, the net GDP effect, as calculated by MAGNET, is larger than the direct value of production when costs are directly calculated (taking into account only the difference in production costs between conventional and bio-based applications, and no indirect economic effects). This implies a multiplier effect larger than one.

A substantial part of the multiplier effect of biofuel production can be explained by increases in wages, since the production of biomass is relatively labour intensive. In total, around 26% of the costs of producing, transporting and converting biomass are labour costs and almost all labour is used for the production and pre-treatment of the biomass. A shift from conventional to bio-based production increases the direct use of labour. The resulting increase in wages is transmitted to other sectors in the economy as higher wages

would imply more spendable income, hence production and consumption increases. Another important contributor to the multiplier effect are lower oil and fuel prices as a result of the substitution of oil based fuel production by bio-based fuel production, which in turn benefits the entire economy.

These effects are higher in the scenario with higher oil prices, since a higher oil price means that the impact of biofuel production has a larger impact on the price of fuel. The opposite effect occurs in case of the lower oil price scenario, but biofuels remain competitive.

The same mechanisms described above apply to the macroeconomic impacts of the production of chemicals, electricity and gas. Given the assumptions, the production of chemicals results in the highest net GDP effect of the four bio-based applications considered, making it very competitive when compared to its conventional counterpart. However, the change in value of production costs is larger than the GDP effect which leads to a multiplier effect which is less than one. The increased production in the chemical industry, which is relatively labour intensive compared to the other bio-based applications and conventional sectors considered in this study, increases the demand for labour. This results in a reduced competitiveness of the service sector and the 'other industries' sector which compete for labour with the chemical industry. This effect reduces the volume of labour and the production volume in these sectors (i.e. services and 'other industries'). Moreover, imports also

increase to maintain the level of consumption of services and 'other industries' sectors, which results in a negative trade balance effect.

Last, given the assumed efficiency of conversion technology, costs of conversion, biomass price and oil price, the production of bioelectricity and biogas are shown not to be competitive with their conventional counterparts and hence their prices rise, while employment, production, consumption and exports fall.

However, in the context of this novel research line, both the approach and MAGNET have several drawbacks and shortcomings. For example, the analyses presented in this report assume that one unit of bio-based product replaces an equal amount of conventional product (in terms of energy). In reality the use of bio-based products changes the demand and supply and price of conventional products. Also the demand and supply of biomass is considered in a static manner that only partially accounts for the impacts on land use and agricultural production and consumption. These effects can only be modelled by expanding MAGNET with new sectors that supply biomass or convert biomass into energy or materials; such work is currently being developed for future analysis on the subject.

Overall, based on the assumed efficiency of the conversion technology, costs of conversion, biomass prices and oil price, the analysis of biomass applications suggests that biomass would be better used in the production of second generation biofuels or biochemicals industries.

1 Introduction

In 2012, the European Commission (EC) launched the Bioeconomy Strategy and Action Plan with the objective of establishing a resource efficient and competitive society that reconciles food security with the sustainable use of renewable resources. More specifically, the Bioeconomy Strategy is aimed at five societal challenges 1) Ensuring food security; 2) Managing natural resources sustainably; 3) Reducing dependence on non-renewable resources; 4) Mitigating and adapting to climate change; and 5) Creating jobs and maintaining European competitiveness. The focus of the Action Plan is on 1) investing in research, innovation and skills; 2) reinforcing policy interaction and stakeholder engagement; and 3) enhancing markets and competitiveness in the bioeconomy.

To promote and monitor the development of the European Union (EU) bioeconomy, the EC launched the Bioeconomy Information System Observatory project (BISO) in February 2013 with the objective to set-up a Bioeconomy Observatory. That observatory must bring together relevant data sets and information sources, and use various models and tools to provide a coherent basis for establishing baselines, monitoring, and scenario modelling for the bioeconomy. Moreover, the EC started the Systems Analysis Tools Framework for the EU Bio-based Economy Strategy project (SAT-BBE) in November 2012, with the purpose to design an analysis tool useful to monitoring the evolution and impacts of the bioeconomy.

BISO and SAT-BBE are complementary projects. The BISO project aims at providing a comprehensive insight in the availability of data and tools that could be helpful when developing the conceptual analysis framework of the bioeconomy. While the SAT-BBE project aims at developing an analysis tool for monitoring the evolution of the bio-based economy based on both quantitative and qualitative analytical models and tools in order to advise the BISO project on the types and sources of data and tools that need to be considered. Moreover, BISO will also assemble and implement the data and tools that lie beyond the conceptual framework to be designed in SAT-BBE into an information system.

At the same time, the EU is committed to combat climate change and to increase the security of its energy supply. To these ends, the EC has set ambitious greenhouse gas

emission and energy use reduction targets, which are known as the “20-20-20” targets for 2020:

- A 20% reduction in EU greenhouse gas emissions compared to 1990 levels
- A 20% rise of the EU share of renewable energy consumption
- A 20% improvement in the EU’s energy efficiency.

The 20% rise targeted increase for renewable energy consumption is implemented in the Renewable Energy Directive (RED) (EC 2009). In addition, the RED also includes a mandatory share of 10% renewable energy in transport for each member state.

The RED of the EC and various national policies, such as the Incentive Scheme for Sustainable Energy Production in the Netherlands, have resulted in a rapid increase in the use of renewable energy in the EU, from 8.5% in 2005 to 12.7% in 2010 (EC 2013). The production of energy from biomass currently accounts for more than two thirds of total renewable energy use in the EU (EC 2014). In the RED, Biomass is defined as the biodegradable fraction of products, waste and residues from biological origin from agriculture (including vegetal and animal substances), forestry and related industries including fisheries and aquaculture, as well as the biodegradable fraction of industrial and municipal waste. Biomass can be used for the production of various types of energy, such as heat and electricity, but also for liquid biofuels for transport and biogas.

Bioenergy¹ is currently, the most important source of renewable energy, both globally and in the EU and is expected to remain so in the future. The contribution of bioenergy to the total primary energy supply in the EU increased from 2.8% in 1990 to 7.7% in 2011 and is expected to increase to 10.2% in 2020 (IEA 2013). This means that more than 60% of the renewable energy use will be met by bioenergy.

The production of heat and electricity from solid biomass is by far the most important type of bioenergy, where its share

¹ Bioenergy is [renewable energy](https://www.iea.org/topics/bioenergy/) derived from biomass which includes biological materials such as plants, animals, woods, waste and alcohol fuels (<https://www.iea.org/topics/bioenergy/>).

in final consumption is expected to increase from 4.9% in 2010 to 8% in 2020 (Atanasiu 2010). The use of biogas and liquid biofuels is also expected to increase within the EU over the next decade, but with a limited contribution to the 2020 renewable energy target in the large majority of member states.

However, not only the demand for biomass for energy production is increasing. Rapid economic growth in some regions of the world and an increase in global population to 9 billion people in 2050 requires a move towards more sustainable, “triple performing” types of primary production which embrace economic, social and environmental objectives.

To this end, a wide variety of existing models and tools can be, and partially already have been, used to monitor and evaluate the impact of the bioeconomy on land use change and food security (Edwards *et al.* 2010, Laborde 2011, Plevin *et al.* 2013) (Rathmann *et al.* 2010, Tyner 2010, Banse *et al.* 2011, Ciaian *et al.* 2011, Kim *et al.* 2011, Timilsina *et al.* 2011, Kavallari *et al.* 2014).

Recently, M'Barek *et al.* (2014) have provided an overview of the bioeconomy in the EU and argued for the need to adapt data and tools (such as social accounting matrices and CGEs) to these new challenges.

In addition to the aspects covered in the studies above there is a need for comprehensive assessments of the macroeconomic impacts of emerging bio-based sectors, technologies and applications. Examples are the use of biomass for the production of second generation biofuels, biochemicals, bioelectricity and biogas. Such assessments provide insight into the factors, mechanisms and relationships that determine the macroeconomic effects of the use of different bio-based applications in the EU. Such insights can help policy makers to design efficient and effective bio-based policies that contribute to economic growth and employment generation. However, only a limited number of studies have been carried out that investigate both the direct and indirect economic implications of a bio-based economy in the EU. Some of these studies are discussed below in order to show the relevance of comprehensive economic assessments.

A relevant example is the study ‘*An approach to describe the agri-food and other bio-based sectors in the European Union*’ of the Institute for Prospective Technological Studies of the Joint Research Centre - EC (Cardente *et al.* 2012). The study is based on a set of SAMs for the EU-27 with a detailed disaggregated agricultural sector (AgroSAMs) for the year 2000 (Hertel and Tsigas 1997). The SAMs are used to identify key sectors of the bioeconomy and to extract the main tendencies in the behaviour of an economy. For this purpose, all sectors of an economy can be ranked according to a hierarchy derived from two types of indexes: a backward linkage (BL) and a forward linkage (FL), traditionally obtained from a symmetrical input-output table (SIOT). The BL indicator analyses the effect on the rest of the economy of a

change in the final demand of a sector. The FL evaluates the effect of a joint change in the final demand of all sectors on the production of a specific sector. Potential key sectors are sectors with a BL greater than 0.9, independently of its FL level. The results showed that livestock and related products (including fodder, milk and dairy products) present the highest BL within these sectors at the European level. Energy and water sectors are also important potential key sectors. On the other hand, some primary sectors - durum wheat, soy beans and sunflower seeds, grapes, fresh and vegetables, fruits and nuts - cannot be considered as key agri-food and other bio-based sectors at the EU level, although they may be key for some countries. The same observation applies to chemicals, rubber and plastic products. Further research may use the methodology on an updated database for a detailed pan-EU diagnosis. The limits of this approach are evident, as many changes in the EU economies have taken place within a decade. However, the AgroSAMs are the EU database providing details of all the relevant sectors mentioned. An update of the AgroSAMs for the year 2007 is on-going and will provide more recent data and results. A key limitation of SAM analysis is that no price and income effects are taken into account and also that other macroeconomic correlations and interactions are ignored. Investigating these links and correlations requires the use of a Computable General Equilibrium (CGE) model. However, only a limited number of CGE studies have been carried out on the bio-based economy, as further discussed below.

An example of a study that considers both direct and indirect effects is the study of Hoefnagels *et al.* (2010), which uses the LEITAP CGE model (currently called the MAGNET model) in combination with bottom-up analyses to evaluate the terms of value added, employment shares and the trade balance of the bio-based economy in the Netherlands for 2030. The results of the projections show that substitution of fossil energy carriers by biomass can have positive economic effects, as well as reducing GHG emissions and fossil energy requirement. The key factors to achieve these targets are enhanced technological development and the import of sustainable biomass resources into the Netherlands.

In the same year, Nowicki *et al.* (2010) carried out a related project aimed at improving the modelling of the bio-based economy with a national CGE model for the Netherlands (ORANGE). This study shows that, by using expert knowledge, it has been possible to integrate technical bio-based data into the original economy-based database of the model. ORANGE is used to model the effects of substitution of bio-based polylactic acid (PLA) as an intermediary product within the plastics industry, in place of oil based substances. The effects are calculated for the national economy, but also for agricultural commodity prices and land markets. Results show that the bio-based economy will create a new demand for agricultural commodities for the production of goods that are now using primary or intermediary materials coming from the oil based economy. This shift between two economic systems will (a) create greater demand for agricultural output and, as a consequence; (b) require more

land for the agricultural sector. At the moment of writing a more detailed assessment of the macroeconomic impacts of the bio-based economy in the Netherlands is carried out using a combination of the ORANGE and MAGNET models referred to above.

In 2012, a CGE modelling study was completed in which the use of residues from palm oil production was used for various bio-based applications in Malaysia (Van Meijl *et al.* 2012). The results show that the macroeconomic effects are primarily influenced by the production and conversion costs of bio-based products compared to the price of fossil energy based systems. The relatively large differences between net GDP effects and the revenues connected to the use of palm oil biomass are the opportunity costs which are not zero in an economy that has not a lot unused resources in addition to palm waste. In other words, the collection, transportation and processing of palm biomass into ethanol and other products take resources (labour, capital and other inputs) from other activities if it is assumed that for example there is full employment in Malaysia (which is not an unreasonable assumption). Therefore, the emergence of a bio-based economy influences directly and indirectly many other sectors within the economy, for example, the education, financial and innovation systems. Therefore, the successful development of a bio-based economy requires a coherent set of government policies covering agricultural, energy, transport, infrastructure, education, financial, export and technology policies.

Also relevant is the study of Taheripour and Tyner (2010), which is based on the GTAP model. They investigated the interaction between biofuel use on other policies and on government and household income in the United States. Results indicate that the biofuel policy implemented raised the price of agricultural commodities and hence reduced the need for agricultural subsidies (in the US the level of agricultural subsidies is linked to the price of agricultural commodities). This effect partially relieves the impact of the

ethanol subsidy policy on government spending. Taheripour and Tyner also consider the impact of the ethanol policy on government spending and income tax. The results show that these mechanisms determine to a large extent the impact of biofuel policy on prices of agricultural commodities, GDP and welfare, but also on fossil fuel prices and consumption and thereby also GHG emissions.

The results of the studies discussed above, and also the modelling frameworks that are being developed in BISO and SAT-BBE, show that the economy-wide effects of bio-based applications can only be evaluated using CGE models if one wants to capture all the sectoral inter-linkages in the economy raising direct and indirect effects. Therefore, the objective of this study is to gain insight in the factors, mechanisms and correlations that determine the macroeconomic effects of a more bio-based EU. This is done using the MAGNET (Modular Applied GeNeral Equilibrium Tool) global recursive dynamic CGE model, which enables an evaluation of the main mechanisms of the impact of bio-based applications on consumption, production, prices, GDP, trade balance and employment for the economy as a whole and for the different sectors individually in the economy.

Crucial for the macroeconomic effects of the bio-based applications is the efficiency of technologies to collect and convert biomass into bioenergy (e.g. biofuel, bioelectricity or biogas) or biochemicals, and the costs relative to fossil resources-based technologies. Therefore, the (development) price of fossil-based substitutes is explicitly considered in this study. Also important for the macroeconomic effects is the use of production factors (labour and capital) and intermediate inputs for bio-based production, which differ between different bio-based applications. In other words, the production of bio-based products competes for production factors and inputs with other sectors of the economy. The results of this study will be used in the SAT-BBE and BISO project when developing analysis tools for monitoring the evolution of the bio-based economy.

2 Database

The data used in this study is based on the GTAP database version 8 (Narayanan *et al.* 2012) which includes data on bilateral trade patterns, production, consumption and the intermediate use of commodities and services. It includes the dual reference years of 2004 and 2007 (in this case the 2007 reference year is used), all monetary values of the data are in million US\$. The database covers 129 regions and 57 commodities. For computability, the database has been aggregated into 22 regions and 32 commodities of which 26 can be considered bio-based, following the SAT-BBE definition. The sectoral aggregation includes the new sectors such as second generation biofuel, bioelectricity, biogas and biochemicals as well as several primary sectors (e.g. cereals and oil seeds), processed products (e.g. dairy and meat products), industry and resources (e.g. coal, oil, petroleum and chemicals) and services (e.g. financial and business services). The regional aggregations include the

EU and its main trading partners, such as the USA, Canada, China, Russia etc. Furthermore, each region's economy was disaggregated according to nine accounts².

To create the 2030 database, projections of GDP and population are assumed in line with USDA macroeconomic projections³. Projections by the World Development Indicators (WDI) are the main source of data for labour force. Data for capital stock projections are taken from the OECD⁴. Lastly, assumptions on the evolution of crude oil, gas and coal prices follow projections by the International Energy Agency (IEA 2011) see Table 1. These projections are based on the baseline scenario (referred to as Current Policies scenario in the IEA report), which assumes no changes in policies. All other parameters values follow the standard MAGNET model (Woltjer *et al.* 2013) as described further in the following section.

Table 1: Projections of the energy prices in the baseline (in \$/GJ⁵).

	2007	2010	2030
IEA crude oil imports	11.2	11.9	20.5
Natural gas imports EU	6.7	6.7	11.3
OECD stem coal imports	2.9	3.7	4.4

3 Model

The model used to analyse the macroeconomic consequences of a more intense bio-based EU is MAGNET (Modular Applied GeNeral Equilibrium Tool)⁶. MAGNET is a recursive dynamic global computable general equilibrium (CGE) model developed by LEI⁷. MAGNET builds on the standard GTAP model⁸ (Hertel and Tsigas 1997), by including different modules that can be switched on and off depending on the policy question at hand.

The behavioural relationships used in MAGNET are those found in the standard GTAP model and correspond to neo-classical optimization assumptions: Producers are perfectly competitive and use technology characterized by Constant Elasticity of Substitution (CES) production functions over primary inputs (e.g. labour and capital) and Leontief production functions across intermediate inputs (e.g. agricultural, manufacturing or services sectors). Both labour types (skilled and unskilled) and capital are fully mobile between sectors and across the same region but immobile between countries, while land (which is agriculture specific) and natural resources exhibit restricted mobility. All five factors of production are fully employed. Last, technological change is assumed exogenous in the model.

Domestic demand is satisfied by composite commodities composed of domestic and imported commodities. A regional household accumulates income from the factors of production and ad valorem taxes, which are then appropriated in Cobb-Douglas fashion (i.e. fixed shares) over non-homothetic private demands, public demands and savings (investment demand). The price systems are linearly homogenous and thus only changes in relative prices matter. Consequently, the model has a global numeraire (world price index of primary factors), which is a benchmark of value against which changes in all other prices can be measured

Gross trade flows, modelled as import demands, are differentiated by region of origin using the Armington (1969) specification. Regional savings are collected by a global bank, which then assigns regional investments subject to a

rate of return or a fixed share rule. Once the closure rules are defined, exogenous policy shocks initiate an interaction between economic agents, subject to a series of accounting identities and market clearing equations, which ensure a new 'counterfactual' general equilibrium solution.

In order to analyse the bio-based sectors and their inter-linkages with the rest of the economy the following modules are included: first the land use modules relating to endogenous land supply (which allows land to shift in and out of agriculture and accounts for increasing costs of conversion as land becomes scarce), land transformation between sectors (accounts for cost adjustments due to the land mobility for different uses) and substitution possibilities between feed inputs in the livestock sectors (Van Meijl *et al.* 2006; Eickhout *et al.* 2008; Neumann *et al.* 2011). The land use modules relating to endogenous land supply are included to account for the indirect effects of the use of biomass, since in this paper only biomass from residues, waste and abandoned agricultural land are considered, see further Section 4.2.

Second, a module encompassing the activities of first generation biofuels and their interactions with agricultural sectors and capital-energy substitution or fossil fuel – biofuel substitution is also included (Banse *et al.* 2008; Banse *et al.* 2011).

Third, additional behavioural and accounting equations are included to explicitly characterise EU agricultural policy mechanisms (i.e. milk and sugar production quotas, single farm payment, pillar 2 payments).

On the consumption side, a dynamic CDE (Constant Difference of Elasticities) expenditure function was implemented that allows for changes in income elasticities when purchasing power parity (PPP)-corrected real GDP per capita changes. In the area of factor markets modelling, segmentation and imperfect mobility between agricultural and non-agricultural labour and capital was introduced accounting for diverging wages and returns to capital. More details about the MAGNET model can be found in Woltjer *et al.*, (2014).

Lastly, for the purpose of this study, further modelling was carried out in MAGNET in order to take into account bio-based applications in EU. The bio-based modelling and data needs deserve a separate section which follows.

⁶ MAGNET is part of the integrated Modelling Platform for Agro-economic Commodity and Policy Analysis (iMAP) hosted by the European Commission's Joint Research Centre, Institute for Prospective Technological Studies (M'barek *et al.* 2012).

4 Biomass availability and production costs.

In order to analyse the macroeconomic effects of a bio-based in EU, four very diverse bio-based applications are considered, and are further described in section 4.4:

1. Biofuels
2. Biochemicals
3. Bioelectricity
4. Biogas

All four bio-based applications use lignocellulose biomass as feedstock. Information on this biomass feedstock is taken from the Biomass Futures (BF) project; further details can be found in Section 4.2.

The following sections describe how these bio-based applications are modelled in MAGNET, and then their availability and production, pre-treatment, transport and conversion costs in the EU in 2030 are presented.

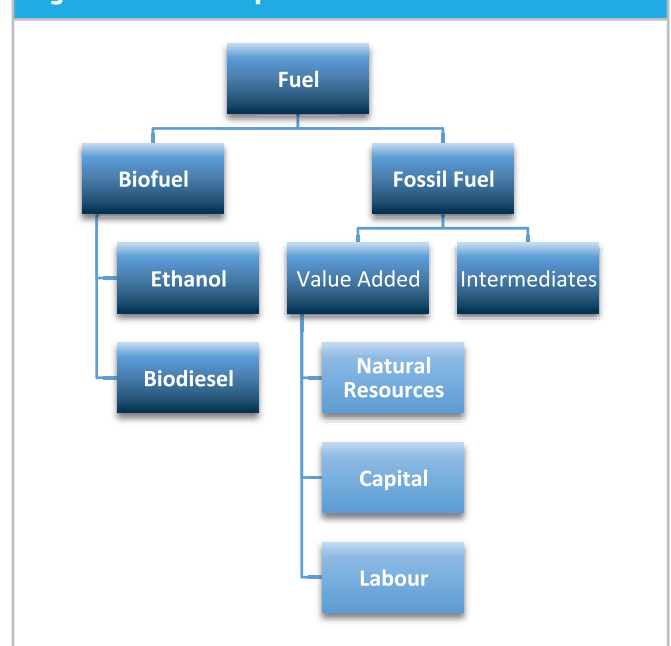

4.1 Modelling bio-based sectors in MAGNET

Macroeconomic impacts are evaluated by introducing bio-based chains into MAGNET by means of a shift in the application from conventional application (i.e. fuel, chemicals, electricity and gas) to a bio-based application (i.e. biofuel, biochemicals, bioelectricity and biogas). This is necessary given that MAGNET does not currently represent these bio-based sectors individually, therefore, in order to model the bio-based applications and to make the results comparable with their counterpart conventional applications, it is assumed that part of the energy from the conventional sectors production is replaced by the bioenergy from the biomass sector. More specifically, it is assumed that 1 EJ⁹ of biomass is used and it replaces 1 EJ of the conventional application while taking into account the conversion efficiencies and costs of converting biomass into bio-based

products. The data used to this end is taken from the Targets IMage Energy Regional simulation model (TIMER) energy model (De Vries *et al.* 2001). This approach ensures that the shift in technology is consistent with the cost data in the TIMER energy model and with the GTAP database tailored to MAGNET. This approach is similar to the one used in the macroeconomic impact assessment of a bio-based economy in Malaysia (Van Meijl *et al.* 2012).

Further adjustments have been made in MAGNET for the petroleum sector (i.e. fuel) (Figure 1). Given the flexibility provided by MAGNET (e.g. flexible constant elasticity of substitution) to adapt the production structure of a sector to the needs at hand, in this study the production structure for the fuel sector is adapted to account for the first generation biofuels. To this end, at the top of the nest, fuel is produced by blending fossil fuels (with its intermediates inputs of production) and first generation biofuels (i.e. ethanol or biodiesel).

Figure 1: Fuel CES production structure in MAGNET

9 1 EJ (exajoule) = 10¹⁸ J (joule).

4.2 Biomass availability and production costs

Data on biomass availability and costs in the EU are taken from the Biomass Futures (BF) project¹⁰ that was funded by the EC. The BF project provides a comprehensive analysis of sustainable biomass availability and supply options up to 2030. This project first analyses the technical potential of different biomass feedstock types. Then, it translates these technical potentials into economic and environmentally sustainable potentials for the present and in 2030, potentials differ per biomass feedstock type (Elbersen *et al.* 2012).

In total, the BF project distinguishes between 10 types of biomass feedstock which are aggregated into four for this study, these are:

1. Wastes (animal waste and verge grass),
2. Agricultural residues (straw and pruning),
3. Forestry residues (landscape care wood, primary, secondary and tertiary forest residues) and
4. Perennial crops (woody and grassy energy crops).

The BF also includes round wood and additional harvestable round wood which are not considered here as they are too expensive to be economically viable (> 15 US\$/GJ). Rotational crops are also not considered as the chosen bio-based applications require lignocellulosic biomass.

Therefore, only sustainable biomass sources are considered here, namely surplus residues (residues that are available but currently not used in the EU) and woody and grassy energy crops produced on surplus agricultural land in the EU (cropland and grassland that are expected to be abandoned according to economic outlook studies in the BF project's reports).

The final results are described in Table 2, where the cost and supply of biomass projections are included for the EU in 2030. The costs in the table are the average costs of supply of raw (i.e. untreated) biomass at the farm gate. The total average production costs of biomass in the EU in 2030 are 4.9 US\$/GJ biomass.

Table 2: Biomass availability and production costs in 2030

	Sustainable supply	Average costs
Biomass considered	EJ	\$/GJ
Wastes	0.2	3.5
Agricultural residues	2.4	4.5
Forestry residues	3.6	5.3
Perennial crops	1.5	0.0
Total supply / average costs	7.6	4.9

Source: Own elaboration based on the Biomass Futures' project

The BF project only provides data on total costs (Elbersen *et al.* 2012), but in this study disaggregated cost structures are needed in order to include the bio-based applications in MAGNET. To this end, the cost structures of the four types of biomass feedstock considered are collected and described in Table 3.

First, the cost structure of waste collection is based on data from a World Bank' report (Cointreau 1994) in which capital, labour and operation & maintenance (O&M) costs account for 10%, 70% and 20% of the total collection costs respectively. Second, for agricultural residues, it is assumed that the same cost structure of the agricultural sector in the GTAP database applies. Last, for forestry residues and perennial crops it is assumed the forestry sector's cost structure is as in the GTAP database. Note that the Services sector is not the same as the Services sector in the GTAP database, but rather it is an aggregated sector that includes 13 sectors in the GTAP database (e.g. air transport, communications, business and financial services, recreation and other services).

Table 3: Biomass feedstock's cost structures (% of total costs)

	Waste	Agricultural residues	Forestry residues	Perennial crops
Land	0	0	0	0
Unskilled labour	70	45	25	25
Skilled labour	0	4	1	1
Capital	10	25	55	55
Petro	14	4	4	4
Electricity	0	3	1	1
Services	6	19	14	14
TOTAL	100	100	100	100

4.3 Biomass pre-treatment and transport costs

Data about the costs of transportation and pre-treatment of biomass were taken from the literature (Hoefnagels *et al.* 2011; C2ES 2013) and added to the costs of biomass supply, see Table 4. It is assumed that regardless of the biomass application, every type of biomass needs to be pelletized¹¹ to reduce the costs of transport and storage. Estimates of the costs of pelletizing biomass found in the literature vary widely due to differences in scale and in costs

of drying (i.e. the fuel type and fuel price). In this study the costs of pelletizing are estimated to be 3.0 \$/GJ in 2030. The average costs of transporting the biomass from pre-treatment facilities to end users are set at 0.9 \$/GJ biomass (Hoefnagels *et al.* 2011) and subdivided into capital, fuel, labour and services (C2ES 2013).

The costs of transport and pre-treatment increase the costs of biomass from 4.9 \$/GJ to 8.8 US\$/GJ. The total costs of biomass is in the same order of magnitude as values from other sources such as the TIMER and GREEN-X energy models (Hoefnagels *et al.* 2011), although the ranges are large.

Table 4: Biomass transport and pelletizing cost structures (in \$/GJ and % of total costs)

	Transport	Pelletizing	Transport & Pelletizing	Unit
Total costs	0.9	3.0	3.9	\$/GJ
Land	0	0	0	%
Unskilled labour	35	30	31	%
Skilled labour	0	0	0	%
Capital	12	17	16	%
Petro	37	4	12	%
Gas	0	44	34	%
Electricity	0	2	2	%
Services	16	3	6	%
TOTAL	100	100	100	%

Source: Own calculations

11. Pelletizing is the process of compressing a material into the shape of a pellet.

4.4 Conversion efficiency and costs

The costs of converting biomass into biofuels, biochemicals, bioelectricity and biogas as well as the cost of conventional (fossil) systems are taken from the TIMER model (Stehfest *et al.* 2014) and from other sources when TIMER data were not available as further explained below for each biomass sector. TIMER is a cost optimisation model of the energy sector. TIMER determines the demand for energy services with population and income as primary drivers and the mix of final energy carriers and the technologies to produce them chosen on the basis of their relative costs. Key processes that determine these costs include technology development and resource depletion, and also preferences, fuel trade assumptions and policies. The model output demonstrates how energy intensity, fuel costs and competing non-fossil supply technologies, such as bioenergy, develop over time. The TIMER data and any other data used are translated into cost structures that are consistent with the classification of sectors in the GTAP 8 database¹² as shown in Table 5. The cost structures assumed in this project are shown in Table 5. In MAGNET, the production of fuel and other petroleum products is included in the petro sector, which in this study is referred to as the fuel sector.

Fuels

The costs and conversion efficiency of producing second generation biofuels are based on TIMER data for biomass gasification and subsequent methanol production. According to the TIMER model this is the most promising technology for the production of second generation biofuels. According to TIMER projections this technology will be used primarily in the year 2030. For the costs of conventional fuel production (gasoline and diesel from fossil oil) the data used is from (Palou-Rivera and Wang 2010; Energy Almanac 2013). Note that in MAGNET/GTAP fuels are produced in the petro sector.

Chemicals

In the TIMER model various technologies to produce chemicals are considered. In this study we consider the replacement of high value chemicals that are made from conventional oil. TIMER includes data about the costs and conversion efficiency of both oil- and bio-based high value chemicals.

Electricity

In this study we assume that the production of bioelectricity replaces electricity from coal and gas only, and not the production of other electricity systems. Coal and gas account

for 51% of the electricity consumed in the EU in 2007. In the case of coal, two technologies are considered, namely steam electric power generation and gasification and combined cycle, while for gas only combined cycle technology is assumed. For bioelectricity we assume combined cycle power generation technology. All data about on conversion efficiency and costs are based on TIMER.

Gas

Data about the production costs and efficiency of synthetic natural gas (SNG) from biomass were not available from the TIMER model. However, the technology used for SNG production is similar to the technology of methanol production, except that efficiency is 10% higher compared to the production of methanol (Van der Meijden *et al.* 2010; Van der Drift 2011). Therefore, TIMER data about the production of methanol were used and adjusted for the 10% difference in conversion efficiency. Data about the production costs and cost structure of gas were derived from the price of gas according to the IEA (2011) and data about the cost structure of gas production is from the MAGNET model.

In Table 5, the columns named 'CONV' and 'MAGNET' show the cost structure of conventional (i.e. fossil feedstock (oil, gas, coal) based) chains as found in the GTAP database in MAGNET. The columns with headings 'CONV' and 'Other sources' show the cost structure of conventional chains based on data from the TIMER model and other sources. Differences between the cost structures of conventional chains from the MAGNET model and from the TIMER model and other sources are partially the result of differences in classification and scope. The cost structures in MAGNET are representative for an entire sector, i.e. cost structures are based on the costs of the conventional production of fuels, gas, electricity and chemicals plus various associated activities, such as administration, marketing, storage, transport, research & development, etc.

The cost structures from the TIMER model and from the literature only include the costs of the production of fuels, gas, electricity and chemicals but do not include the other economic activities associated with these sectors (e.g. marketing, research and development). This means that the production value of the sectors that produce fuel, gas, electricity and chemicals is higher than the production value calculated based on the production level and cost structures from the TIMER model and other sources. The production of fuel, electricity and chemicals accounts for 39%, 13% and 16% of the total turnover in these sectors as projected by MAGNET. The production value of the gas sector is lower compared to what one would expect based on the costs of gas production and amount of gas produced. This is potentially the result of fact that gas production is partly in the gas sector (that includes production) as well as in the crude oil sector (which includes exploration).

The columns named 'BIOB' show the cost structure of bio-based applications, whereby the contribution of biomass

12 For a detail description of the GTAP sectors see (GTAP 2013). Also a description of the GTAP 8 Data Base is accessible online at: https://www.gtap.agecon.purdue.edu/databases/v8/v8_sectors.asp.

is shown as a separate sector. The columns named 'BIOB-combined' show the combined cost structure of biomass conversion ('BIOB') and biomass supply that are given in the previous sections. The sector 'Biomass', which is used in the BIOB cost structures, is not a separate sector in MAGNET, but rather refers to the use of biomass for the production of bio-based applications.

Note that a shift from conventional to bio-based is assumed not to affect the use of natural resources. The reason is that

since natural resources are scarce resources, a change in their use may have large and unrealistic effects on their price and thereby distort the macroeconomic impacts. This approach is consistent with the cost structures in the TIMER model and other sources that are used in this report, none of which consider costs related to natural resources. However, we acknowledge that this aspect deserves further attention, especially in the case of gas, since gas is a sector that uses natural resources. The other conventional sectors do not use natural resources directly.

5 Baseline and Scenarios

5.1 Baseline scenario

One of the crucial aspects of any policy analysis, both at micro- as well as at macro-levels, is an appropriate model of the baseline. In this case, as MAGNET is a dynamic model, it allows us to develop a baseline scenario up to 2030 without explicitly considering an increase in the use of biomass for energy or chemicals but including current relevant policies.

In MAGNET, similar to other recursive dynamic CGE models, important key macroeconomic variables are modelled exogenously¹⁴, i.e. GDP projections and population growth. In this study the macroeconomic and population projections of the USDA are used (USDA 2013).

Furthermore, as mentioned in Section 2, the model is shocked so that the world prices of fossil fuel, gas and coal are assumed to follow the levels projected by the International Energy Agency (IEA 2011). At the European level, three policies are taken into account, the first two relate to the CAP policy, first is a change in the sugar CAP white sugar policy where EU is expected to lower its support on prices by 36%¹⁵. Second, the elimination of milk quotas, and last a target budget for first generation biofuels is fixed as the projection of the price of oil is quite high, it is expected that EU will reduce their biofuels subsidies as currently is the case.

5.2 Bio-based scenarios

Comparing with a contemporary baseline (that is without bio-based applications (e.g. second generation biofuels or biochemical)) a comparative static scenario assessments are carried out to evaluate the impact of the adaptation of bio-based applications in Europe in 2030.

1. Only biofuels
2. Only biochemicals
3. Only bioelectricity
4. Only biogas

In all cases a fixed amount of biomass (e.g. 1 EJ) will be considered to evaluate the relative macroeconomic effects of the different chains. We will assume that all bio-based products replace domestic production of conventional products. To make the results comparable, it is assumed that 1 EJ lignocellulose biomass is converted into fuel, electricity, gas or chemicals. We assume that the final product (i.e. fuel, electricity, gas or chemicals) that is produced from 1EJ biomass input replaces an equal amount of conventional production (e.g. fossil fuel in the case of biofuels) on energy basis. It is expected that the net macroeconomic effects will vary due to differences in cost structures (amount of labour, capital and other costs), conversion efficiency and price of conventional chains and price of biomass.

The sensitivity of the mechanisms that determine the macroeconomic and sector economic effects will be tested for the price of oil. Testing the sensitivity of the results for a 25% higher oil price and a 25% lower oil price (experiment 2 only, as this is the only economically attractive chain with a large potential based on the assumed cost structures). The oil price can be expected to have an impact on the profitability and macroeconomic impacts.

¹⁴ In order to obtain policy results, which include GDP as one of the model's endogenous variables, two further steps were needed. First, projections of GDP growth were translated into the growth of technological progress (the latter was endogenously calculated by the model). Second, given calculated rates of technological progress from the first step (now considered exogenous) the values for GDP growth were endogenously generated by the model separately for the baseline and policy scenarios.

¹⁵ For further details see: http://europa.eu/rapid/press-release_IP-05-1473_en.htm?locale=en

6 Results

In this section the impacts of the six comparative static bio-based economy scenarios are investigated by comparing their effects with the baseline scenario.

6.1 Conventional vs bio-based production costs

A key determinant of the macroeconomic impacts of bio-based systems in the EU is the difference in production costs between conventional and bio-based applications. The production costs of conventional and bio-based chains in 2030 are shown in Table 6, assuming a biomass price of 8.8 \$/GJ (including transport and pre-treatment) and assuming the increases in conventional energy prices as projected by the IEA (IEA 2011) (see Table 1).

	Conventional	Bio-based
Fuel	27.2	21.3
Fuel 25% higher oil price	33.9	21.3
Fuel 25% lower oil price	21.6	21.3
Chemicals	43.9	23.1
Electricity	16.5	21.8
Gas	11.3	19.3

Source: Own calculations.

Looking at Table 6, one can conclude that the production of second generation biofuels and biochemicals is competitive compared to the production of fuels and chemicals from oil. The production of conventional fuel depends to a large extent on the oil price, which accounts for approximately 80% of the production cost (Table 5). Another important factor is that the costs of biomass are relatively constant to 2030. However, the results show that even if a 25% lower oil price in 2030 is assumed, the production costs of second generation biofuels are lower than the costs of conventional

fuel production (*ceteris paribus*). The production of biogas and bioelectricity is uncompetitive at the assumed biomass prices, conversion efficiencies and costs and price of natural gas and coal in 2030.

6.2 Total production value and total GDP effect

In this section we evaluate the impact of the use of 1 EJ biomass per bio-based application on the production value for the four sectors (i.e. fuel, chemicals, electricity and gas) and on EU's GDP. This is done in two different ways to illustrate the importance of the indirect economic effects which can only be captured by a CGE model, which takes into account economy-wide inter-linkages.

First, the expected change in production value is calculated based on the conversion efficiency and costs of bio-based and conventional applications¹⁶. This is done assuming that 1 EJ lignocellulose biomass is converted into fuel, electricity, gas or chemicals. It is also assumed that the final product (i.e. fuel, electricity, gas or chemicals) that is produced from 1 EJ biomass input replaces an equal amount of conventional production (e.g. fossil fuel in the case of biofuels) on energy basis. In MAGNET, the cost structure of the fuel, chemicals, electricity and gas sectors is split into a part that is (partially) replaced by the bio-based chain (i.e. the conventional chain) and a part that is not affected by the bio-based chain (i.e. all economic activities that are not related to the conventional production of energy and chemicals and that are not (directly) affected by the introduction of bio-based applications). This approach ensures that the shift in applications is consistent with the cost data in the TIMER energy model and with the GTAP database used in MAGNET.

Table 7 shows the increase in value of production of bio-based products per sector (based on 1 EJ biomass input) and the decrease of production value of conventional fuel, chemicals, electricity and gas and the net change value.

Then, the macroeconomic impact is calculated in two different ways; first the net change of value of production

¹⁶ The production value is in this report the same as production costs, as neoclassical assumptions are taken with zero profits.

(third column in Table 7) is used as a proxy for the direct macroeconomic effect. The results (Table 7) show that the costs of collecting, transporting and converting 1 EJ of biomass into biofuel, biogas, bioelectricity and biochemicals are in the same order of magnitude, ranging from 10.2 to 11.8 billion US\$ (first column in Table 7).

More important are the differences in the costs of producing an equal volume (on energy basis) of the conventional counterpart, which differs between 6.2 billion US\$ for gas to 22.4 billion US\$ for chemicals (second column in Table 7). The difference in the value of production is the shock introduced in MAGNET which can be considered to be a proxy for a direct production value effect (third column, Table 7). The results also show that the value of conventional fuel production depends mainly on the price of oil.

Table 7: The impact of biomass applications on the production value and GDP in the EU (billion US\$).

	Cost calculations (spreadsheet)			CGE model calculations (MAGNET)	
	Change of value of bio-based production	Change of value of conventional production	Net change of value of production	Net GDP effect MAGNET	Multiplier Effect
1 Fuel	10.7	-13.7	3.0	5.1	1.7
2 Chemicals	11.8	-22.4	10.6	6.0	0.6
3 Electricity	10.2	-7.7	-2.5	-3.0	1.2
4 Gas	10.7	-6.2	-4.5	-5.1	1.1
5 Fuel 25% higher oil price	10.7	-16.6	5.9	11.0	1.9
6 Fuel 25% lower oil price	10.7	-10.9	0.2	0.6	2.9

Source: Own calculations.

Second, the total net change in production value of the four shocks is evaluated using results from MAGNET after implementing the '1 EJ shocks' (fourth column, Table 7). These show how the production value of the sectors has changed in response to the shocks. The results are then compared with the results as derived with the first method mentioned above. The difference between the two methods is the result of the many indirect effects on factor prices and intermediate inputs, and on consumption, production, trade to name a few. These indirect effects can be summarized as the 'multiplier effect' (fifth column, Table 7), which is defined as the ratio between the net GDP impact calculated by MAGNET and the net GDP effect calculated based on production value data (i.e. the costs of production).

The results show that the macroeconomic income effect, calculated from the change in production value (first method), varies between -4.5 billion US\$ for biogas to 10.6 billion US\$ for biochemicals. However, MAGNET predicts for biogas

a net GDP effect of -5.1 billion US\$. The multiplier effect for biogas application is thus -5.1/-4.1 or 1.1. The lowest multiplier effect was found to be for biochemicals (0.6).

These results show that the macroeconomic effects depend not only on the difference in bio-based application, but also on indirect effects. In the following sections, the differences in multiplier effects between bio-based applications are analysed in more detail by investigating some of the most important macroeconomic variables.

6.3 Prices

One of the first effects of introducing bio-based applications is that production costs change and as a result output prices also change for fuel, chemicals, electricity and gas sectors (see Table 8).

Table 8: The impact of biomass applications on prices (%).

	Scenario ¹⁷					
	Fuel	Fuel -25%	Fuel +25%	Chemicals	Electricity	Gas
Agrifood	-0.01	-0.01	-0.01	-0.03	-0.01	0.00
Industry	-0.06	-0.03	-0.09	-0.15	-0.01	0.01
Crude oil	-0.01	-0.01	-0.01	-0.03	-0.01	0.00
Petro	-0.83	-0.39	-1.23	-0.35	-0.04	0.02
Gas	0.21	0.36	0.15	0.04	-0.47	0.56
Coal	0.03	0.00	0.05	-0.12	-2.43	0.01
Electricity	-0.02	0.00	-0.05	-0.01	0.19	0.03
Chemicals	-0.08	-0.03	-0.14	-0.93	-0.01	0.01
Other Industry	0.02	0.00	0.03	-0.01	0.00	0.00
Services	0.00	0.00	0.00	0.02	-0.01	0.00

Source: Own calculations with MAGNET.

¹⁷ Each column shows the change in prices for each sector of the economy (in the row) when biomass is used only on the scenario specified (i.e. scenario1: biomass is used on the production of 2nd gen. biofuels only).

As we have seen in section 6.2 the production of biofuel and biochemicals is competitive with conventional production systems. In the first scenario, in which only second generation biofuels are introduced, the largest impact is as expected on the price of the petro sector where price drops by 0.83%, this is when the oil price is 20.5 US\$/GJ (first column, Table 8). This effect is smaller in the case of a lower oil price (15 US\$/GJ, second column, Table 8) and larger in the case of a higher oil price (26 US\$/GJ, third column Table 8) namely -0.39% and -1.23%, respectively. In the second scenario, where only biochemicals are produced using biomass, recall that it was shown that biochemical were found to be competitive when compared to conventional production and given the initial assumptions, as a result the price of chemicals decreases by 0.93%. Bioelectricity and especially biogas (third and fourth scenarios respectively) are much more expensive compared to conventional electricity and gas production, which is also visible in the results on Table 8 where their prices are higher. The price of gas increases by 0.56% and the price of electricity by 0.19%.

Changes in prices in the fuel, chemicals, electricity, and gas sectors also affect prices in other sectors. For example, the use of biomass in the fuel sector not only affects the petro sector (where second generation biofuels are blended in) but also affects the prices of agrifood sectors (by -0.01%) or chemicals (by -0.08%), probably because the petro sector is important as an intermediate input for the chemicals or even increasing the price of gas sector (by 0.21%).

Other causal correlations are relevant when explaining the price effects, as CGE effects take place, demand for factors of production change in various sectors and therefore factor prices are also affected. For example, wages change due to the changes in employment from the introduction of bio-based applications (Table 9). This in turn, affects the wages and employment in other sectors. These changes also (partially) explain price effects and multiplier effects, as further discussed in the following sections.

6.4 Employment

The introduction of bio-based applications changes the use of labour and capital¹⁸ in the economy. This partially explains the “multiplier effects” seen in section 6.2. Especially important is the production of biomass, which is a relatively labour intensive activity. In total 26% to 28% of the costs of producing, transporting and converting biomass are labour costs and almost all labour is used for the production and pre-treatment of the biomass (see Table 3 to Table 5). Based on these assumptions, a shift from conventional to bio-based production increases the use of labour.

The increased demand for labour in sectors using bio-based applications, results in an increase in of the cost of labour (i.e. wages) so the rest of the sectors in the economy decrease their employment of labour, assuming that the supply of labour is fixed and there is full employment (Table 9).

Table 9: The impact of biomass applications on wages (%).

¹⁸ The impact on capital use is not analysed as the effects are almost negligible.

¹⁹ Each column shows the change in wages for each sector of the economy (in the row) when biomass is used only as in the scenario specified (i.e. scenario1: biomass is used on the production of second generation biofuels only).

In the case of the production of bioelectricity the impact on wages is almost zero because a shift to labour intensive technology is compensated by a decrease in production that is the result of the higher price of bioelectricity. This effect is also visible in the case of the production of gas, in which case the wages move in opposite direction.

The case of fuel and chemicals (when they include biofuel and biochemicals) are different, as these sectors are competitive when compared to their conventional counterparts (as seen in section 6.2). In the case of fuel and for an oil price of 20.5 US\$/GJ (first column, Table 9) the increased production of biofuel increases its demand for labour, and as it is labour intensive, it demands more labour pushing wages higher. A 25% lower oil price (second column, Table 9) results in a

lower increase of wages as the price of products from the fuel sector decreases less. As a result, production increases less compared to the first scenario, and thus the value of employment and wages increase less. The opposite effect occurs in the case of a higher oil price (third column, Table 9).

The use of bio-based applications also impacts the use of labour and the total value of employment (Table 10). Table 10 is divided into two parts, part A shows the impact on employment value (in MUS\$ and taking into account changes in relative prices) and part B the impact on employment volume (in MUS\$ considering prices as fixed at the base year value). The bold numbers in the Table 10 show the impact on employment in the sectors that shift to these bio-based applications.

²⁰ Each column shows the change in employment for each sector of the economy (in the row) when biomass is used only as in the scenario specified (i.e. scenario1: biomass is used on the production of second generation biofuels only).

The production of bio-based chemicals has the largest direct impact on employment value and volume, followed by the fuel sector. The value of employment increases by 6,894 MUS\$, compared to 1,901-3,462 MUS\$ for the other chains, while the volume rises by 3,450 MUS\$, compared to 1,148-1,920 for the other chains. The reason for the large increase in production is that both the conventional and bio-based chemical industry are relatively labour intensive (the bio-based chemical industry even more than the conventional industry even more so than the conventional industry, due to the use of labour for the production of biomass, see Table 5). Further, the chemical industry uses the service sector and 'other industries' sector as intermediates, both of which are also labour intensive sectors which account for 90% of the employment in the EU.

Therefore, the increase in the use of labour affects the wages and production volume of other sectors. Especially important are the deliveries of the labour intensive services sector to the bio-based sectors, as can be seen in the cost structures (Table 5). The value of employment is an important component of the GDP effect and these results thus partially explain the positive multiplier effects.

Part B of the table shows the employment volume effect (in M\$ constant prices). The results show that the increase in employment value (part A) is about twice as high as the increase in employment volume in constant prices. These results show that the price of labour increases, which accounts for about half of the increase in employment value.

Further, the net economy wide effect is negligible as the supply of labour is fixed, but sectoral changes are substantial. The increase in employment in the sectors that shift to bio-based applications is compensated by a decrease of employment in other sectors.

6.5 Production

The introduction of 1 EJ biomass use results in price changes and in changes in production volume in the sectors that switch from conventional production to bio-based production. As expected, the largest impact on production is observed for the sectors that implement the bio-based applications (Table 11).

Table 11: The impact of biomass applications on production volume (%).

21 Each column shows the change in production for each sector of the economy (in the row) when biomass is used only as in the scenario specified (i.e. scenario1: biomass is used on the production of second generation biofuels only).

The introduction of biofuel induces an increase in production of the petro sector of 0.42%, because of the lower production costs and price of fuel. This in turn decreases the production of the crude oil sector (by 0.47%), as 60% of the costs of petro sector in MAGNET consist of crude oil and this has been replaced by biofuel. This explains the decrease of the crude oil price (Table 8).

Therefore, a large extent of these impacts is due to the price of oil, a higher oil price (as in the case of scenario fuel +25%) leads to a relatively lower price effect of biofuel production and thus a higher production effect. On top of this, the production of first-generation biofuels also increases (data not shown), which, together with the increase in GDP, also partially explains the impact on the agrifood sector (-0.06% drop in production and a 0.05% price increase). Moreover, the production of gas increases in the fuel scenarios, partly because of the use of gas for the pre-treatment of the biomass (see Table 5), but also because of the positive GDP effect.

In the case of chemicals, production increases substantially (1.78%). This increase is the result of the relatively large difference in production costs between bio-based chemicals and chemicals made from oil. The production costs of biochemicals are about half of the costs of conventional chemicals (Table 6), which results in an incentive to expand.

This (partially) explains the decrease in production volume and prices in the crude oil sector and the petro sector (fourth column, Table 11 & Table 8).

The substitution of conventional electricity produced from gas and coal by bioelectricity increases the price of the electricity sector (as cost of producing bioelectricity is higher than conventional electricity). As a result, the production of electricity in the EU decreases by 0.08% (fifth column, Table 11). The use of gas and coal for electricity generation decreases even further, which explains the decrease in production and prices in the gas and coal sectors.

The use of biomass for the production of biogas decreases the production volume of the gas sector by 0.91% since biogas is less competitive than its conventional counterpart). This is the combined effect of the use of gas for biomass pre-treatment (i.e. for drying the biomass), the substitution of conventional gas with biogas, and as a result of the higher costs of production of biogas (sixth column, Table 11).

6.6 Consumption

The introduction of bio-based applications also affects consumption in the EU as shown in Table 12.

	Scenario ⁵

²² Each column shows the change in consumption for each sector of the economy (in the row) when biomass is used only as in the scenario specified (i.e. scenario1: biomass is used on the production of second generation biofuels only).

The largest impact on consumption is observed for the sectors that become partly bio-based (which are highlighted in black). The consumption from the petro and chemicals sectors increases in the cases of the fuel and chemicals scenarios, while electricity and gas consumption decreases in the respective scenarios. The shift in production induces a price effect that drives the change in consumption. Starting with the change in fuel consumption, it increases by 0.56% for an oil price of 20.5 US\$/GJ (first column, Table 12) and ranges between 0.27-0.83% for the other two oil price scenarios. The increase in fuel consumption also impacts the consumption of other sectors such as crude oil in which price increases by 0.39% even though production decreased by 0.47%, this can be explained by the trade effects described in the next section. The consumption of chemicals is around the same magnitude as fuels, it rises by 0.57%. On the other hand, and as expected, the consumption of the electricity and gas sectors fall by 0.14% and 0.31% respectively (production felt as prices rose because they are now less competitive than their conventional counterparts).

Also it is interesting to note that changes in fuel consumption are higher than the changes in production (0.56% in consumption vs 0.42% in production). These results are opposite to the case for the chemical industry in which the production increases by 1.78%, but consumption only by 0.57%. This is due to trade effects (as further analysed in the section below).

6.7 Trade

The use of biomass changes the trade balance of the EU as shown in the table below. As in previous tables, the impact on the sectors that use the bio-based applications is shown in bold. The production of biofuel leads to an increase in the

balance of trade (e.g. the increase of exports is higher than the increase in imports) by 3.1 billion US\$ (for an oil price of 20.5 US\$/GJ, first column, Table 13). This is a result of lower production costs, which make the petro sector in the EU more competitive compared to other regions. Also, the export of oil increases, due to the reduced consumption from substitution of oil with biomass for the production of fuel. The trade effect is smaller in the case of a lower oil price due to the lower price effect of biofuel production (second column, Table 13). However, the favourable trade effect is compensated by reduced exports in other sectors, especially in the 'other industries' and the services sectors.

The largest impact on the trade balance occurs in the chemicals sector which rises by 16 billion US\$, on the other hand, the total net effect is the largest but it is negative, with a trade balance decrease of 4.8 billion US\$, this is again due to the negative trade balances of the service (in which exports decrease) and other industry sectors (in which imports increase). These changes are in turn the result of increases in the price of labour due to direct and indirect increases in the use of labour for the production of chemicals. In other words, the services and the 'other industries' sectors become less competitive as a result of the competition for labour with the chemical industry. The size of the negative total net trade balance in the chemical sector in turn partially explains the low multiplier effect compared to the other bio-based applications (last column, Table 7).

Trade balances for the electricity and gas sectors fall, as they are less competitive than before, it is no surprise that EU imports rise as their production has fallen. The net trade balance effect in the electricity sector is mainly caused by the gas and coal sectors whose prices fall and as a result their exports increase.

Table 13: The impact of biomass applications on Trade balance²³ (value in billion US\$).

²³ Trade Balance is defined as export minus imports.

²⁴ Each column shows the change in trade balance for each sector of the economy (in the row) when biomass is used only as in the scenario specified (i.e. scenario1: biomass is used on the production of second generation biofuels only).

7 Concluding remarks

In this report potential macroeconomic impacts of the use of different bio-based applications are analysed for the EU in the year 2030. To make the results comparable it is assumed that 1 EJ lignocellulose biomass is converted into second generation biofuel, bioelectricity, biogas or biochemicals and that the final product replaces an equal amount of conventional (e.g. fossil energy in the case of biofuel) product (on energy basis).

The results clearly show that the total net GDP effects of bio-based applications are to a large extent determined by indirect macroeconomic effects. Such effects can only be evaluated with economic models, such as the MAGNET (Modular Applied GeNeral Equilibrium Tool) global CGE model used in this study.

Given the assumed efficiency of conversion technology, costs of conversion, biomass price and oil price, the production of second generation biofuels and biochemicals are the competitive sectors when compared to their conventional counterparts in the year 2030 for the EU, while the production of bio-based electricity and gas is not (Table 7). Hence, replacing conventional fuels and chemicals by biofuels and biochemical will result in an increase in GDP. In the case of the fuel sector, the net GDP effect as calculated by MAGNET is larger than the direct value of production when costs are directly calculated (taking into account only the difference in production costs between conventional and bio-based applications, and no indirect economic effects). This implies a multiplier effect larger than one.

A substantial part of this multiplier effect can be explained by increases in wages, since the production of biomass is relatively labour intensive, in total around 26% of the costs of producing, transporting and converting biomass are labour costs, and almost all labour is used for the production and pre-treatment of the biomass. Then, a shift from conventional to bio-based production increases the direct use of labour. The increase in wages is transmitted to other sectors in the economy and in turn it has a positive impact on the employment, production, consumption and trade of the fuel sector. Another important contributor to the multiplier effect is the lower oil price as a result of the substitution of oil based fuel production by bio-based fuel production, which in turn benefits the entire economy. These effects are higher in the scenario with higher oil prices, since a higher oil price means that the impact of biofuel production has a larger

impact on the fuel price. The opposite effect occurs in the lower oil price scenario but still it makes biofuels competitive.

The same mechanisms described above apply to the macroeconomic impacts of the production of chemicals, electricity and gas. Given the assumptions, the production of chemicals results in the highest net GDP effect of the four bio-based applications considered, making it very competitive when compared to its conventional counterpart. However, the change in value of production costs is larger than the GDP effect, which leads to a multiplier effect which is less than 1. With the chemical industry being rather labour intensive compared to other bio-based sectors and their conventional equivalents, the increased production in this sector increases the demand for labour, This results in a reduced competitiveness of the service sector and the 'other industries' sector which compete for labour with the chemical industry. This effect reduces the volume of labour and the production volume in these sectors (i.e. services and 'other industries'). Moreover, imports also increase to maintain the level of consumption of services and 'other industries' sectors, which results in a negative trade balance effect.

Last, bioelectricity and biogas are shown not to be competitive with their conventional counterparts and hence their prices rise, their employment, production, consumption and exports fall, making it clear that, given the assumptions used in the analysis biomass would be better used in the second generation biofuel or biochemicals industries.

However, in the context of this novel research line, both the approach and MAGNET have several drawbacks and shortcomings. For example, the analyses presented in this report assume that one unit of bio-based product replaces an equal amount of conventional product (on energy basis). In reality the use of bio-based products changes the demand and supply and price of conventional products. Also the demand and supply of biomass for bio-based applications is considered in a static manner that only partially accounts for the impacts on land use and agricultural production and consumption. See the work of Smeets *et al.* (2014) for an assessment of the impact on land use and food security of the use of wheat straw for bioenergy. These effects can only be modelled by expanding MAGNET with new sectors that supply biomass or convert biomass into energy or materials; such work is currently being developed for future analyses on the subject. Another important issue is that the supply of

labour in the EU is assumed to be fully used in 2030, while unemployed people and part time workers may meet the increase in demand for labour. This can be investigated by assuming a more flexible labour supply function. Lastly, the analysis assumes that the EU is the only region in the world to use bio-based applications; an extension to this analysis could be to include other regions such as the USA, Canada and Malaysia.

Overall, based on a set of assumptions, the analysis of biomass applications suggests that biomass would be better used in the production of second generation biofuels or biochemicals industries.

JRC Mission

As the Commission's in-house science service, the Joint Research Centre's mission is to provide EU policies with independent, evidence-based scientific and technical support throughout the whole policy cycle.

Working in close cooperation with policy Directorates-General, the JRC addresses key societal challenges while stimulating innovation through developing new methods, tools and standards, and sharing its know-how with the Member States, the scientific community and international partners.

*Serving society
Stimulating innovation
Supporting legislation*
