A two-phase near- β titanium alloy (Ti-10V-2Fe-3Al, or Ti-1023) in its as-forged state is employed to illustrate the feasibility of a Bayesian framework to identify single-crystal elastic constants (SEC). High Energy X-ray diffraction (HE-XRD) obtained at the Diamond synchrotron source are used to characterize the evolution of lattice strains for various grain orientations during in situ specimen loading in the elastic regime. On the other hand, specimen behavior and grain deformation are estimated using the elastic self-consistent (ELSC) homogenization scheme. The XRD data and micromechanical modelling are revisited with a Bayesian framework. The effect of different material parameters (crystallographic and morphological textures, phase volume fraction) of the micromechanical model and the biases introduced by the XRD data on the identification of the SEC of the β phase are systematically investigated. In this respect, all the three cubic elastic constants of the β phase (C_{11}^{β} , C_{12}^{β} , C_{44}^{β}) in the Ti-1023 alloy have been derived with their uncertainties. The grain aspect ratio in the ELSC model, which is often not considered in the literature, is found to be an important parameter in affecting the identified SEC. The Bayesian inference suggests a high probability for non-spherical grains (aspect ratio of $\sim 3.8 \pm 0.8$): $C_{11}^{\beta} = 92.6 \pm 19.1$ GPa, $C_{12}^{\beta} = 82.5 \pm 16.3$ GPa, $C_{44}^{\beta} = 43.5 \pm 7.1$ GPa. The uncertainty obtained by Bayesian approach lies in the range of ~ 1 -3 GPa for the shear modulus $\mu' = \frac{C_{11}^{\beta} - C_{12}^{\beta}}{2}$, and ~ 7 GPa for the shear modulus $\mu'' = C_{44}^{\beta}$, while it is significantly larger in the case of the bulk modulus $\frac{C_{11}^{\beta} + 2C_{12}^{\beta}}{3}$ (~ 17 -24 GPa).

1. Introduction

Titanium and its alloys are attractive in the aeronautic industry due to their high strength to density ratios. The near- β titanium alloy Ti-10V-2Fe-3Al (Ti-1023) developed in the 1970s is often used in the forged pieces of aircraft for landing gears and rotor systems [1]. Its in-service microstructure is multiscale and complex. After forging, it is composed of hexagonal primary α_p nodules (micrometric size) embedded in a cubic β matrix with millimetric grains (β/α -forged state). Further aging partially transforms the β matrix

to secondary α_s platelets of nanometric size [2]. The alloy potentially exhibits remarkable mechanical behavior: yield stress up to 1200 MPa with a ductility of 7%. However, these properties are highly sensitive to local microstructure variations, which are not fully controlled in large forged pieces. In fact, the elastic properties of this alloy are far from being fully understood yet. At least, there is a reasonable agreement in the literature when it comes to the single-crystal elastic constants (SEC) of the α phase. However, for the β (BCC) phase, the published SEC C_{11}^{β} , C_{12}^{β} , C_{44}^{β} span very different values, refer to Table 1. These SEC define three independent elastic moduli, the shear moduli, defined as $\mu'' = C_{44}^{\beta}$ and $\mu' = \frac{C_{11}^{\beta} - C_{12}^{\beta}}{2}$ and the bulk modulus, $K = \frac{C_{11}^{\beta} + 2C_{12}^{\beta}}{3}$. The anisotropy ratio, $A = \frac{2C_{44}^{\beta}}{C_{11}^{\beta} - C_{12}^{\beta}} = \frac{\mu''}{\mu'}$ [3], is found to range over very large val-

ues from 1.4 to 8, see Table 1. The differences are possibly due to chemical compositions of the β phase, although one cannot sweep out the difficulties to measure local elastic constants in a multi-phase polycrystalline specimen. Such lack of accuracy impedes a predictive understanding of the material's behavior. For example, in the study by Raghunathan et al [14], where the forged and aged state have been studied, the strong difference in the identified SEC for the β phase is a possible result of microstructure as well as the chemical composition of the β phase. A recent study [4] on polycrystalline Ti-6Al-2Sn-4Zr-6Mo alloy with X-ray diffraction reports a decrease in SEC of the β phase by 10% (towards the single-phase alloy) when accounting for the load partitioning from the β phase to the α phase, a feature that will be naturally taken into account with the Self-Consistent model used here.

Prior research on this alloy has been focused on ex-situ mechanical tests and micromechanical modeling to explain the elastic and viscoplastic properties [23,24]. Some studies have been carried out to quantify the elastic constants in the β -titanium alloys due to the strong relationship between the shear modulus (μ') and the stability of the phase [25]. Other studies have also focused on the correlation of shear modulus (μ') to the Young's modulus [26,27]. Recently, Lhadi et al [28] have shown that SEC corresponding to different anisotropy ratios (of 2.4, 3, and 8.3) can all lead to the same effective Young moduli and similar macroscopic behavior in the elastic regime, but very different inter-granular stresses in the course of elasto-plastic deformation.

The standard SEC characterization involves experiments on large single crystals using classical methods such as ultrasonic wave velocities [29,30], rectangular parallelepiped resonance [31]. However, it is rather difficult to produce single crystals with exact composition to that of a phase within a multi-phase alloy. In the literature, several studies on single-phase microstructures have adopted an inverse approach using the elastic self-consistent model (ELSC) to identify the diffraction elastic moduli (DEM) from the X-ray diffraction (XRD) analysis and the macroscopic stiffness [17,18,32,33]. This can be challenging in the case of a multiphase alloy where the SEC of each phase is inherently different due to crystal symmetry. A variety of micromechanical models exist that take into account the crystallographic texture and grain morphology to establish the elastic properties of a polycrystal [34-38]. Given the computational simplicity, the two-phase interactions in the model are often approximated through an average procedure using an elastic homogeneous equivalent medium (HEM). The self-

consistent scheme [37,39,40] has also been successfully applied to study the load-partitioning in titanium alloys [14,18,33,41-44].

However, studies [15,17,18] with inverse identification by the least-squares method have reported that the DEM for Ti-alloys can be insensitive to the bulk modulus, thus resulting in several possible SEC that satisfies the lattice strain evolution i.e. the associated uncertainties are rather large. In the literature [17,18], this is addressed by evaluating the SEC for a fixed bulk modulus, which is a theoretical approximation. Recently, a study on β -Timetal-18 [19] has employed high energy X-ray diffraction and a micromechanical analysis of stress-strain inhomogeneities with a fast Fourier transform (FFT)-based formulation (MASSIF) to identify the SEC of the β phase. A grain-to-grain analysis in the MASSIF framework suggested a strong effect on the elastic anisotropy, i.e., higher anisotropy ratio ($A=3.5$) provided better correlation of all the strains components.

Part of the variability reported in Table 1 may come from chemical composition variations, and it is not the scope of the present paper to discuss this aspect. We want to stress that multiple SEC have been identified for the β phase and most of the studies have used inverse identification and have only provided one unique value for the SEC of the β phase without estimating the role of different microstructural parameters and none of them provide an uncertainty estimate on the identified value. In the current study, to quantify the uncertainties and also to study the effect of different material parameters on the SEC identification, a Bayesian framework combined with an inverse identification approach to probe a large C_{ij} space is employed. The Bayesian framework provides the advantage of exploring the large C_{ij} space while generating a distribution of acceptable values. For example, such a framework has already been used in the context of spherical indentation measurements to identify the SEC for single-phase materials [45-48].

The objective of this paper is to present the Bayesian framework in synergy with high-quality XRD data acquired during tensile loading at the DIAMOND synchrotron source and the ELSC model. This is applied to a near β Ti-1023 alloy to estimate the uncertainties on the SEC of the cubic (β) phase from XRD data. The combination of XRD and ELSC modeling is often employed in the literature to evaluate the SEC. However, to the best of authors' knowledge, this is the first time that these methods are employed in a Bayesian framework to quantify the uncertainties of SEC for a polycrystalline multi-phase alloy. Here, a Bayesian

framework is elaborated together with the Metropolis-Hasting algorithm [49] and the ELSC model [37, 38] to evaluate the experimental data, with a particular focus on XRD data evaluation. This framework is then applied to the experimental data (macroscopic stiffness and XRD lattice strains), and the results are discussed along with the literature. Different parameters in the ELSC micromechanical model are explored and the experimental errors influencing the quantification of uncertainties of the SEC are discussed.

2. Methods

2.1. Material

For our study, an ($\alpha + \beta$) forged billet of β metastable titanium alloy Ti-10V-2Fe-3Al (by wt. %) was provided by Timet, France. The β transus of this alloy is $795^\circ\text{C} \pm 5^\circ\text{C}$. The billet was obtained by several forging/annealing steps in the β (above β transus) and α/β domain (at 760°C). Samples were extracted from the core of the billet. A controlled microstructure composed of primary α_p nodules embedded in a β matrix was obtained by carrying out additional heat treatment of 760°C for 1 hour followed by water quenching on the samples. Moving forward, this is referred to as “as-forged” state. All investigated specimens had identical microstructure.

Several sections were cut and polished to observe the microstructure under the scanning electron microscope (SEM). The volume fraction of the primary α_p phase was measured to be $15 \pm 3\%$. The α_p nodules were mostly equiaxed with an average diameter of 2-3 μm from several backscattered images using ImageJ software [50]. As expected, no secondary α lamellae (α_s) were present. Additional Electron Back-Scattered Diffraction (EBSD) measurements were carried out using a Zeiss AURIGA 40 electron microscope equipped with the AZTEC Oxford instrument system and the Symmetry camera. Fig. 1 shows the multi-scale microstructural aspects of the Ti-1023 as-forged alloy. Several orientation maps were acquired with 0.5 μm step size (much smaller than the average α nodules diameter).

An EBSD analysis revealed that the microtexture consists of millimetric long prior β grains along the forging axis (with an aspect ratio between 8 – 10) as a result of the forging process. These long prior β grains were partially fragmented in equiaxed sub-grains (with misorientation angles of 3° - 15°) of diameters ranging from

5 to 10 μm . The α_p nodules were located at the prior β grains and the β sub-grain boundaries.

Neutron diffraction analysis was performed on a $1 \times 1 \times 1\text{ cm}^3$ sample to characterize the crystallographic texture of both α and β phases at the 6T1 spectrometer of the French neutron source at LLB, using a wavelength of 1.159 \AA . Complete pole figure measurements were carried out for three β reflections (110, 200, 311) and five α reflections (00.2, 11.0, 10.0, 10.1, 10.2). The Orientation Distribution Function (ODF) was calculated using the spherical harmonics method thanks to the ATEX software [51]. Measured pole figures revealed a rather moderate texture with a texture index of ~ 2 for the α phase and ~ 3 for the β phase. Furthermore, most of the grains are preferably aligned along the $\langle 110 \rangle_\beta$ direction parallel to the forging axis of the billet, which is also the loading axis of the samples, see Fig. 2. Pole figure analysis from Fig. 2 indicates that the Burgers Orientation Relationship (BOR) between the α_p and β phase is still respected in average (all poles of $\{0001\}_\alpha$ and $\{110\}_\beta$ overlap as well as $\langle 11\bar{2}0 \rangle_\alpha$ and $\langle 111 \rangle_\beta$).

2.2. In-situ high energy X-ray diffraction tensile experiments

The in-situ high energy X-ray diffraction (HEXRD) tensile experiments were carried out at room temperature at the I12 beamline in the Diamond Light Source, UK [52]. Cylindrical specimens having a diameter of 1cm were cut from the core of the billet using electrical discharge machining (EDM). These samples were then heat-treated to obtain the as-forged microstructure and were then machined into tensile specimens with gauge sections of 4 mm in diameter and 26 mm in length conforming with the ASTM-E8 standards [53].

Fig. 3 shows the complete experimental setup. A monochromatic beam of 70.45 keV (wavelength $\lambda = 0.17599\text{ \AA}$) with a cross-section of $500 \times 500\text{ }\mu\text{m}^2$ was employed in transmission geometry, leading to a diffraction volume of $0.5 \times 0.5 \times 4\text{ mm}^3$. This diffraction volume corresponds to 6-8 prior β grains, however, it is reminded that the β grains are fragmented into β sub-grains of 5-10 μm diameter thus providing enough grain statistics to form complete and continuous Debye-Scherrer diffraction rings, refer to 2D diffractogram in Fig. 3. The diffracted X-rays rings were recorded on a 2D Pilatus 2M CdTe area detector (1475×1679 pixels, pixel size 172 μm) kept at $\sim 0.9\text{ m}$ from the specimen. Thanks to the high X-ray flux and fast readout time of the detector, the diffraction patterns were sampled continuously every $\sim 1\text{ s}$.

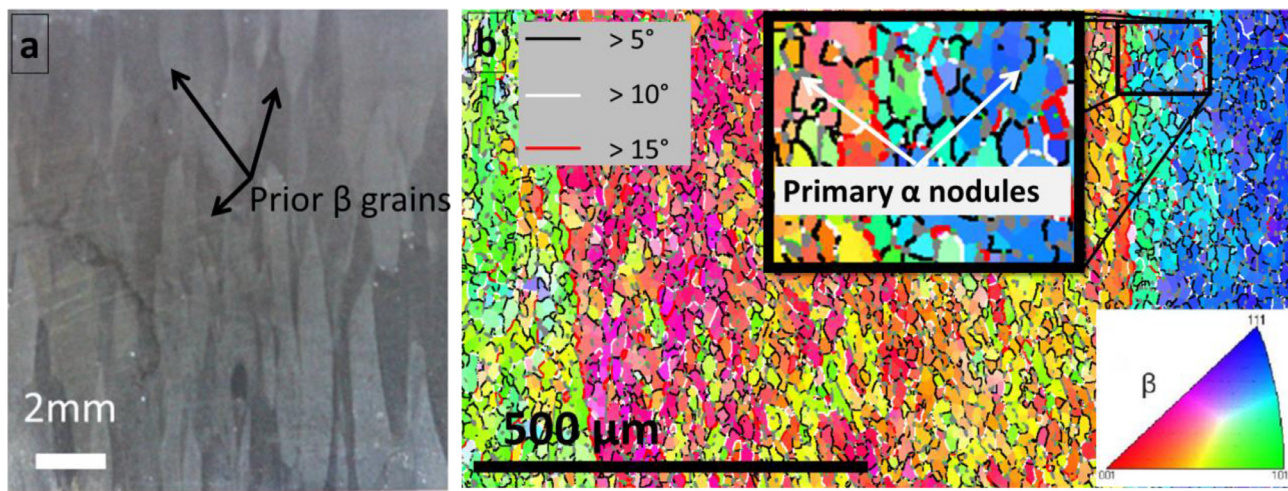

Fig. 1. (a) an optical micrograph of Ti-1023 as-forged microstructure along the forging axis (also tensile axis here) with millimetric prior β grains, (b) a section of the β -IPF map along the forging axis with black, white and red lines indicating the boundary misorientations of $>5^\circ$, $>10^\circ$ and $>15^\circ$ respectively, the inset shows a magnified view of β -IPF map with primary α nodules in gray.

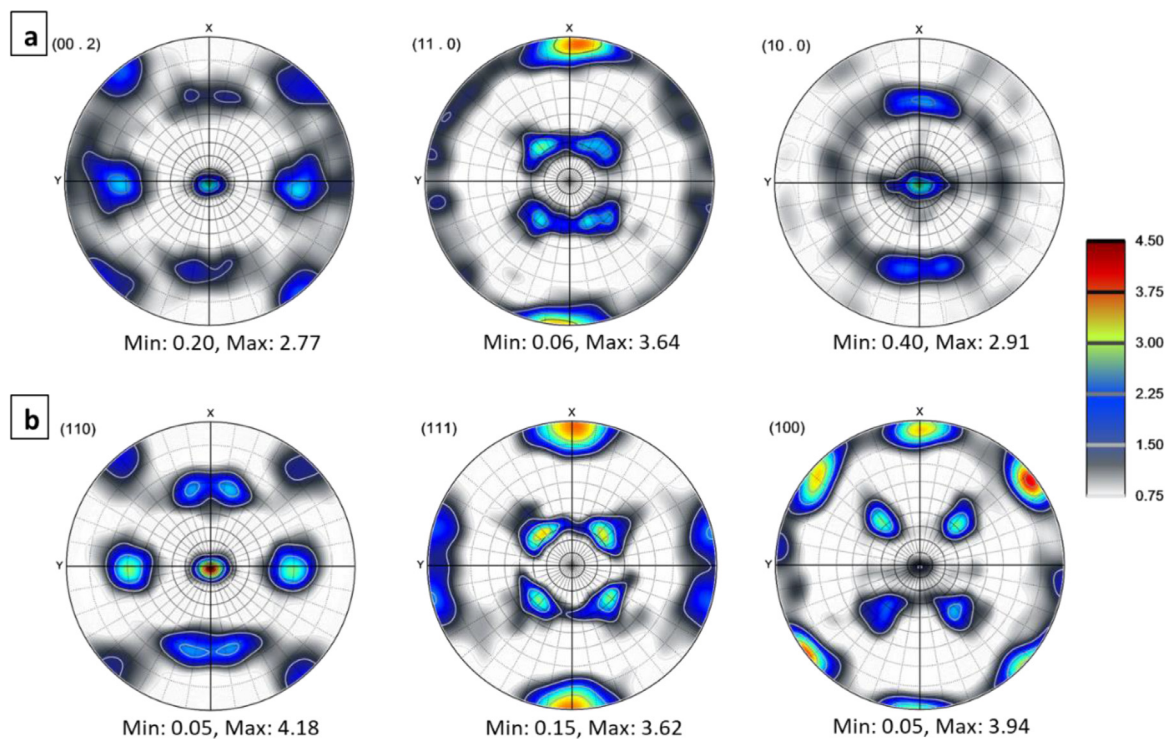

Fig. 2. Pole figures of the (a) α and (b) β phase of the 'as-forged' Ti-1023 alloy measured by neutron diffraction (forging axis and also tensile axis lies in the center of pole figures)

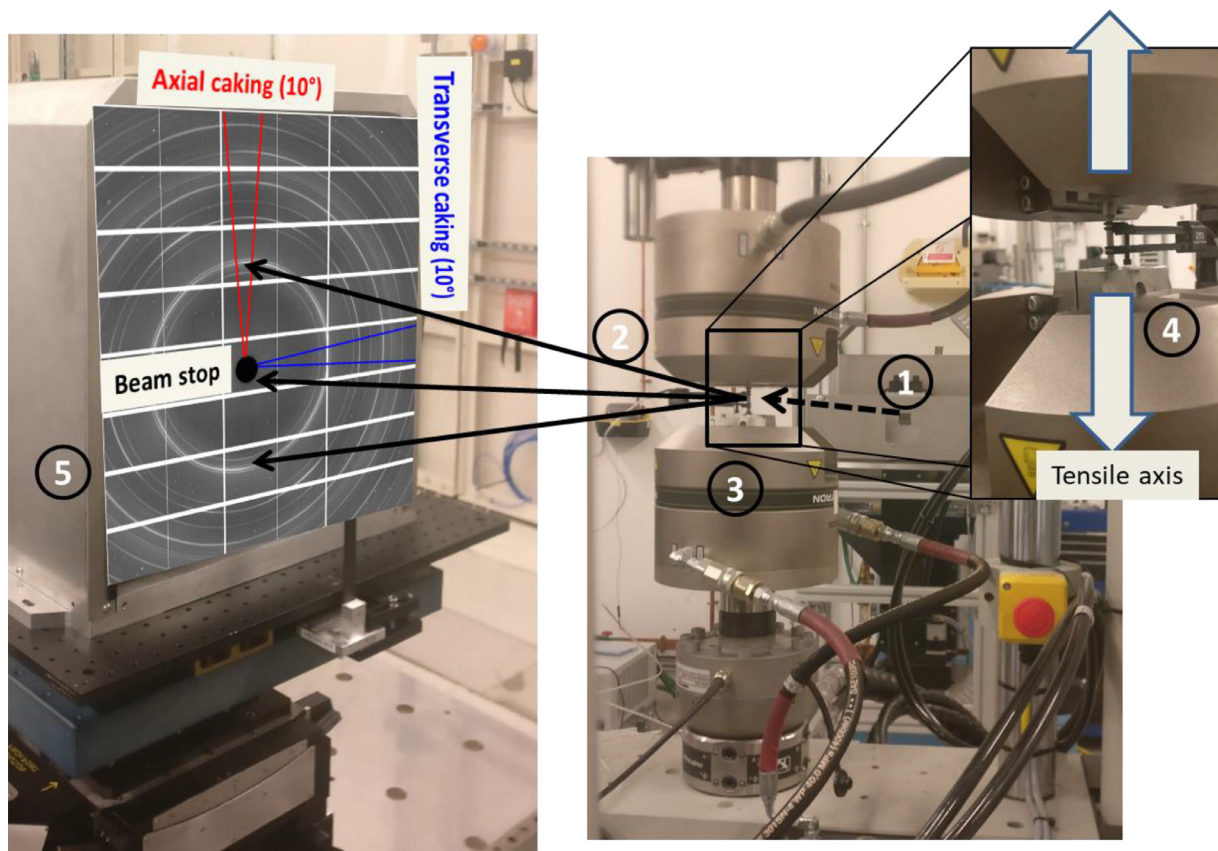

Fig. 3. High energy in-situ XRD setup at Diamond I12 beamline, UK. The setup includes (1) incident X-ray beam (70 keV; beam size: 500 μ m x 500 μ m), (2) diffracted X-ray beam, (3) Instron rig (100 kN capacity), (4) Inset with sample between grips and contact extensometer of 5mm travel, (5) Pilatus 2M detector with sample diffraction pattern of the studied alloy (1475x1679: pixel size: 172 μ m).

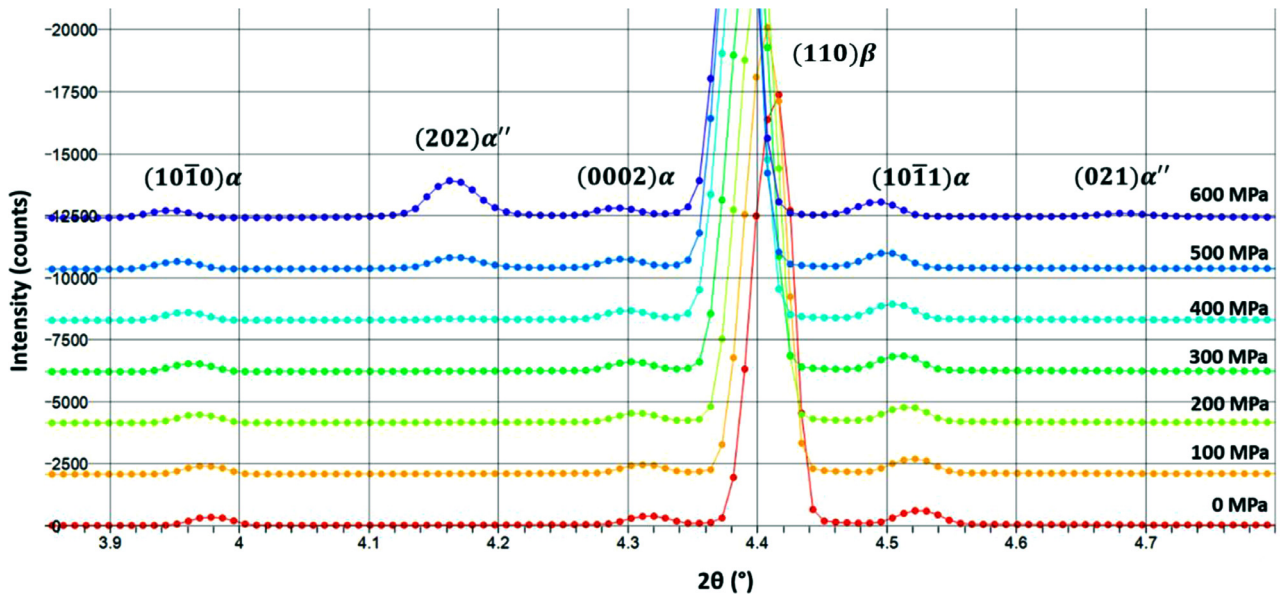

Fig. 4. 1D XRD spectra, obtained by integration of complete 2D XRD rings, for the monotonous tensile test at different stress levels (0 – 600 MPa) for Ti-1023 alloy. The martensite peaks (α'') appear close to 400 MPa

The deformation tests were performed on an Instron 100 kN rig at a nominal strain rate of 10^{-4} s^{-1} . The macroscopic strains were measured using a contact extensometer. The campaign includes a continuous tensile test, a load-unload cyclic test, and a series of increasing uni-axial tensile interrupted tests. This campaign was originally designed to study the elastic and plastic response of the material under various deformation paths and small plastic strain; only the elastic part is presented in this paper. The stress-interrupted tensile tests were performed to increase the diffracting volume i.e., every 50 MPa increment up to ~300 MPa the sample was held at constant stress and a 72° rotation of the Instron rig (along the tensile axis) was carried out with $2^\circ/\text{s}$ and the diffraction patterns sampled every 2° were then summed to get a single diffraction pattern. In Fig. 4, the stress-induced martensitic transformation peaks can be observed in the XRD spectra starting at ~400 MPa (~0.6% total strain), which is not surprising considering the low volume fraction of the α phase [54–57]. Since our objective is to identify the SEC, data analysis was carried out in the purely elastic regime prior to phase transition (macroscopic stresses up to ~300 MPa). Hence, the analysis is performed from the continuous tensile tests up to 300 MPa, four load-unload cycles performed at (200, 250, 300, 350 MPa), and stress-interrupted tensile tests up to ~300 MPa. Rietveld refinement of XRD patterns at zero applied stress validates the SEM measurements of 15% volume fraction for the α phase.

XRD data analysis: The analysis of the XRD spectra provides important information concerning the deformation mechanisms and load transfer among different grains/ phases. For the current study, the XRD data analysis is limited to the lattice strain evolution with applied stress. However, considering the nature of the study, several aspects of XRD data processing that can result in additional uncertainties are carefully evaluated. The common source of uncertainty comes from the geometrical calibration of the experimental setup [58,59]. The errors are introduced possibly during the conventional three-step data analysis process: (i) geometrical calibration of the experimental setup, (ii) conversion of the 2D azimuthal data to 1D (2θ vs intensity) and (iii) peak-fitting for lattice strain evaluation. The diffraction data collected here exhibit a good quality with reduced background and noise levels (maximum peak intensity ~18000 cts, signal/noise ratio ~130).

The geometrical calibration of the detector was performed by a standard calibrant powder of CeO_2 (SRM674 from NIST). The recorded 2D XRD rings are processed by “caking” [60] along the azimuth ψ . Both the axial and transverse direction (refer to Fig. 3) caking is carried out (here caking angle of $\Delta\psi = \pm 5^\circ$ is used). The integration along ψ yields a 1D diffraction pattern. Additionally, the characterization of the image noise was done using multiple images acquired under the same geometrical configuration as in [61]; this indicates the photon noise source to be the sole contributor (not shown here) and therefore, an error model where the standard deviation of intensity is proportional to the square root of average intensity is employed during the peak fitting. The 1D pattern is then fitted with a Pseudo-Voigt function to resolve parameters related to the shape of the peak, the position (2θ), and Full-Width Half Maximum (FWHM). Each peak/ reflection is treated separately during the fitting. In the Ti-1023 alloy with $\alpha + \beta$ phases, the majority of the α and β diffraction peaks could be satisfactorily fitted, while the overlapping α/β peaks were ignored. The XRD data calibration and integration were carried out using the PyFAI library [62], while the peak fitting was carried out using Fityk software [63].

The in-situ XRD data interpretation is based on the relative changes in the measured values of the Bragg angle θ . The lattice strain ε_{hkl} is represented in microstrain (10^{-6}) units by the following relation:

$$\varepsilon_{hkl} = -\cot(\theta_{hkl}) \Delta \theta_{hkl} \times 10^6 \quad (1)$$

where $\Delta \theta_{hkl} = \theta_{hkl} - \theta_{0,hkl}$ is the difference in peak position calculated from the current θ_{hkl} and the $\theta_{0,hkl}$ calculated at the start of the test. Fig. 5 shows the XRD peak analysis for $(10\bar{1}0)\alpha$ reflection plotted with respect to applied stress. For better comparison and representation, both the lattice strains and applied stresses are normalized by dividing them with the magnitude of maximum applied stress of each respective test (around 300 MPa, which slightly varies between tests), such that the resulting normalized strains have unit microstrain/MPa. Fig. 5a shows the normalized macroscopic strain-stress curves with the dashed line representing the linear regression fit of the data from all tests. Fig. 5b and 5c show the normalized axial and transverse lattice strains of $(10\bar{1}0)\alpha$ reflection along with the linear regression. Very similar data quality

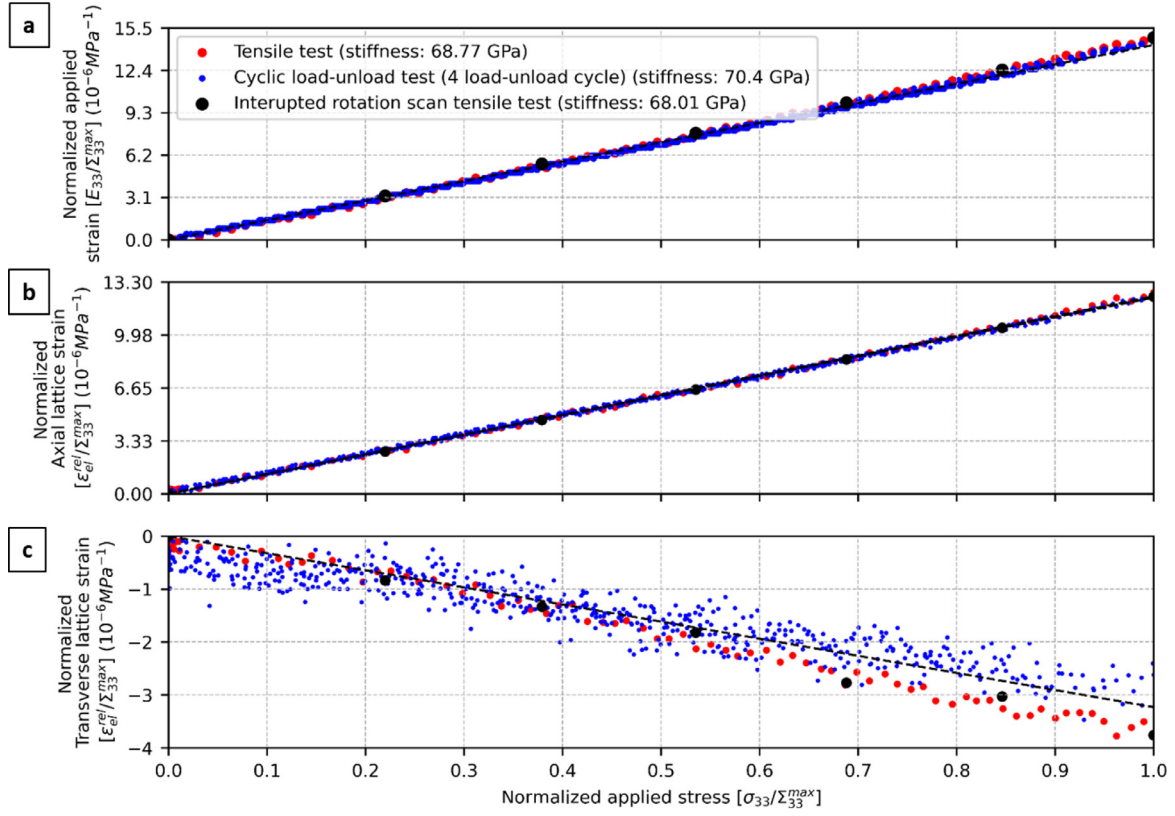

Fig. 5. Elastic response of Ti-1023 alloy (data points up to the martensite trigger stress ≈ 400 MPa). The top plot (a) corresponds to continuous tensile strain-stress data, middle plot (b) corresponds to the evolution of normalized axial (10 $\bar{1}0$) elastic lattice strains versus normalized applied stress (linear regression fit is carried out and shown by the solid dashed line), bottom plot (c) corresponds to the evolution of normalized transverse (10 $\bar{1}0$) elastic lattice strains versus normalized applied stress. All the data points are normalized by dividing them with maximum applied stress of the respective test (see text).

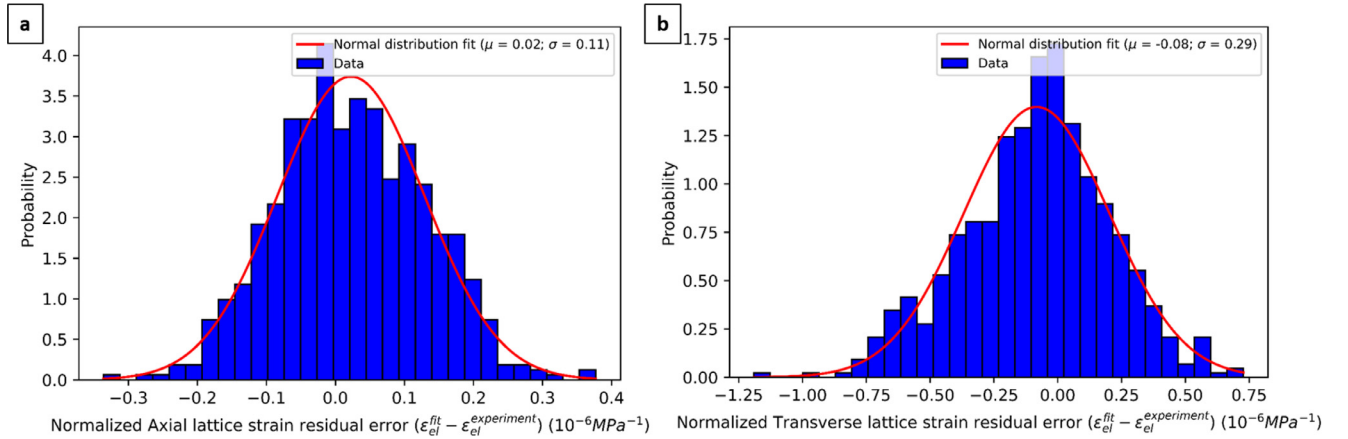

Fig. 6. Statistical distributions of normalized (a) axial and (b) transverse (10 $\bar{1}0$) lattice strains residual error along the linear regression fit of data shown in Fig. 5. The red line is the associated fit of the dispersion by a normal distribution, the parameter of which is indicated in the legend.

has been obtained for other (hkl) reflections for both the α and β phases.

The linear regression fit data is used as the average lattice strains and the scatter of experimental data at given stress around the fit is taken as the standard deviation for lattice strains. Fig. 6 shows the distribution of lattice strains from the different tests compared to their linear fit for both axial and transverse directions at applied unit stress. Following this procedure, other axial and transverse reflections of both α and β phases are processed and are presented in the results section. All lattice strains for both α and β phases are found to follow a nearly normal distribution similar to Fig. 6. It should also be noted that not all reflections

could be used: especially, the stiffest (222) β reflection is out of the detector capture range; the reflections (211) β and (10 $\bar{1}3$) α is not available due to peak-overlapping and the (0002) α transverse reflection lie in the detector dead zones.

It is reminded here that the observed lattice strain variability includes errors coming from data acquisition (e.g. photon noise), data processing and the variation of lattice strains from one experiment to another (as illustrated in Fig. 4c). The obtained dispersions in the lattice strains are representative of the material itself and provide a realistic range of average strains for the Bayesian inference to fit. Other relevant error sources during the experimental acquisition were found to be minimum/negligible. In sum-

mary, the experimental data used for the Bayesian inference include, along with their variability,

- 8 axial reflections and 4 transverse reflections for the α phase,
- 4 axial reflections and 2 transverse reflections for the β phases, and
- the effective axial elastic stiffness of the material.

These data are indicated in Table 2 and plotted in Fig. 7.

2.3. Bayesian framework with HEXRD and elastic self-consistent (ELSC) modeling

Description of the elastic self-consistent (ELSC) model: The self-consistent scheme is one of the most popular homogenization methods to simulate the behavior of multiphase polycrystalline materials. This framework [37,38] is implemented here to describe the elastic properties of the two-phase ($\alpha+\beta$) polycrystalline aggregate. The ellipsoidal inhomogeneity (each representing a single crystal orientation in a given phase) is embedded in an infinite homogeneous equivalent medium (HEM), whose behavior is supposed to be the behavior of the multi-phase polycrystal. The constitutive relations for a heterogeneous linear elastic aggregate can be described as:

$$E = M^{eff} : \Sigma \quad (2)$$

where the quantities E and Σ are the macroscopic strain and stress tensors and M^{eff} is the effective elastic compliance tensor of the polycrystal. The constitutive elastic behavior for each orientation ' r ' between the average strains ε^r and average stresses σ^r over the volume occupied by r yields:

$$\varepsilon^r = m^r : \sigma^r \quad (3)$$

where m^r is the elastic compliance tensor of orientation r . In the homogenization theory, the stress concentration relationships between σ^r and Σ can be described as:

$$\sigma^r = B^r : \Sigma \quad (4)$$

where B^r is the average stress concentration tensor for each orientation r in a given phase (α/β). This tensor is evaluated considering each Eshelby's ellipsoidal inhomogeneity r embedded in an infinite HEM subjected to homogeneous stress Σ :

$$B^r = (m^r + \tilde{M})^{-1} : (M^{eff} + \tilde{M}) \quad (5)$$

where \tilde{M} is the constraint tensor defined by the following expression [64]:

$$\tilde{M} = (I - S^{Er})^{-1} : S^{Er} : M^{eff} \quad (6)$$

where I is the fourth-order unit tensor and S^{Er} is the elastic Eshelby tensor [36] for a given inhomogeneity that can exhibit any ellipsoidal morphology. In equation (2), the effective elastic compliance tensor of the polycrystal M^{eff} is given by:

$$M^{eff} = \langle m^r : B^r \rangle : \langle B^r \rangle^{-1} \quad (7)$$

where the brackets $\langle \cdot \rangle^r$ denote the volume average over all the grains of the polycrystal: $\langle \cdot \rangle^r = \sum_r f_r \langle \cdot \rangle^r$ with f_r the volume fraction of orientation r . When replacing B^r in equation (7) by its expression (5), one ends up with an implicit equation for M^{eff} that is solved using a fixed-point algorithm [65]. For more details on the Eshelby tensor evaluation, the readers are referred to [64,66].

In the ELSC model, each mechanical phase is defined by its orientation (three Euler angles with the Bunge convention: ϕ_1, Φ, ϕ_2) and a volume fraction f_r . For each grain orientation, if the plane

normal of the given (hkl) plane is aligned within $\pm 5^\circ$ of solid angle (same as experimental configuration, see Fig. 3) with the sample axis, then that grain contributes to that (hkl) diffraction subset. To obtain the normalized elastic strains corresponding to different (hkl) families of grains as in Fig. 5b and 5c, $\frac{\varepsilon_{hkl}^{simulation}}{\Sigma_{33}^{max}}$, average strains (sometimes denoted as mesoscopic strains in the literature) of the diffracting grains are multiplied by their volume fraction and summed over the overall volume fraction of grains in the subset. This is then normalized by the maximum applied tensile stress. For a given loading direction of the specimen (uniaxial traction here), a compact representation of the $\varepsilon_{hkl}^{simulation}$ can be defined as the function of the diffraction condition (solid angle with the macroscopic axis $\psi = \pm 5^\circ$), texture (ϕ_1, Φ, ϕ_2), phase elastic constants, volume fraction ($f_\alpha + f_\beta = 1$), and morphology (spheres or prolates defined by the aspect ratio: α_{AR}, β_{AR}).

$$\frac{\varepsilon_{hkl}^{simulation}}{\Sigma_{33}^{applied}} = f\left(\psi, \phi_1, \Phi, \phi_2, f_\beta, C_{11}^\beta, C_{12}^\beta, C_{44}^\beta, C_{11}^\alpha, C_{12}^\alpha, C_{13}^\alpha, C_{33}^\alpha, C_{44}^\alpha, \alpha_{AR}, \beta_{AR}\right) \quad (8)$$

It is worth noting that the elastic self-consistent model used here is very good in evaluating the effective elastic properties of polycrystalline materials, probably owing to the random character of the considered microstructure that qualitatively resembles the one of real polycrystals. Comparisons with full-field simulations that provide reference numerical solutions already showed that the ELSC scheme gives very accurate estimates for the elastic behaviour, not only for the effective behaviour but also for the first (grain average strain and stress) and second (fluctuation inside grain families) moments, eg. see [67–70]. One of the limitations of the ELSC is that advanced microstructural parameter, such as orientation relationship between neighboring grains, can hardly be taken into account.

Bayesian inference: Bayesian framework combined with standard linear model (SLM) [71], reduced-order FE models [45] has recently been used to estimate the intrinsic material properties of metals. Here the Bayesian inference technique is very briefly explained, for more details, the readers are referred e.g. to the work of Rappel et al. [71–74]. In brief, we are evaluating a simplified Bayes theorem [75]: considering a random variable " θ ", its probability density function for a given experimental dataset " x " can be evaluated by applying Bayes theorem: the probability of " θ " occurring for a given set of " x ", or $P(\theta|x)$ (also called "posterior distribution") is expressed as statistical inference model below:

$$P(\theta|x) = \frac{P(x|\theta) P(\theta)}{P(x)} \quad (9)$$

where $P(\theta)$ is the probability distribution of the variable " θ " in the absence of " x " and is also called the "prior distribution". $P(x|\theta)$ is called the "likelihood function" that evaluates the probability of the data " x " occurring for a given " θ ". The numerator of the Bayes formula is rather easy to formulate, while there are difficulties involved in calculating the denominator $P(x)$. In general, this quantity can be calculated by integrating over all possible values of " θ ",

$$P(x) = \int_{\theta} P(x|\theta) d\theta \quad (10)$$

For a simple and trivial model, this parameter is rather easy to evaluate and is often discarded as a normalization factor [45,71], while in some non-trivial models, this can be extremely difficult to estimate in a closed-form way. To simplify, this is often addressed by taking the ratio of two probabilities with Markov chain Monte Carlo (MCMC) [76]. In short, this constructs a Markov chain,

which proposes a jump for the random variable “ θ ”, to carry out the Monte Carlo sampling. The jump proposed in a Markov chain is often carried out by a Metropolis sampler. The acceptance probability of a jump is calculated by the ratio of [equation \(9\)](#) for the current “ θ^{current} ” and the proposed “ θ^{proposed} ”, thus cancelling out the denominator ([equation 11](#)). The proposed value is accepted if the acceptance is higher than a value randomly sampled between 0 and 1:

$$\text{Acceptance probability} = \min \left(1, \frac{P(x|\theta^{\text{proposed}}) P(\theta^{\text{proposed}})}{P(x|\theta^{\text{current}}) P(\theta^{\text{current}})} \right) \quad (11)$$

The objective of Bayes formula ([equation 9](#)) is to calculate the posterior distribution, $P(\theta|x)$, such that the unknown material parameter “ θ ” can be deduced from sampling the posterior distribution. The integrals defining the Monte Carlo and Metropolis sampler algorithm can be further referred in [71].

Application to Ti-1023 alloy: For the identification of SEC of the β phase in Ti-1023, a Bayesian framework is employed with the ELSC model to evaluate the likelihood function, which evaluates the probabilities of the macroscopic stiffness ($YM^{\text{simulation}}$) as well as the grain family elastic strains ($\varepsilon_{hkl}^{\text{simulation}}$) against the experimental ($YM^{\text{Experiment}}$) stiffness and XRD lattice strains ($\varepsilon_{hkl}^{\text{Experiment}}$) for different sets of material parameters. As can be seen from [equation \(8\)](#), the elastic strain $\varepsilon_{hkl}^{\text{simulation}}$ depends on 15 different variables (for fixed boundary conditions). As a preliminary approach, out of the 15 variables all but the SEC of the β phase is assigned a fixed value based on the experimental observations.

- The ODF calculated from neutron diffraction data has been used to discretize the texture of both phases using the ATEX software [51]. The discretization yields ~2250 orientations for the β phase and ~4500 orientations for the α phase weighted by volume fraction.
- The volume fraction for the α phase is fixed, $f_\alpha = 0.15$ ($f_\beta = 0.85$), based on Rietveld analysis of XRD patterns and SEM image analysis.
- The diffraction solid angle for simulation ($\psi = \pm 5^\circ$) is also fixed to comply with the experimental caking angle.
- As a preliminary approach, the α and β grains morphology are reasonably assumed to be equiaxed and therefore are represented as spherical inhomogeneities in the ELSC model (*i.e.* $\alpha_{AR} = 1, \beta_{AR} = 1$). However, this will be later changed to prolate morphology (section IVb) to study its influence on the identification process; in that case, the grain shape considered in the model actually rather corresponds to the β sub-grains than to the elongated prior β grains.
- The SEC of the α phase (C_{ij}^α) are fixed due to a substantial agreement reported in the literature. Therefore, the SEC identified by Hearmon et al [77] are considered, based on a previous study performed on the same alloy [42]: $C_{11}^\alpha = 160$ GPa, $C_{12}^\alpha = 90$ GPa, $C_{44}^\alpha = 46.5$ GPa, $C_{33}^\alpha = 181$ GPa, $C_{13}^\alpha = 66$ GPa.
- The SEC of the β phase (C_{ij}^β) is kept free for optimization and inference.

The Bayes formula adapted to the Ti-1023 alloy reads

$$P(D_{\text{simulation}}|D_{\text{XRD}}) = \frac{P(D_{\text{XRD}}|D_{\text{simulation}}) P(D_{\text{simulation}})}{P(D_{\text{XRD}})} \quad (12)$$

where D_{XRD} is a vector consisting of both micro and macro data: (hkl) dependent lattice strains ($\varepsilon_{hkl}^{\text{Experiment}}$) and macroscopic stiffness ($YM^{\text{Experiment}}$). $D_{\text{simulation}}$ is an output vector obtained from the ELSC model consisting of (hkl) dependent elastic strains ($\varepsilon_{hkl}^{\text{simulation}}$) and macroscopic stiffness ($YM^{\text{simulation}}$). $P(D_{\text{simulation}})$ is the prior

distribution and here it is defined as a uniform distribution, meaning that the values of the free variables are considered with equal probabilities within the material design space.

The likelihood function, $P(D_{\text{XRD}}|D_{\text{simulation}})$, is evaluated from the difference between the experimental dataset and the output of the ELSC model. It is reminded again that the experimental data point in our case follows a Gaussian distribution (see [Fig. 6](#)). The probabilities of distribution in the Bayesian inference is often represented in the log scale for numerical stability and simplicity, instead of the usual [0,1] interval. The log-likelihood function here is the sum of log-probabilities of the individual data point and can be written as,

$$\text{Log} (P(D_{\text{XRD}}|D_{\text{simulation}})) \propto - \sum_{i=1}^n W_i \left(\frac{1}{2} \log(2\pi) + \log(SD_i) + \frac{(D_{\text{simulation}}^i - D_{\text{XRD}}^i)^2}{2SD_i^2} \right) \quad (13)$$

where ‘i’ represents data points (here ‘n’ = 19, corresponding to the micro and macro experimental data points, see [table 2](#)). The SD_i is the standard deviation and W_i is the weight of each data point discussed in the next sections. The available data points sometimes may not produce a well-defined posterior distribution, *i.e.* the uncertainties of the distribution can be high. In such cases, additional experimental data points help to reduce the uncertainties or a careful weighing of the data points can lead to a well-defined posterior distribution. This is achieved through the W_i term in [equation 13](#). In the current study, the weighing is used as a way to counter-balance the fact that there is more α phase reflection, *i.e.*, giving intrinsically less importance to the α phase data fitting since its volume fraction is much lower in reality.

We employ the adaptive Metropolis algorithm to search the material space during the sampling to increase efficiency. The Metropolis algorithm proposes a small increment of the available free variables based on their variance and a new probability density function is calculated. To avoid non-physical results in the simulations, only the SEC satisfying the Born elastic stability conditions [78] for cubic ([equation 14](#) for β phase) and transverse isotropy ([equation 15](#) for α phase) are considered:

$$C_{11}^\beta - C_{12}^\beta > 0; \quad C_{11}^\beta + 2C_{12}^\beta > 0; \quad C_{44}^\beta > 0 \quad (14)$$

$$C_{11}^\alpha > |C_{12}^\alpha|; \quad 2(C_{13}^\alpha)^2 < C_{33}^\alpha(C_{11}^\alpha + C_{12}^\alpha); \quad C_{44}^\alpha > 0 \quad (15)$$

The efficiency of Metropolis sampling strongly depends on the initial guess and the variance of the proposal distribution of the free variables. For a good initial guess, a weighted least-squares optimization with an unconstrained Nelder-Mead algorithm was employed. MCMC sampling is also performed with additional free material parameters to assess the effect on the SEC identification and is discussed in the results section.

All the simulations are carried out using a script written in python interfacing pymc library for MCMC sampling [79] with Scipy’s least-squares minimization [80] and a python implementation of the elastic self-consistent scheme developed at PIMM, Paris.

3. Results

3.1. In-situ XRD lattice strain analysis

The lattice (axial and transverse) strains for all considered peaks of both the α and β phases at applied unit stress along with the macroscopic stiffness are presented in [Table 2](#).

Both the axial and transverse lattice strains of all peaks present a Gaussian distribution. The standard deviations are the results of the variation of lattice strains from one experiment to another. Comparatively, the standard deviations of all reflections are quite

Table 2

Statistics of axial and transverse lattice strains distribution for different reflections extracted from the regression fit for applied unit stress.

α/β reflections	Mean of axial lattice strains distribution (10^{-6} MPa $^{-1}$)	Standard deviation of axial lattice strains distribution (10^{-6} MPa $^{-1}$)	Mean of transverse lattice strains distribution (10^{-6} MPa $^{-1}$)	Standard deviation of transverse lattice strains distribution (10^{-6} MPa $^{-1}$)
10-10 α	12.35	± 0.11	-3.58	± 0.2
0002 α	9.16	± 0.14	-	-
10-11 α	11.46	± 0.2	-3.88	± 0.2
11-20 α	10.70	± 0.1	-4.81	± 0.18

Young's modulus (YM)	69.77	± 0.8	-	-

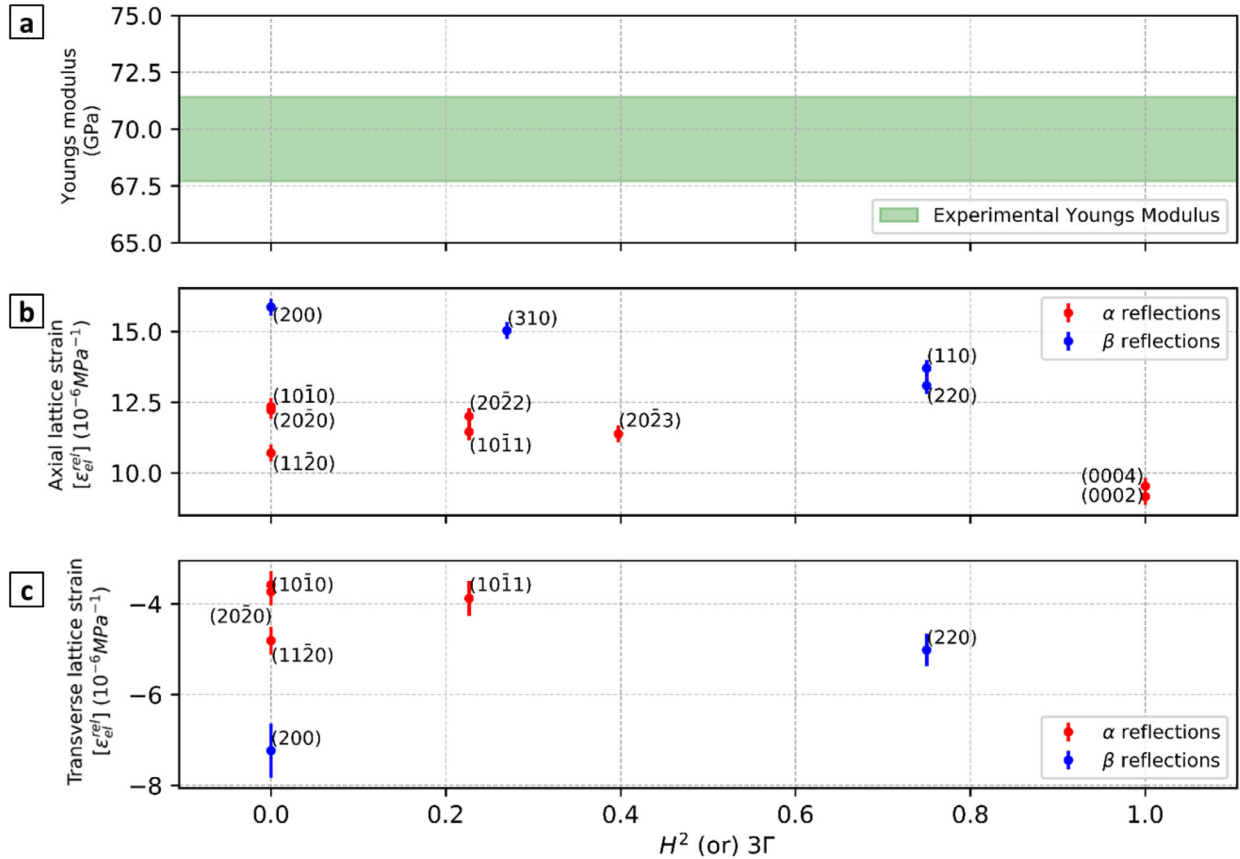

Fig. 7. Elastic response of Ti-1023 alloy. (a) the macroscopic Young's modulus data (shaded region corresponds to one standard deviation of the data), (b) and (c) the axial and transverse lattice strain per applied unit stress for different reflections plotted with respect to the orientation parameter. The orientation parameter to consider is H^2 for the HCP α phase and 3Γ for the BCC β phase.

low, suggesting very minimal variation in texture and microstructure among the tested specimens, and good XRD data.

To better understand the relationship between the different (hkl) peaks, the lattice strains are plotted as a function of the orientation parameter [81]. The orientation parameter effectively expresses the orientation dependency of the elastic stiffness in terms of the Miller indices. The orientation parameter Γ^{hkl} for the cubic system varies between 0 and 1/3 i.e. 0 for the most compliant reflection (hkl) and 1/3 for the stiffest (hkl) and is defined as:

$$\Gamma^{hkl} = \frac{h^2k^2 + h^2l^2 + k^2l^2}{(h^2 + k^2 + l^2)^2} \quad (16)$$

while for the hexagonal system (in hkl notation), the orientation parameter varies from 0 (most compliant (hk.l)) to 1 (stiffest (hk.l)) and is defined as:

$$H^2 = \frac{l^2}{\frac{4}{3} \left(\frac{c}{a}\right)^2 (h^2 + k^2 + hk) + l^2} \quad (17)$$

where h, k, l are the Miller indices of the considered reflection and (c, a) are the unit cell dimensions of the hexagonal crystal system.

Fig. 7a presents the range of macroscopic stiffness (Young's modulus) for the as-forged Ti-1023 alloy. Fig. 7b and 7c present the grain-scale lattice strains (axial and transverse) at applied unit stress as a function of the orientation parameter. The stiffest and compliant (hkl) reflections can be identified directly from the plot

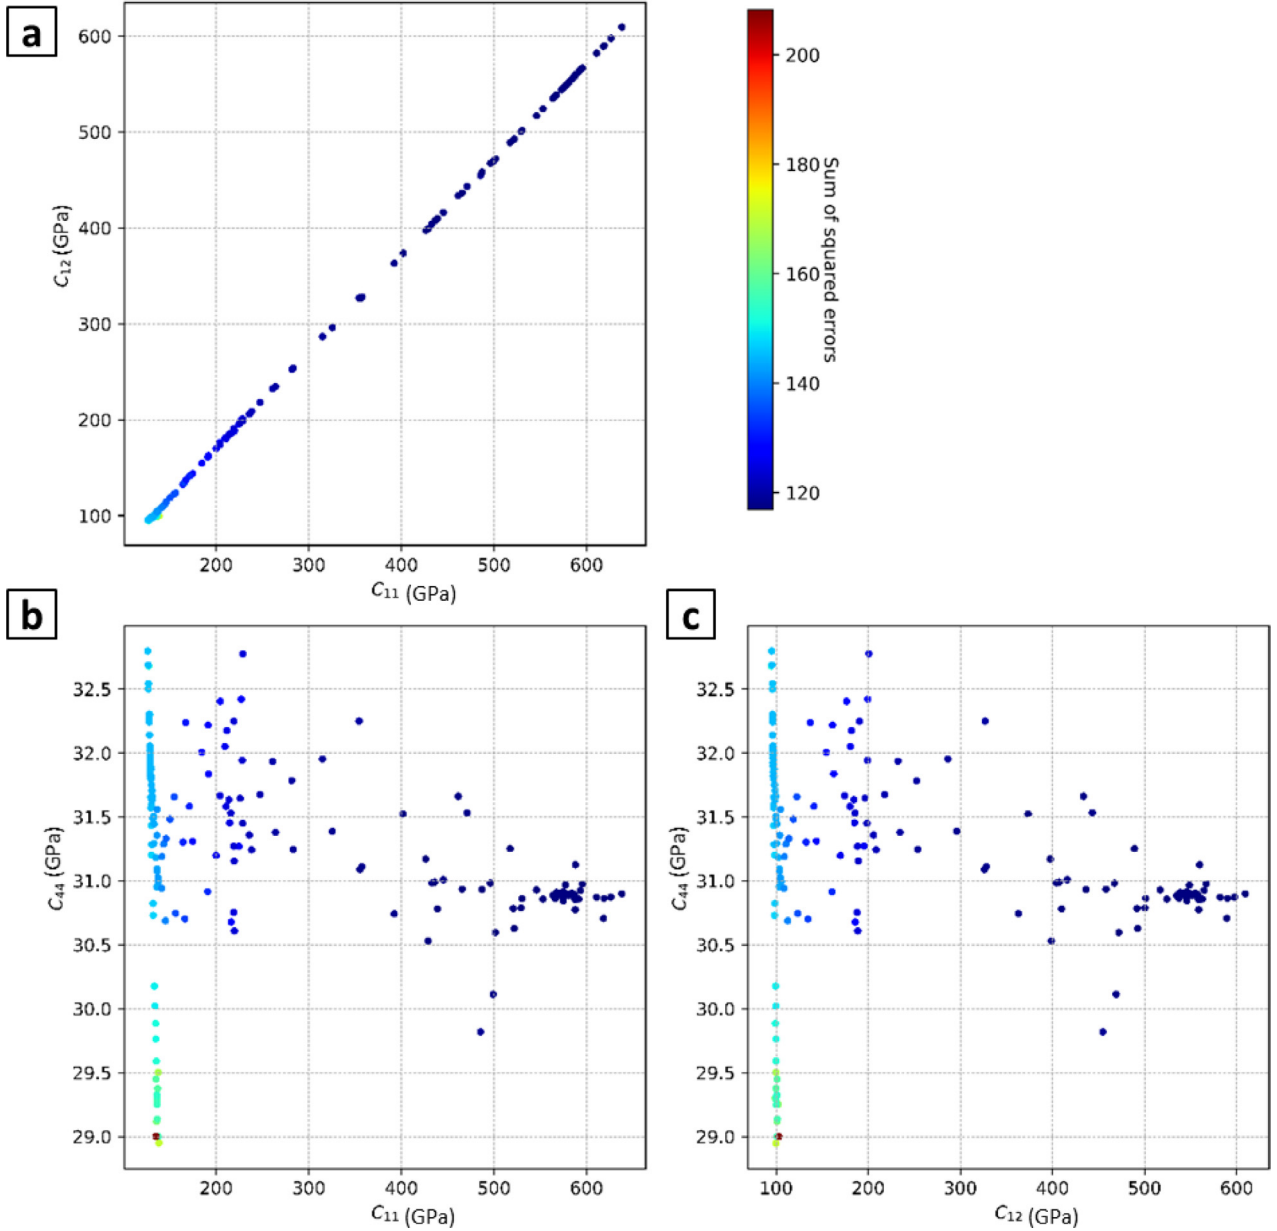

Fig. 8. Correlation between different SEC of the β phase (the color code corresponds to the sum of squared differences between the experimental data from XRD and the simulated data from the self-consistent model).

thanks to the orientation parameter. In the axial direction for the β phase, the most compliant is the (200) grain family. For the α phase, the most compliant is the (10 $\bar{1}$ 0) reflection and the stiffest is the (0002) reflection. While in the transverse direction (200) is still the most compliant one for the β phase and (11 $\bar{2}$ 0) is the most compliant one for the α phase. By transverse isotropy the planes perpendicular to the (0002) basal plane in α phase i.e. the (10 $\bar{1}$ 0) and (11 $\bar{2}$ 0) should have similar elastic properties. The difference between the behavior of (10 $\bar{1}$ 0) and (11 $\bar{2}$ 0) probably arises due to the constraints in the local environment of the grains, as the environment of α grains is not random but associated with a phase transition. This has also been observed in near α Ti-834 [33]. This experimental data set (1 data point for Young's modulus, 6 data point for the β phase, and 12 data point for the α phase) along with its variance is used to evaluate the SEC of the β phase with the Bayesian model.

3.2. Elastic constant identification from in-situ HEXRD and Bayesian inference

In this section, the results from Bayesian inference concerning the assessment of the range of single-crystal elastic constants, for the cubic β phase in Ti-1023, conforming to the experimental XRD dataset are presented.

Firstly, a least-squares optimization with the ELSC model was carried out to find a good initial guess for the three SEC of the β phase ($C_{11}^{\beta}, C_{12}^{\beta}, C_{44}^{\beta}$) that describes the experimental data well ($\epsilon_{hkl}^{Experiment}$ and macroscopic stiffness). Fig. 8 shows the obtained correlation among the SEC of the β phase for which the sum of squared errors is less than 200. The least-squares minimization indicates that the two constants C_{11}^{β} and C_{12}^{β} shares a linear relationship i.e., $C_{11}^{\beta} \approx C_{12}^{\beta} + 33$ GPa. The C_{44}^{β} identified by the least-squares

Table 3
Least-squares analysis of C_{ij}^β parameter.

	C_{11}^β (GPa)	C_{12}^β (GPa)	C_{44}^β (GPa)	A	μ' (GPa)
This study (weighted Least-squares fit)	136	103	29	1.76	16.5

(~31 GPa, refer to Fig. 8b and 8c) is comparatively lower and closer to the low modulus β Ti-alloys. Adding both micro and macro experimental parameters to the minimization problem has narrowed down the exploration range of C_{ij}^β constants. However, the least-squares analysis failed to give a unique minimum value, instead multiple C_{11}^β , C_{12}^β values satisfy both experimental lattice strains and macroscopic stiffness, refer to similar and multiple low sum-of-squared errors in Fig. 8. This implies that the considered experimental data of lattice strains and macroscopic stiffness are more sensitive to the cubic shear moduli $\mu'' = C_{44}^\beta$ and $\mu' = \frac{C_{11}^\beta - C_{12}^\beta}{2}$, than to the bulk modulus of the β phase, $K = \frac{(C_{11}^\beta + 2C_{12}^\beta)}{3}$. This is common for the β phase in Ti-alloys. Studies on the Ti-24Nb-4Zr-8Sn [18] and Ti-36Nb-5Zr [17] alloys have shown similar sensitivity of the XRD data to the SEC of the β phase. This is often addressed by fixing the value of C_{11}^β and C_{12}^β (or bulk modulus K) constants.

The absence of a unique value found by the least-squares minimization, suggests that the associated uncertainties for the C_{11}^β , C_{12}^β are much higher than for C_{44}^β . Instead of fixing the bulk modulus K, as a first approach, weights W_i equal to the volume fraction of their corresponding phases were assigned to each data points i.e. more importance is given to lattice strains of the significant phase. Here we have considered $W_i = 0.15$ for all the 12 data points of the α phase, $W_i = 0.85$ for all the 6 data points of the β phase, and $W_i = 1.0$ for the macroscopic Young's modulus. It is reminded that this kind of rational approach of adding weight to the data point is critical in our case, as not many (hkl) reflections are available for building a complete dataset.

Least-squares optimization is carried out again with weights for each data point. Adding weights to the data point results in a local minimum being identified for the C_{ij}^β that satisfy the experimental data set. The two constants C_{11}^β and C_{12}^β still shares a linear relationship i.e., $C_{11}^\beta - C_{12}^\beta = 33$ GPa. The C_{ij}^β parameter with the lowest sum-of-squared error is presented in Table 3.

To measure the uncertainties associated with the identified C_{ij}^β and the influence of different material parameters, MCMC simulations are carried out. The C_{ij}^β values suggested by the least-squares optimization is used as an initial guess for the MCMC sampling. Similar weights to that of the least-squares are employed for the MCMC sampling. The crystallographic texture and the grain morphology both play an important role in the global and local elastic properties. Due to the analytical nature of the calculations, statistically significant orientation is fixed and is discretized from the ODF, while the grain morphology is varied. Hence two different cases (corresponding to grain as a sphere and a prolate spheroid) of MCMC sampling are carried out and the results are discussed below.

Case I: Spherical grains

MCMC simulations were carried out with priors having a uniform distribution of a given range, refer to Table 4. A large range of values for C_{11}^β and C_{12}^β was employed based on the inference from the least-squares results that suggests multiple values for C_{ij}^β .

A total of 250,000 successful iterations (with 150,000 iterations to tune the variance) were carried out to assess the range of SEC

Table 4

The available search range of values for the prior variables.

Variable	Search range (GPa)
C_{11}^β	70-500
C_{12}^β	60-500
C_{44}^β	25-60

Table 5

Correlation coefficient of the multivariate distribution presented in Fig. 9.

	C_{11}^β	C_{12}^β	C_{44}^β
C_{11}^β	1	0.998	-0.432
C_{12}^β	0.998	1	-0.376
C_{44}^β	-0.432	-0.376	1

possible to describe the experimental dataset. Fig. 9 shows the 2D marginal posterior distribution of the range of three SEC of the β phase. The maximum a-posteriori estimate (MAP) of the multivariate distribution is close to the one suggested by the weighted least-squares estimate. The posterior distributions of C_{ij}^β present a normal distribution with well-defined peaks.

The peak probability values of both C_{11}^β , C_{12}^β and C_{44}^β are within the literature identified values for the β phase. The standard deviation on both C_{11}^β and C_{12}^β is rather large (~24 GPa) compared to that of the C_{44}^β (~1 GPa). The correlation coefficients of the multivariate distribution (C_{11}^β , C_{12}^β and C_{44}^β) are presented in Table 5. A strong positive correlation can be seen between C_{11}^β and C_{12}^β .

Fig. 10 shows the multivariate distribution of the anisotropy ratio (A), shear modulus (μ'), and bulk modulus (K). The MCMC-identified anisotropy ratio (~1.7) lies in the lower spectrum of the literature range (1.4 to 8), refer to Fig. 10a. Fig. 10b presents a sharp peak for the bulk modulus with a MAP of ~124GPa.

The correlation coefficients of the multivariate distribution of anisotropy ratio, bulk modulus, and shear modulus are presented in Table 6. A strong negative correlation can be seen between the anisotropy ratio and the shear modulus.

Fig. 11 shows the agreement between the simulated and experimental dataset for the identified C_{ij}^β constants. A reasonably good agreement is seen for both the α and β phase lattice strains and also the Young's modulus lies within the experimental range, refer to the dashed lines for the median value of the distribution in Fig. 11. For the β phase, good agreement is seen for the axial lattice strains, while the simulated transverse elastic strains are slightly different from the experimental data, especially the (220) reflection.

The SEC obtained by the Bayesian approach for the β phase ($C_{11}^\beta = 134.3 \pm 24.3$ GPa, $C_{12}^\beta = 101.5 \pm 24.5$ GPa, $C_{44}^\beta = 28.8 \pm 1.13$ GPa) agrees well with the elastic behavior of the Ti-1023 alloy i.e. both the micro and macro experimental data are fitted reasonably well with the ELSC model.

Case II: Ellipsoidal grains (prolate spheroids)

In this case, the effect of β phase morphology is also quantified along with the SEC. The effect of morphology is often simplified and is rarely considered in the literature. Here, we have considered

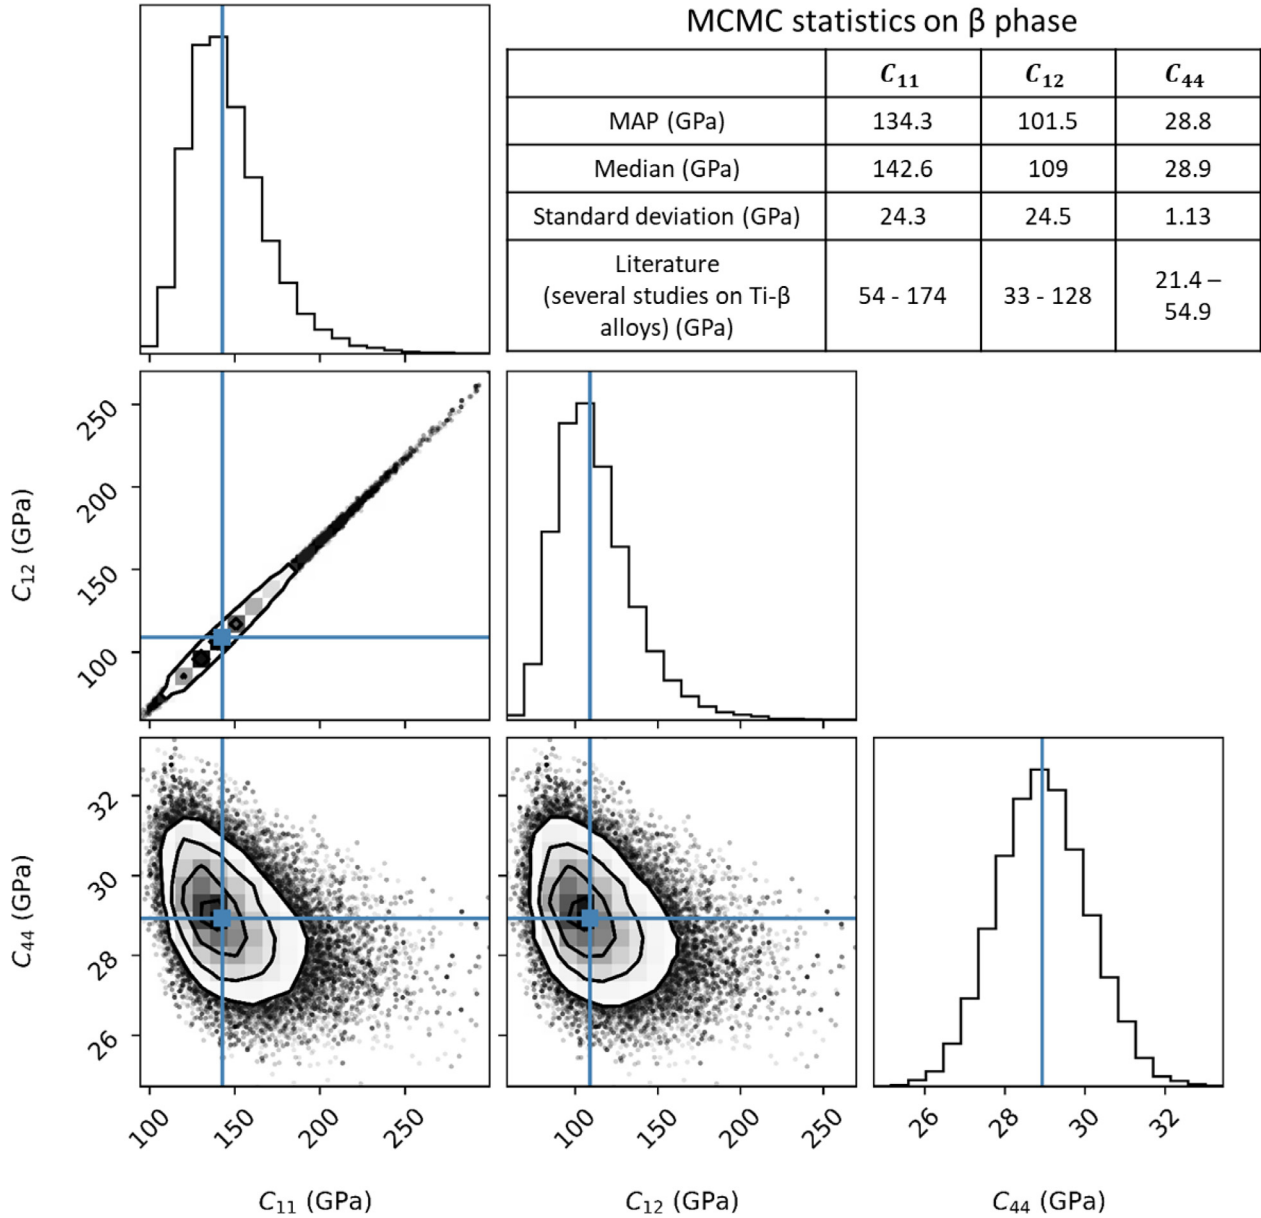

Fig. 9. MCMC sampling of the three single-crystal elastic constants of the β phase with median of the distribution highlighted with vertical and horizontal lines. The contour lines define the high probability regions of the distribution (grayscale colormap for both contour and density plots: black representing high probability regions and gray representing lower probability region).

Table 6
Correlation coefficient of the multivariate distribution presented in Fig. 10.

	Anisotropy ratio (A)	Bulk modulus (K)	Shear modulus (μ')
Anisotropy ratio (A)	1	-0.105	-0.955
Bulk modulus (K)	-0.105	1	-0.136
Shear modulus (μ')	-0.955	-0.136	1

the morphology of the β phase (β_{AR}) to be a free variable in the MCMC analysis. This choice is motivated by the complex morphology of the β grains revealed by EBSD analysis: prior β grains are elongated (aspect ratio 8-10) and partially fragmented into sub-grains locally disoriented up to 15° . Clusters of low angle misoriented sub-grains can act as one grain [82]. The morphology of the α phase remains fixed at $\alpha_{AR} = 1$, this is motivated by image analysis clearly showing the globular shape. A total of 250,000 MCMC iterations (with 150,000 iterations to tune the variance) were car-

ried out with priors having uniform distribution similar to Table 4. Additionally, the aspect ratio was allowed with a uniform distribution between $1.0 < \beta_{AR} < 10$. The morphology of the β phase is considered to be of a prolate spheroid ($a = b < c$) with the long axis of the ellipsoid aligned with the tensile axis (Fig. 1).

The 2D marginal posterior distributions of the C_{ij}^β and β_{AR} are shown in Fig. 12. Significant changes are seen in the posterior distribution of C_{ij}^β , with an aspect ratio (β_{AR}) showing a peak value of

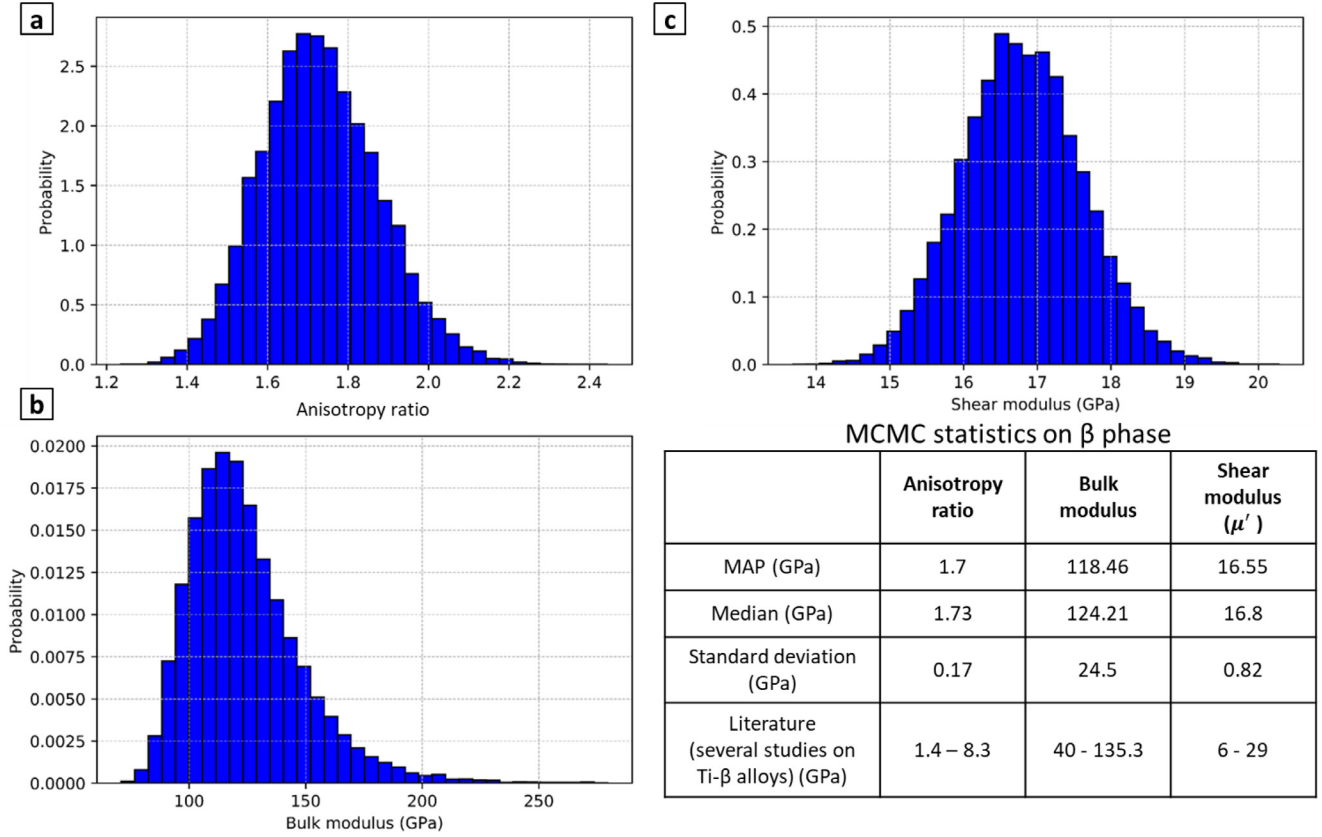

Fig. 10. MCMC sampling of the anisotropy ratio (A), bulk (K) and shear (μ') moduli of the β phase

Table 7
Correlation coefficients of the multivariate distribution presented in Fig. 12.

	C_{11}^β	C_{12}^β	C_{44}^β	Aspect ratio
C_{11}^β	1	0.953	-0.702	-0.376
C_{12}^β	0.953	1	-0.462	-0.177
C_{44}^β	-0.702	-0.462	1	0.619
Aspect ratio	-0.376	-0.177	0.619	1

~3.8. The aspect ratio is lower than the experimental average of the prior β grains and is consistent considering the experimental microstructure in which the prior β grains are partially fragmented. The peak values of the posterior distribution of C_{11}^β , C_{12}^β and C_{44}^β are well within the literature range. In comparison to the previous case with spherical inclusion, the value of C_{44}^β has increased while the shear and bulk modulus values have decreased significantly. Also, the standard deviation of C_{11}^β , C_{12}^β constants have decreased, while it has increased for the C_{44}^β . The SEC obtained by the Bayesian inference is ($C_{11}^\beta = 92.6 \pm 19.1$ GPa, $C_{12}^\beta = 82.5 \pm 16.3$ GPa, $C_{44}^\beta = 43.5 \pm 7.1$ GPa). The correlation coefficients of the multivariate distribution (C_{11}^β , C_{12}^β , C_{44}^β and aspect ratio) are presented in Table 7. Aspect ratio has moderate positive correlation with C_{44}^β . The correlation between C_{11}^β and C_{44}^β has also increased (compared to the spherical case, refer Table 5) as a result of freeing the aspect ratio.

Fig. 13 presents the posterior distribution of the anisotropy ratio, shear modulus (μ'), and bulk modulus (K). No well-defined peak is seen for the anisotropy ratio, multiple values between (3 – 9) show significant probabilities. These values are however

much higher than the values for spherical inclusion (Fig. 10). The theoretical bulk modulus K can be calculated from experimental macroscopic Young's modulus assuming a Poisson's ratio of 0.36, $K = \frac{E}{3(1-2\nu)}$, equals to $K = 83$ GPa, which is in line with the predicted value: $K = 88$ GPa. The bulk modulus is also closer to the value (~100 GPa) suggested by the first-principle analysis of Ti-V binary alloys. The shear modulus (μ') peaks at ~5.6 GPa, which is also closer to Raghunathan et al. [14] observation for Ti-1023 alloy with similar microstructure as the current study. The ensemble of the C_{ij}^β constants identified by Raghunathan et al. [14] lies within the Bayesian identified distribution.

The correlation coefficients of the multivariate distribution of anisotropy ratio, bulk modulus, and shear modulus for the ellipsoid case are presented in Table 8. A moderate positive correlation is seen between the bulk modulus and the shear modulus.

Fig. 14 shows the experimental and simulated data for the identified C_{ij}^β and β_{AR} . By varying the aspect ratio of the β phase, a better agreement is achieved with the transverse lattice strain of the β phase, which was not seen with the previous case. Overall, allowing the aspect ratio of the β phase as a free variable in the optimization process improves the fitting and thereby minimizing the uncertainty on the identification of the SEC of the β phase.

It should also be noted that simulations with a higher number of iterations (~1 million) were also carried out, but the results were similar. Bayesian inference of the C_{ij}^β with sphere and prolate morphology presents two different trends.

For most β -type titanium alloys, the μ' ranges from 10 to 30 GPa and the μ'' from 35 to 45 GPa (refer to Table 1). In the case of the sphere morphology, the shear modulus ($\mu' = \sim 17$ GPa) was within the literature range while the $\mu'' = \sim 29$ GPa was lower

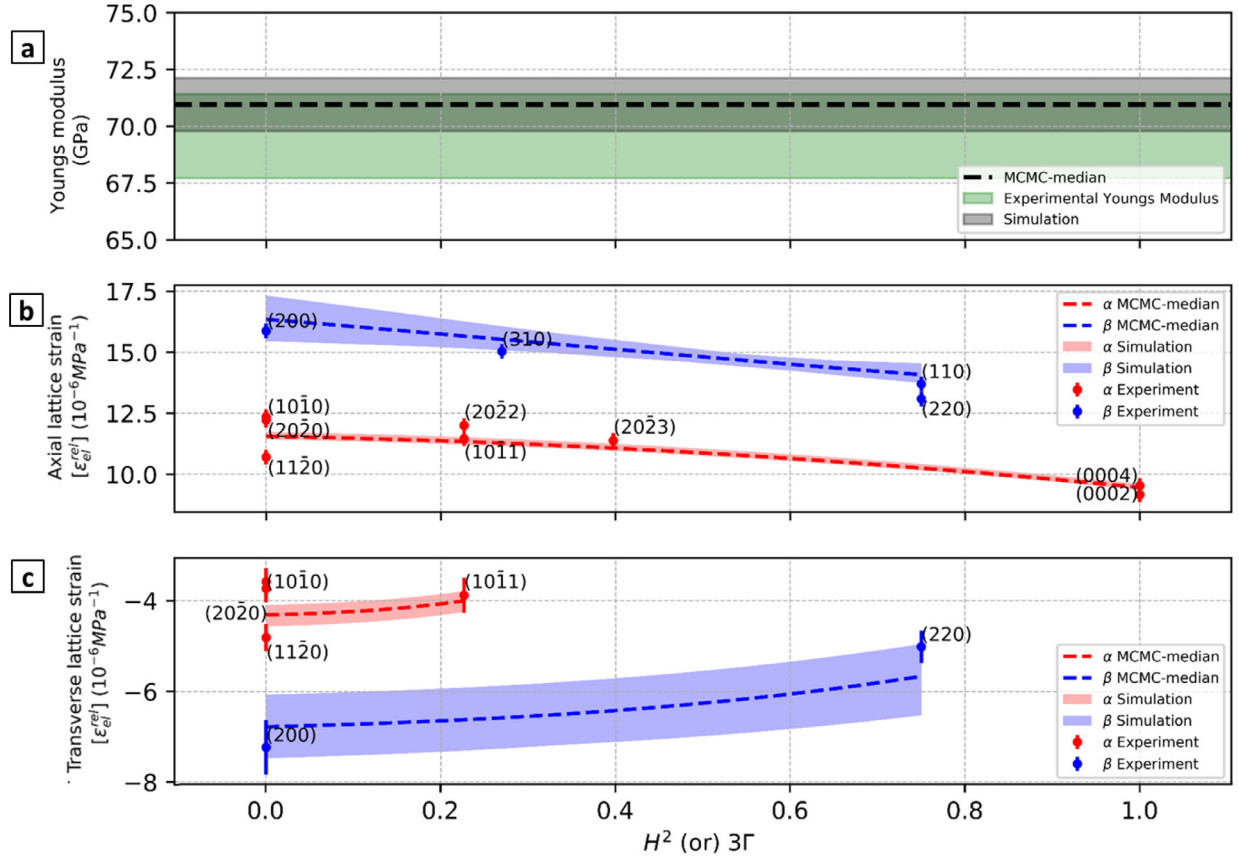

Fig. 11. The top plot (a) corresponds to Young's modulus data (shaded region corresponds to the data scatter), middle plot (b) corresponds to the axial lattice strain per applied unit stress for different reflections plotted with respect to the orientation parameter, bottom plot (c) corresponds to the transverse lattice strain per applied unit stress for different reflections plotted with respect to the orientation parameter. The dashed lines indicate the median value on the posterior distribution obtained by the MCMC simulation, and the shaded region indicates the three standard deviations.

Table 8
Correlation coefficient of the multivariate distribution presented in Fig. 13.

	Anisotropy ratio (A)	Bulk modulus (K)	Shear modulus (μ')
Anisotropy ratio (A)	1	-0.001	-0.001
Bulk modulus (K)	-0.001	1	0.42
Shear modulus (μ')	-0.027	0.42	1.00

than most of the β Ti-alloys. While for the prolate morphology, an inverse trend was seen with $\mu'' \approx 43$ GPa value being well within the literature range and the $\mu' \approx -5.6$ GPa being lower than most of the β Ti-alloys.

4. Discussion

4.1. In-situ XRD data bias

The lattice strains of different (hkl) reflections strongly affect the choice of the identified SEC, especially, when the analysis itself is concerned with the uncertainty measurement. For instance, obtaining precise lattice strains values require careful processing of the 2D XRD data. Conventional data analysis is a multi-step process from detector calibration to peak fitting, which is prone to errors. Here, we have tried to minimize this by including only the non-overlapping (hkl) reflections with good intensities. Due to the large material parameter space probed, to be efficient only the axial and transverse reflections were considered for the fitting. But in theory, we should be able to use the complete in-plane strains and even a complete strain pole-figure to reduce the uncertainty on the identified elastic constants. In the case of well-defined and

separate peaks, one could even employ the 2D XRD-DIC technique [83] to analyze the complete in-plane strains with quite a good accuracy.

In the present study, the grain shape is found to be an important factor during the identification process. Especially it improved the fitting on the transverse lattice strains. The transverse reflections show a higher degree of peak asymmetry and lower intensity and hence the standard error for some of the transverse reflections is higher than their axial counterparts. For example, the (200) axial peak comes only from all the (100) aligned axial grains whose normal is aligned with the tensile axis, while the (200) transverse peak can have a contribution from (100) and (110) axially aligned grains, and more generally all (hk0) grains. The axial behavior of (100) is representative of one-grain family (100), while the transverse behavior is an average of all (hk0) grain families. This leads to dispersion in the transverse lattice strains which in turn leads to higher standard deviation in the identified elastic constants. However, such effects should be minimized in the current study due to the diverse experimental dataset used to calculate the average lattice strains. The effect of texture on the identified SEC is further detailed in section Vc. The higher standard deviations in the identified SEC can be further addressed by defining weights of individual

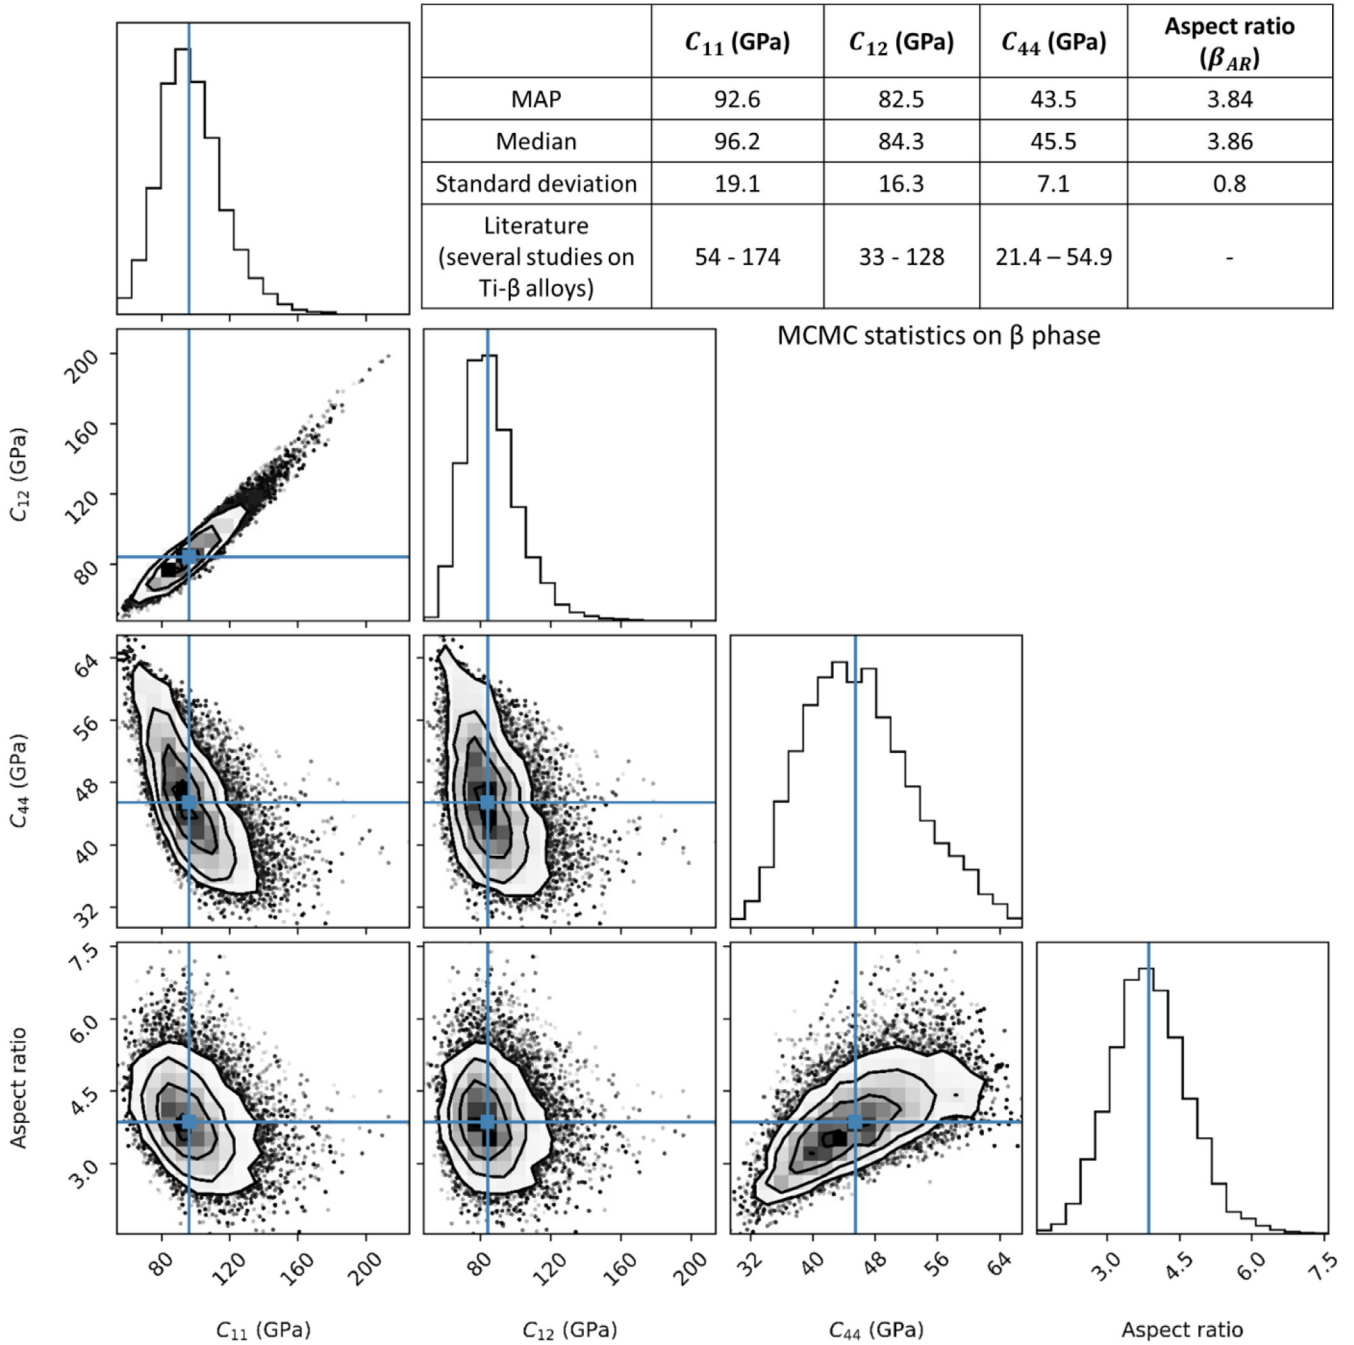

Fig. 12. MCMC sampling of the three single-crystal elastic constants of the β phase and the aspect ratio (β_{AR}) (grayscale colormap for both contour and density plots: black representing high probability regions and gray representing lower probability region).

(hkl) reflection proportional to the integral area of the (hkl) peak in XRD spectra. Alongside, other aspects of the XRD data such as the FWHM could also be used to gauge the stress/strain asymmetry, if required.

The discrepancy between the literature value of C_{44}^{β} and the one identified from MCMC distribution could possibly stem from the experimental measurement errors (in the XRD or stiffness analysis, and as well as the experimental techniques employed in the literature). Similar disagreement in the C_{44}^{β} was also seen in the case of SEC identified from indentation modulus of BCC Fe-3%Si alloy [45]. It was suggested that this could be improved by identifying specific reflections in the experimental dataset that could refine the C_{44}^{β} estimate. It should also be noted that the litera-

ture identified SEC for β Ti-alloy vary both in chemistry as well as in microstructure. Hence, trying to find any correlation among the current identified values and the literature ones may not be fruitful.

4.2. β phase stability of Ti-1023

In literature, it is reported that for the β -type titanium alloys, the shear modulus (μ') dictates the stability of the β phase and can be adjusted by the β -stabilizing elements. It was also reported that a lower value of μ' in BCC indicates increased instability with respect to shear on {110} plane along $\langle 1\bar{1}0 \rangle$, which results in a martensitic transformation [18]. This is the case especially here

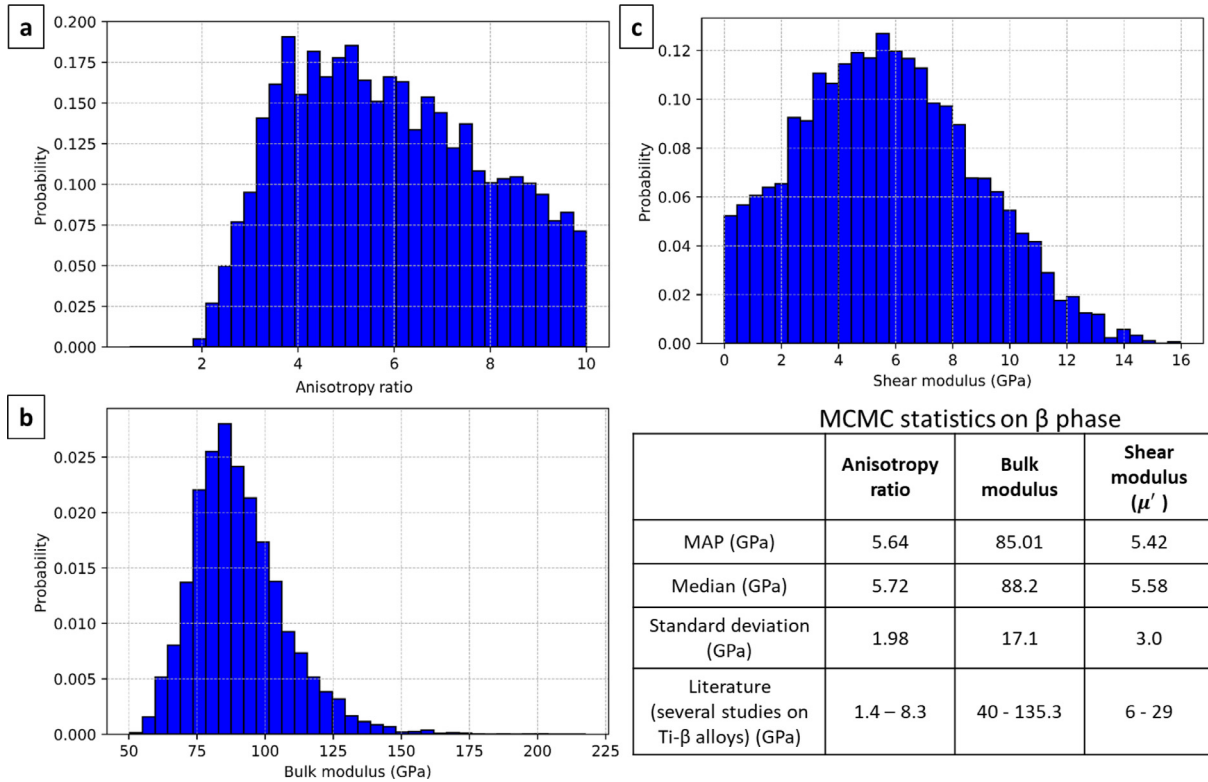

Fig. 13. MCMC sampling of the anisotropy ratio A , bulk (K) and shear (μ') moduli of the β phase.

Fig. 14. Top plot (a) corresponds to Young's modulus data (shaded region corresponds to the data scatter), middle plot (b) corresponds to the axial lattice strain per applied unit stress for different reflections plotted with respect to the orientation parameter, bottom plot (c) corresponds to the transverse lattice strain per applied unit stress for different reflections plotted with respect to the orientation parameter. The dashed lines indicate the median value on the posterior distribution obtained by the MCMC simulation, and the shaded region indicates the three standard deviations.

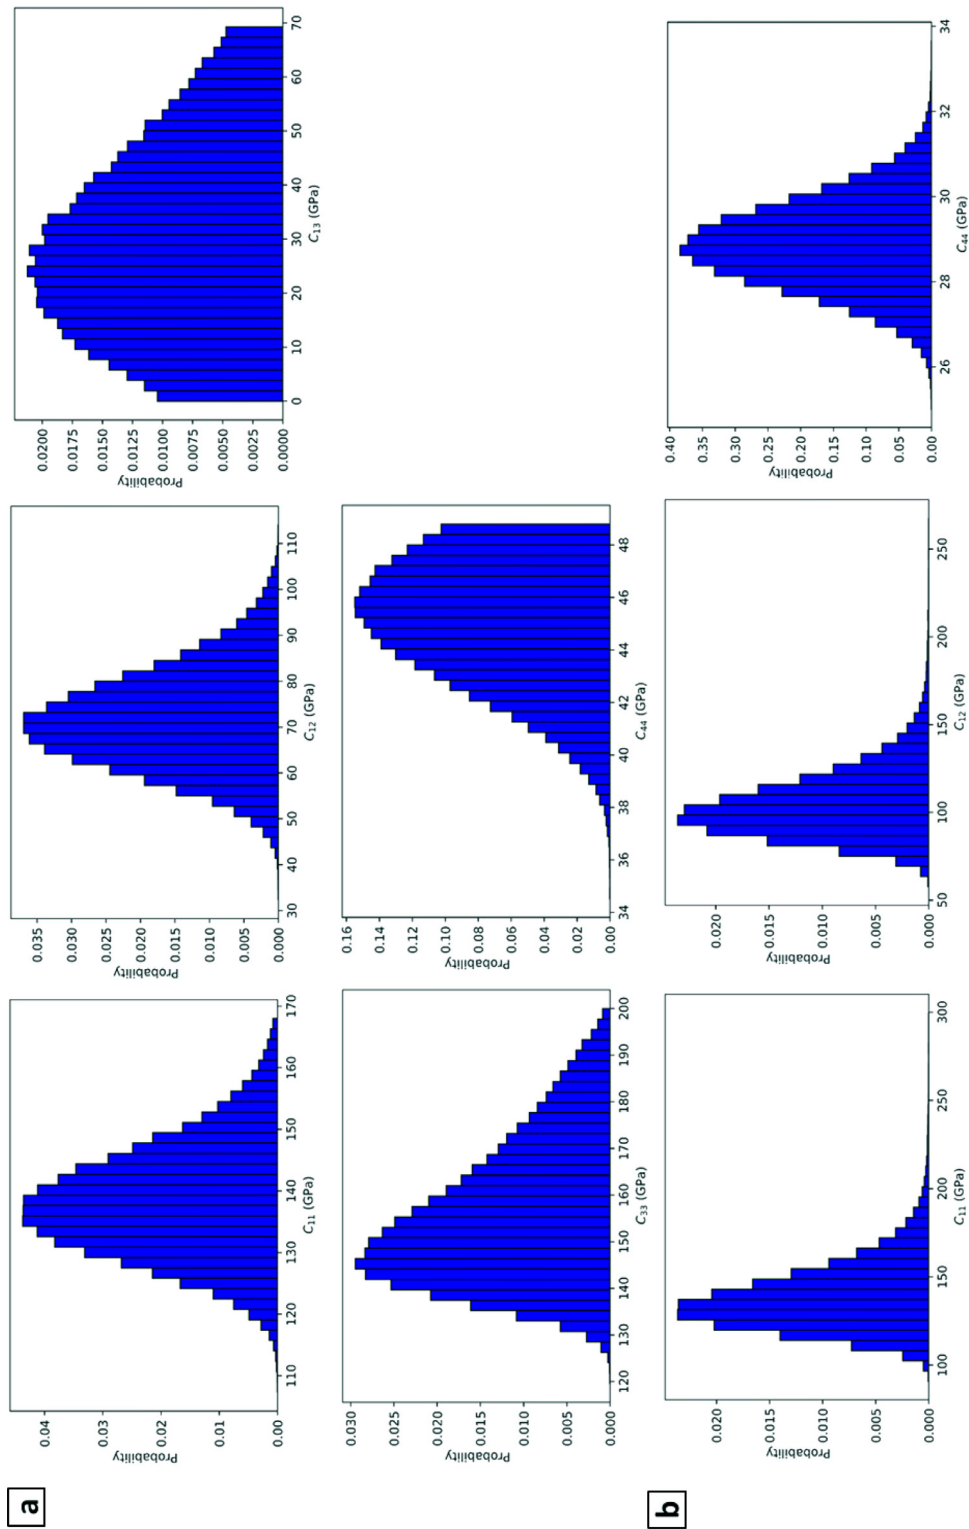

Fig. 15. MCMC sampling of the (a) five SECs of the α phase and (b) three SECs of the β phase.

where a martensitic transformation is seen at stresses above ~ 400 MPa. This was also verified with the Bayesian inference (for prolate spheroid) suggesting a low shear modulus ($\mu' \sim 5.6$ GPa) for the available experimental data. Here, the softening of the shear modulus μ' or μ'' still needs to be explained. The difference in one of the shear modulus (μ'') can stem from the chemical composition of the alloy as suggested by the first-principles studies on $\text{Ti}_x\text{V}_{1-x}\text{C}$ [84], wherein the shear modulus, Young's modulus, and hardness

seem to be proportionally increasing with the V concentration. A study on low Young's modulus Ti-39Nb [15] alloy suggested the polycrystalline Young's modulus is proportional to the shear modulus (μ'' and μ'). Here, for the as-forged Ti-1023 the Young's modulus (~ 70 GPa) is lower than most of the β Ti-alloys in the literature. Consequently, one can argue that the lower value of μ' or μ'' modulus could be a direct consequence of the macroscopic Young's modulus.

4.3. Effect of α and β crystallographic textures on the MCMC sampling

It is recalled that in the current study, the tested samples did not show a very sharp texture for both the α and β phase. To analyze the impact of texture on the SEC identification, a random texture was generated for both the α and β phases (as in [23]), and was employed during the MCMC sampling. A total of 250,000 iterations (with 150,000 iterations to tune the variance) were carried out with spherical morphologies for the grains. The results of the random texture analysis are presented in Table 9 along with the case of experimental texture. It is observed that texture does not influence the identified SEC significantly. They are practically the same within their uncertainties. The results are in line with the fact that the (hkl) lattice strains in textured material do not vary by more than few percent of the (hkl) lattice strains in a texture free aggregate [85].

4.4. Influence of the α phase on the MCMC sampling

In all previous cases, the SEC of the α phase has been fixed because there is agreement on the SEC in literature. The effect of SEC of the α phase on the MCMC sampling is considered while keeping spherical grain shape for both α and β phases, thereby equation (8) is now a function of 8 free variables.

$$\frac{\varepsilon_{hkl}^{simulation}}{\Sigma_{33}^{max}} = f\left(C_{11}^\beta, C_{12}^\beta, C_{44}^\beta, C_{11}^\alpha, C_{12}^\alpha, C_{13}^\alpha, C_{33}^\alpha, C_{44}^\alpha\right)$$

Since the number of free variables is higher (5 for the α phase and 3 for the β phase), subsequently the number of MCMC iterations were also increased to 2 million (with 1 million iterations to

tune the variance of the proposal distribution) to explore a large space range of $C_{ij}^{\beta\alpha}$. The range of prior probed during MCMC sampling is presented in Table 10.

Fig. 15 shows the multivariate posterior distribution of the C_{ij}^β and C_{ij}^α . The correlation coefficients of the multivariate distribution (C_{ij}^β and C_{ij}^α) are presented in Table 11. The strong correlation between C_{11}^β and C_{12}^β is still maintained, additionally positive correlation can also be seen between C_{11}^α and C_{12}^α and between C_{33}^α and C_{13}^α .

The MCMC statistics of the posterior distribution is provided in Table 12. Interestingly, allowing the C_{ij}^α as a free variable has no significant effect on the C_{ij}^β posterior distribution. Small changes in the median and standard deviation of C_{11}^β and C_{12}^β are seen, while the ($C_{11}^\beta - C_{12}^\beta$) remains rather constant. There is no agreement on the MCMC identified C_{ij}^α values with the literature (except for the C_{44}^α constant). The wider distribution of some of the C_{ij}^α constants ($C_{13}^\alpha, C_{33}^\alpha$) suggest low sensitivity of the changes to the experimental data. This could also be due to the low volume fraction of the α phase (15%). No strong difference is observed in the posterior distribution of the C_{ij}^β when the C_{ij}^α is considered as a free or fixed variable. This leads to a possible conclusion that the C_{ij}^α have a negligible effect on C_{ij}^β uncertainty quantification at the volume fraction of 15%.

Subsequently, the volume fraction of the α phase is also checked for its influence on the MCMC sampling. The volume fraction of the α phase ranges between 12% to 16% with an average of 15% (SEM image analysis and Rietveld refinement of the HEXRD

Table 13

MAP (GPa)	134.3	134.3	101.5	100.4	28.8	29.2
Median (GPa)	142.6	144.3	109	110.3	28.9	29.3
Standard deviation (GPa)	24.3	24.5	24.5	24.7	1.13	1.15

pattern). A total of 500,000 iterations (with 350,000 iterations to tune the variance) were carried out with priors having uniform distribution, see Table 13.

No significant changes are observed in the distribution of C_{ij}^{β} when the volume fraction is considered as a free variable. This suggests that the range (12 - 16%) in the measurement of the volume fraction of the α phase has no significant effect on the posterior distribution of the C_{ij}^{β} constants, refer to Table 14.

In all the above discussion cases, when the morphology of the grains is changed from sphere to prolate, the resulting distribution changes. This suggests that in any combination of free variables in equation (8), the morphology (aspect ratio) of the β -phase has a significant effect on the resulting posterior distribution.

5. Conclusions

An elastic self-consistent scheme (ELSC) for anisotropic polycrystals combined with high energy X-ray diffraction was employed in a Bayesian framework for in-situ mechanical tests to extract the single-crystal elastic constants (SEC) of the β phase of a near- β titanium alloy, Ti-1023. The as-forged state of the Ti-1023 alloy is characterized by Young's modulus of ~ 70 GPa and a strength of around 800 MPa. Moreover, at stress higher than 400 MPa, the formation of stress-induced martensite was clearly revealed by XDR spectra, which demonstrates the low β -phase stability. The in-situ XRD, due to its phase selectivity, allows evaluating the SEC in a multiphase material. The ELSC model was used to predict the (hkl) specific elastic strains and macroscopic stiffness and was then compared with the XRD (hkl) specific lattice strains and experimental Young's modulus. The versatility of the Bayesian framework was evaluated on the Ti-1023 with an as-forged microstructure. We have systematically investigated the effect of the different intrinsic parameters of the multi-phase material to identify and study their effect on the MCMC sampling of the β phase SEC. The results of this investigation are as follows:

- the SEC for the cubic β phase was extracted first in a framework with spherical grains ($C_{11}^{\beta} = 134.3 \pm 24.3$ GPa, $C_{12}^{\beta} = 101.5 \pm 24.5$ GPa, $C_{44}^{\beta} = 28.8 \pm 1.13$ GPa). The constant C_{11}^{β} and C_{12}^{β} were found to be in good agreement with the constants of the pure β phase alloy in the literature, but presented highest relative uncertainty, while the C_{44}^{β} constant has the lowest uncertainty (magnitude is within 10% of the literature). The shear modulus $\mu' = \frac{C_{11} - C_{12}}{2}$ was within the literature range, while the other shear modulus $\mu'' = C_{44}^{\beta}$ modulus had a comparatively lower value.
- The grain morphology parameter of the β phase (β_{AR}) resulted in a significant effect on the MCMC sampling of the β phase SEC. The identified SEC ($C_{11}^{\beta} = 92.6 \pm 19.1$ GPa, $C_{12}^{\beta} =$

82.5 ± 16.3 GPa, $C_{44}^{\beta} = 43.5 \pm 7.1$ GPa) and the aspect ratio $\beta_{AR} = 3.8 \pm 0.8$ results in a distinct bulk modulus, shear modulus coherent with the experimental observations and literature range. The shear modulus μ' was much lower than the literature range, while the μ'' modulus agreed well with the literature. Also, a wide range of anisotropy ratio (3-10), in agreement with the literature scatter, was found to satisfy the experimental data set.

- Texture, volume fraction of the α phase, and even the SEC of the α (C_{ij}^{α}) phase have been found to have an insignificant effect on the identification of the SEC of the β phase for the current experimental dataset, within the texture and volume fraction variations investigated here. It is however worth noting that, more generally, the interplay between crystallographic texture, grain morphology, grain arrangement, and elastic response is a complex and non-intuitive topic that demands testing a large number of different combinations (see for example [86]) and it has therefore been left for future studies.

However, certain local phenomena such as clustering of orientations, morphological orientations, or a phase embedded in a specific environment cannot be analyzed with the standard self-consistent scheme. A future approach would be to couple the Bayesian inference with full-field micromechanical modeling, e.g. based on the Fast Fourier transform (FFT) method [87] to probe different architectures, local environments and spatial arrangements of grains.

6. Data availability

The datasets generated and analyzed during the current study are available from the corresponding author on reasonable request.
