51 **Abstract**

52 Mammalian orthoreovirus (MRV) has been identified in humans, livestock, and wild animals; this wide
53 host range allows individual MRV to transmit into multiple species. Although several interspecies
54 transmission and genetic reassortment events of MRVs among humans, livestock, and wildlife have been
55 reported, the genetic diversity and geographic distribution of MRVs in Africa are poorly understood. In this
56 study, we report the first isolation and characterization of MRVs circulating in a pig population in Zambia.
57 In our screening, MRV genomes were detected in 19.7% (29/147) of fecal samples collected from pigs
58 by reverse transcription-polymerase chain reaction. Three infectious MRV strains (MRV-85, MRV-96
59 and MRV-117) were successfully isolated, and their complete genomes were sequenced. Recombination
60 analyses based on the complete genome sequences of the isolated MRVs demonstrated that MRV-96 shared
61 the S3 segment with different MRVs isolated from bats, and that the L1 and M3 segments of MRV-117
62 originated from bat and human MRVs, respectively. Our results suggest that the isolated MRVs emerged
63 through genetic reassortment events with interspecies transmission. Given the lack of information
64 regarding MRVs in Africa, further surveillance of MRVs circulating among humans, domestic animals,
65 and wildlife is required to assess potential risk for humans and animals.

66

67 **Introduction**

68 Orthoreoviruses, belonging to the genus *Orthoreovirus* in the family *Reoviridae*, are non-enveloped,
69 icosahedral, segmented double-stranded RNA (dsRNA) viruses that infect vertebrates and invertebrates [1].
70 The orthoreovirus genome consists of 10 dsRNA segments divided into three size classes based on the
71 characteristic mobility by gel electrophoresis, including three large segments (L1–L3), three medium
72 segments (M1–M3), and four small segments (S1–S4) [1]. The genome is encased in two concentric capsid
73 protein shells [1]. This structural feature contributes to the thermostability and protease resistance of its
74 virion and play a role in the entry process of orthoreoviruses [2-8]. The genus *Orthoreovirus* is divided into
75 two phenotypic groups, namely fusogenic and nonfusogenic groups, based on the ability to induce cell–cell
76 fusion and syncytium formation [9]. Mammalian orthoreovirus (MRV) is nonfusogenic and includes four
77 major serotypes (MRV1–4) according to the capacity for neutralization and hemagglutination inhibition
78 using type-specific reovirus antisera [1]. The representative prototypes of each serotype are type 1 Lang
79 (T1L), type 2 Jones (T2J), type 3 Dearing (T3D), and type 4 Ndelle (T4N) [10, 11]. The serotype specificity
80 is determined by $\sigma 1$ protein encoded in the S1 segment, which has the largest sequence divergence [12-14].
81 The genome segments of MRV have been exchanged between evolutionarily distinct strains, resulting in
82 unpredicted reassortant viruses containing various combinations of the genome segments [15-19].

83 MRVs have been identified in humans, livestock, and wild animals with a wide host range [2, 19-26].
84 Individual MRVs can infect multiple species; several interspecies transmission and genetic reassortment
85 events involving both humans and animals have been reported [2, 15-19, 26-28]. An MRV strain isolated
86 from a child with acute gastroenteritis had high similarity with MRVs detected in bats, indicating
87 interspecies transmission between bats and humans [26]. Another MRV isolated from a child with
88 encephalitis possessed a reassorted genome between human and porcine MRVs [28]. Other MRVs isolated
89 from pigs with diarrhea in USA emerged via genetic reassortment among different evolutionarily strains
90 from humans, bats, and pigs [2]. These previous reports suggest that livestock and wildlife play an important
91 role in the occurrence of interspecies transmission and genetic reassortment events, and it is therefore better
92 to consider their genomic variations in several hosts to understand their evolution.

93 MRV has a wide geographic distribution, and it has spread to North and South America, Asia, Europe,
94 and Africa [2, 16, 26, 27, 29]. Among African countries, only two MRVs have been reported in Cameroon:
95 a T4N strain, a prototype of serotype 4, isolated from a rodent [11, 30, 31]; and the CMR-HP55 strain
96 detected from children with diarrhea [27]. Although MRVs isolated from pigs have been reported in Japan,
97 China, South Korea, Italy, and the USA [2, 3, 18, 32-35], they have never been detected from pigs in Africa.
98 Understanding the distribution of MRV in Africa is important for veterinary and public health perspectives.
99 In this study, we investigated the prevalence of MRV infection in pigs in Zambia and identified novel MRV
100 strains with evidence of reassortment events between human and animal MRVs.

101 **Results**

102 **Detection of MRV infection in pigs in Zambia**

103 We screened 147 fecal samples collected from pigs in Zambia for the detection of MRV via reverse
104 transcription-polymerase chain reaction (RT-PCR). The MRV genome was detected in 19.7% of the
105 samples (29/147; Table 1). With respect to specific subsets, the MRV genome was detected in 14.3%
106 (1/7) and 15.0% (6/40) of non-diarrheal and diarrheal samples, respectively, collected from suckling pigs
107 and in 29.3% (12/41) and 16.9% (10/59) of healthy and diarrheal fattening pigs, respectively. The MRV
108 genomes were detected in specimens from farms located in the Lusaka, Chilanga, Kafue, and Chibombo
109 districts, suggesting a widespread MRV infection across all examined farms in Zambia.

110 **Isolation and characterization of MRV**

111 The supernatants of fecal suspensions were inoculated onto African green monkey kidney (Vero E6)
112 cells for viral isolation. Obvious cytopathic effects (CPEs) were observed in Vero E6 cells inoculated with
113 fecal samples within a few days. As described in the Methods section, we attempted to isolate MRVs using
114 Vero E6 cells cultivated in Eagle's minimum essential medium (MEM) with either 5 µg/ml trypsin and
115 0.3% bovine serum albumin (BSA) or 2% fetal bovine serum (FBS). In total, 18 of 147 MRV strains
116 (12.2%) were isolated from Vero E6 cells cultivated in MEM supplemented with trypsin and BSA, whereas

117 five MRVs (3.4%) were obtained from cells grown in MEM supplemented with FBS. The isolation
118 efficiency of these two methods was significantly different ($p < 0.01$), indicating that MEM supplemented
119 with trypsin and BSA was more suitable for isolating MRVs from Vero E6 cells than MEM supplemented
120 with FBS. MRV-85, MRV-96, and MRV-117 were isolated from fecal samples collected from Farms B, E,
121 and C, respectively. These representative strains were used for further analyses.

122 Vero E6 cells infected with MRV-85, MRV-96, and MRV-117 exhibited CPEs, as indicated by the
123 rounding of individual cells and characteristic eosinophilic inclusion bodies (Fig. S1). The viral segmented
124 dsRNA was separated via sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE), and
125 the migration patterns of the viral M and S segments of the three MRV strains differed from each other; this
126 finding corresponds with the different genetic backgrounds of these strains (Fig. 1).

127 Bioinformatics analyses of nucleotide sequences obtained via next-generation sequencing and the
128 rapid amplification of cDNA ends (RACE) method revealed that the genomes of isolated MRV strains
129 (MRV-85, MRV-96, and MRV-117) consisted of 10 segments (3915, 3901, 3854, 2304, 2241, 2203, 1433,
130 1331, 1198, and 1196 bp in length) encoding 10 open-reading frames ($\lambda 1$, $\lambda 2$, $\lambda 3$, $\mu 1$, $\mu 2$, μNS , $\sigma 1$, $\sigma 2$,
131 $\sigma 3$, and σNS , Table S3). Although different migration patterns of dsRNA genomes from these strains were
132 observed via SDS-PAGE (Fig. 1F), there was no difference in the length of the respective viral segments
133 among obtained MRV strains based on their nucleotide sequences, suggesting that this property is
134 attributable to differences of the sequence composition as previously observed [36]. The 5'- and 3'-
135 untranslated regions (UTRs) ranged 12–32 and 32–80 bp in length, respectively. Isolated Zambian MRV
136 strains possessed consensus genome sequences of the 5'- and 3'-termini (5'-GCUA and UCAUC-3',
137 respectively) similarly as other reported MRVs [1, 37]. The determined genomic sequences of the MRVs
138 were deposited in the DNA Data Bank of Japan (DDBJ) under the following accession numbers: MRV-
139 85, LC533904–LC533913; MRV-96, LC533914–LC533923; and MRV-117, LC533924–LC533933.

140 **Sequence comparison of each viral segment and encoding protein of MRVs**

141 Homology comparison of the complete genomic sequences among the Zambian MRV strains (MRV-

142 85, MRV-96, and MRV-117) demonstrated that the highest nucleotide identities of the 10 segments
143 ranged from 82.8 to 98.7% (Table 2). Based on eight MRV segments (L1, L2, L3, M1, M2, S1, S2, and
144 S4), Zambian MRV strains shared more than 96.0% identities with each other. Of note, the M3 segment
145 of MRV-117 was divergent from those of the other two strains (82.8–83.0%), and the S3 segment of
146 MRV-96 also had low nucleotide identities with those of the other two strains (89.6–90.0%). Similar
147 results were obtained in comparative analysis focused on the amino acid sequences of nine MRV viral
148 proteins (λ 1, λ 2, λ 3, μ 1, μ 2, μ NS, σ 1, σ 2, and σ 3); however, only the σ NS protein of MRV-96 had high
149 sequence identities with those of the other two strains (97.2–97.8%). These results indicate that while the
150 viral protein encoded in the S3 segment is highly conserved among the Zambian MRV strains, the S3
151 segment of MRV-96 has undergone divergence.

152 To identify MRV strains genetically related to Zambian MRV strains, we conducted BLAST analyses
153 using the sequence of each viral segment (Table 3). Half of the segments (L2, L3, M1, M2, and S4) of
154 Zambian MRV strains were closely related to those of SHR-A, GD-1, and BM-100, which were isolated
155 from pigs in China or the USA [2, 38]. In contrast, the L1 segments of Zambian MRV strains shared the
156 highest nucleotide and amino acid sequence identities (97.1–97.2% and 99.0–99.6%, respectively, Table 3)
157 with that of the MRV WIV8 strain identified in wild bats. Moreover, the nucleotide sequences of the S1
158 and S2 segments of Zambian MRV strains diverged from those of other MRV strains (85.2–88.1%
159 nucleotide identities, Table 3). These results suggest that these segments arise from other uncharacterized
160 MRV strain(s). Despite large divergence among the S2 segments, the amino acid identities of the σ 2 protein
161 of Zambian strains were remarkably high (98.0–98.5%) as compared with those of the bat strain (RpMRV-
162 YN2012). These results suggested that there is little antigenic variation among the σ 2 proteins of these
163 viruses. While the M3 segments of MRV-85 and MRV-96 shared the highest nucleotide and amino acid
164 identities with those of the porcine strain (BM-100) (90.1–90.3% and 95.5–95.7%, respectively) [2], the
165 pairwise nucleotide and amino acid sequence identities of the M3 segment of MRV-117 with that of SI-
166 MRV07 identified in patients with diarrhea who traveled to Southeast Asia was 89.8% and 95.7%,
167 respectively [39]. The S3 segment of MRV-96 shared the highest identity with the HB-B strain isolated

168 from minks in China [21], whereas the S3 segments of the MRV-85 and MRV-117 strains shared the highest
169 sequence identities with the T1/Human/Wash.D.C./clone62/1957 and T3/Bovine/Maryland/clone18/1961
170 strains [40].

171 The MRV S1 segment has been demonstrated to encode the cell attachment protein “ σ 1” which
172 determines the virus serotype [12]. Based on the identity comparison of S1 segments, Zambian MRV strains
173 had the closest genetic relationship with MORV/47Ma/06 belonging to the MRV2 group, which was
174 identified in a common vole in Hungary [22] (Table 3). According to the comparative analyses of the S1
175 segment and σ 1 protein among the Zambian MRV strains, MRV prototypes, and other representative strains,
176 we found that the Zambian MRVs have the highest nucleotide and amino acid sequence identities with type
177 2 serotype MRV strains (61.0–85.2% and 58.0–87.3%, respectively; Table S4). Some of the lower-level
178 identities among Zambian MRV strains and type 2 serotype MRV strains (around 60%) may be due to the
179 large divergence of the domains unrelated to the serotype-specific features of σ 1 protein; similar results
180 were obtained among other type 2 serotype MRVs.

181 **Phylogenetic characterization of Zambian MRV**

182 Phylogenetic trees of each viral segment were constructed using the sequences of Zambian and other
183 representative MRVs. Phylogenetic analysis based on the sequences of S1 segments revealed that Zambian
184 MRVs formed a distinct clade near the branches of bat (SI-MRV05) and rodent (MORV/47Ma) virus strains
185 within the larger clade encompassing the MRV2 strain (Fig. 2A); these results suggest that the isolated
186 Zambian strains might be classified into MRV2. Based on the L2, L3, M1, M2, and S4 phylogenies,
187 Zambian MRV strains clustered with various porcine strains (Fig. S2). The phylogenetic analysis of the L1
188 segment indicated that the Zambian MRV strains were monophyletic with a bat strain (WIV8). MRV-117
189 formed a lineage with the bat strain (WIV8) out of a different lineage consisting of other two Zambian
190 MRVs (Fig. S2). The topologies of the phylogenetic tree based on the S2 segment revealed that a separate
191 unique lineage was formed by Zambian MRV strains. Notably, the Zambian MRV strains were divided
192 into two clusters on the basis of each M3 and S3 phylogeny (Fig. 2B and 2C). Whereas the M3 segments

193 of MRV-85 and MRV-96 were closely related to those of porcine strains, MRV-117 clustered with human
194 strains (SI-MRV07, T1L, and CMR-HP55). Based on the S3 segment phylogeny, MRV-96 was located out
195 of the lineage, containing MRV-85 and MRV-117 and formed the cluster with various MRV strains, such as
196 mink, bat, human, and porcine strains (Fig. 2C). These phylogenetic incongruities suggested the occurrence
197 of reassortment events between the MRV strains of various hosts.

198 To date, only two MRV strains, namely Ndelle (MRV4) and CMR-HP55 (MRV2), have been
199 identified from rodents and humans in Africa, respectively [11, 27, 30, 31]. These strains were detected
200 in Cameroon, and thus prompting an investigation into the evolutionary relationship between the isolated
201 Zambian MRVs and the Cameroonian MRVs in the phylogenetic trees. The phylogenetic analyses of
202 MRVs indicated that the genome segments of Zambian MRVs were distantly related to those of
203 Cameroonian MRVs, excluding for M3 segment. Based on the M3 segment phylogeny, MRV-117
204 clustered with human strains, including CMR-HP55 as mentioned previously (Fig. 2B).

205 **Detection of reassortment events**

206 To further investigate the evidence of genetic recombination in Zambian MRVs, recombination
207 analyses were conducted using SimPlot software. Because MRV-96 and MRV-117 were not grouped with
208 other Zambian MRV strains in the phylogenetic trees based on the sequences of the S3 and M3 segments,
209 respectively (Figs. 2B and 2C), we performed standard similarity plot and bootscan analyses based on
210 individual MRV segments. These analyses revealed that MRV-96 displayed high degrees of sequence
211 similarity and bootstrap support with MRV-85 and/or MRV-117 in the L1–L3, M1–M3, S1, S2, and S4
212 segments, but not in the other S3 segment, which exhibited similarity with the sequences of a bat virus
213 strain (WIV8; Figs. 3A–3C). The analyses for MRV-117 demonstrated high degrees of sequence
214 similarity and bootstrap supports for the L2, L3, M1, M2, and S1–S4 segments among the three Zambian
215 MRVs and for the M3 segment between MRV-117 and a human strain (SI-MRV07) as expected (Fig.
216 3C–3E). The L1 segment exhibited higher similarity and bootstrap support between MRV-117 and a bat
217 strain (WIV8) than those among the Zambian MRVs. These results suggest the occurrence of genetic

218 reassortment events among different MRV strains.

219 **Discussion**

220 Although MRVs are widely distributed in humans, livestock, and wild animals in Asia, Europe, and
221 North, and South America [2, 16, 19-27, 29], they have never been detected from pigs in Africa and their
222 epidemiological information in Africa is limited. In this study, we report the isolation and
223 characterization of MRVs circulating in a pig population in Zambia. In our screening, 19.7% of pigs in
224 Zambia were positive for MRVs, which were detected in all investigated areas, including Lusaka,
225 Chilanga, Chibombo, and Kafue. A similar prevalence of MRV infection was observed in pig populations
226 in the USA, South Korea, and China [2, 18, 32], suggesting that MRV has spread across pig populations
227 globally.

228 Phylogenetic analysis based on the S1 segments of MRV demonstrated that Zambian MRV strains
229 formed a monophyletic group with various MRV2 strains. The isolation of MRV2 in pigs has been
230 reported in Austria and Japan (GenBank accession number JN799419) [35]. A Japanese MRV2 strain
231 was isolated from fecal specimens collected from both diarrheal and apparently healthy pigs, and this
232 result was similar to our findings in Zambia. Further epidemiological studies are required to estimate the
233 impact of MRV2 infection in the pig population worldwide.

234 During the cell entry of MRV, the outer capsid proteins $\mu 1$ and $\sigma 3$ are degraded by luminal or
235 intracellular proteases to generate metastable intermediate particles called infectious subviral particles
236 (ISVPs) for membrane penetration [5-8]. Protease treatment of MRV virions, resulting in the digestion
237 of viral outer capsids and formation of ISVPs, enhances viral entry into cells [2, 41, 42]. The addition of
238 chymotrypsin to cell culture medium promotes the viral growth of MRV1, MRV2, and MRV3 strains in
239 several cell lines [43]. Conversely, some MRV3 strains featuring threonine at position 249 in the cell
240 attachment protein $\sigma 1$ are susceptible to cleavage by trypsin, and treatment with trypsin *in vitro* leads to
241 the cleavage of the viral protein and a resultant 90% reduction of virus infectivity [44]. We demonstrated
242 that MRV was efficiently isolated from fecal samples in Vero E6 cells using trypsin and BSA, suggesting

243 that this procedure is more useful for MRV2 isolation than the virus propagation in Vero E6 cells with
244 medium supplemented with FBS. Despite the clear effect of protease on virus propagation *in vitro*, little
245 information about the evaluation of protease treatment for MRV isolation using clinical and field samples
246 is available. The present study provides an effective protocol for the isolation of MRVs excluding MRV3
247 strains, the $\sigma 1$ protein of which is susceptible to proteolysis.

248 The phylogenetic analyses and recombination analyses based on whole-genome sequences of MRV
249 clearly demonstrated some genetic reassortment events between Zambian MRVs and different MRV
250 strains. Although the S3 segment of MRV-96 had the highest identity to that of the mink HB-B strain,
251 the bat WIV8 strain were predicted as the genetically close strain to MRV-96 via recombination analyses
252 as demonstrated in our dataset. Taken together, these results suggest that the number and diversity of
253 MRV genomic sequences currently maintained in the databank are not sufficient to infer the precise
254 origin of the S3 segment of the MRV-96 strain. Contrarily, the M3 segment of MRV-117 most likely
255 originated from human strains, such as SI-MRV07 and CMR-HP55, but there is no information about
256 human MRV strains in Zambia. Interestingly, these strains were recently detected in patients with
257 gastroenteritis in South Asia and Africa [27, 39], thus suggesting that MRV causing gastroenteritis in
258 humans might present in Zambia. Understanding the consequences of viral reassortment is important to
259 prepare for newly emerging high pathogenic viruses, and further surveillance of MRVs circulating in
260 human and other animals in Zambia is required to enhance veterinary and public health.

261 **Methods**

262 **Sample collection**

263 We selected five farms, each housing more than 500 pigs; farms A and E were located in Lusaka, farm
264 B in Chilanga, farm C in Kafue, and farm D in the Chibombo district. Fecal samples were collected with
265 the cooperation of local veterinary personnel from January to December 2018 [45]. For the collection of
266 fecal samples, some pens were chosen at random, and fresh stools on the floor were collected into tubes.
267 Collected samples were then transported at 4°C to the laboratory and stored at -80°C until analysis. In total,

268 47 and 100 fecal samples were obtained from suckling (0–3 weeks old) and fattening pigs (4–12 weeks
269 old), including those with or without diarrhea, respectively (Table 1).

270 **Detection of MRV by RT-PCR**

271 Fecal samples were suspended in phosphate-buffered saline (PBS) (10% [w/v]) containing 5%
272 antibiotic–antimycotic solution (Anti-Anti; Gibco, Waltham, MA, USA) and briefly centrifuged. Total
273 RNAs were extracted from the supernatants using TRIzol-LS (Invitrogen, Waltham, MA, USA) according
274 to the manufacturer’s instructions. RNA samples were examined to detect MRVs by RT-PCR using two
275 specific primer sets based on the conserved sequence within the L1 and L3 segments as previously
276 described [46-48] (Table S1). The protocol of RT-PCR for detecting the L3 segment was modified from
277 that of the PrimeScript One Step RT-PCR Kit v2 (Takara, Shiga, Japan). The RT-PCR conditions were as
278 follows: an initial reverse transcription step at 50°C for 30 min; a PCR activation step at 94°C for 2 min;
279 43 cycles of 94°C for 30 s, 56°C for 30 s, and 72°C for 30 s; and a final extension at 72°C for 7 min. PCR
280 was performed in a thermal cycler (Applied Biosystems, Foster City, CA, USA). PCR products were
281 subjected to direct sequencing using the Big Dye Terminator v3.1 Cycle Sequencing kit (Applied
282 Biosystems).

283 **Virus isolation**

284 Vero E6 cells were maintained in Dulbecco’s Modified Eagle’s Medium (Nissui Pharmaceutical Co.,
285 Tokyo, Japan) supplemented with 10% FBS, 2 mM L-glutamine, 100 units/ml penicillin, 100 µg/ml
286 streptomycin, 3.5 mg/ml D-glucose, and 1.0 mg/ml NaHCO₃ at 37°C in an atmosphere of 5% CO₂. The
287 supernatants of fecal suspensions were inoculated onto Vero E6 cell cultures, followed by 1 h of incubation
288 at 37°C in 5% CO₂ for virus adsorption. After the inocula were removed, the cells were washed twice with
289 PBS and maintained in MEM (Nissui Pharmaceutical Co.) containing 5 µg/ml trypsin, 0.3% BSA, 2 mM
290 L-glutamine, 4% Anti-Anti, and 1.0 mg/ml NaHCO₃ at 37°C in 5% CO₂. To evaluate the trypsin sensitivity
291 of MRV isolation, confluent monolayers of Vero E6 cells inoculated with each fecal sample were prepared

292 and maintained in MEM containing 2% FBS instead of trypsin and BSA. The supernatants of Vero E6 cells
293 were passaged three times to observe CPEs. The culture medium collected from cells displaying CPEs
294 were filtered through 0.45- μ m membrane filters (Iwaki, Tokyo, Japan) to remove bacterial cells and re-
295 inoculated into the cells. Viral isolation was confirmed by RT-PCR. The morphology and staining features
296 of MRV-infected cells were assessed via hematoxylin and eosin staining.

297 The electrophoretic patterns of the viral dsRNA were observed by SDS-PAGE as previously
298 described [36]. Vero E6 cell monolayers grown in T-175 flasks were infected with the isolated MRVs.
299 The infected cells exhibiting CPEs were subjected to three freeze-thaw cycles, and the debris was
300 removed via centrifugation at $1750 \times g$ at 4°C for 10 min. For virus concentration, the supernatants were
301 ultracentrifuged at 28,000 rpm and 4°C for 2 h using an SW-28 rotor and an Optima L-90K (Beckman
302 Coulter, Brea, CA), and the pellets were resuspended in PBS. Total RNAs were extracted from the re-
303 suspensions using QIAamp Viral RNA Mini Kits (Qiagen, Hilden, Germany) according to the
304 manufacturer's instructions. Viral dsRNAs were purified as previously described [49]. Briefly, extracted
305 total RNAs were mixed with equal volumes of 4 M LiCl and incubated at 4°C overnight. The dsRNAs
306 were precipitated by adding isopropanol and ammonium acetate at -30°C and pelleted via centrifugation.
307 Purified dsRNA was separated by SDS-PAGE using 4–15% gradient gel. MRV genome segments were
308 visualized via ethidium bromide staining.

309 **Whole-genome sequencing**

310 Total RNAs were extracted from the supernatants of MRV-infected cells using QIAamp Viral RNA
311 Mini Kits (Qiagen), and cDNAs were synthesized using a PrimeScript Double Strand cDNA Synthesis Kit
312 (Takara) according to the manufacturer's instructions. The cDNA libraries were prepared using a Nextera
313 XT DNA Library Preparation Kit (Illumina, San Diego, CA, USA) according to the manufacturer's
314 instruction and subjected to whole-genome sequencing on the MiSeq instrument with a MiSeq Reagent Kit
315 v3 (600 cycles) (Illumina). Sequencing data was analyzed using CLC Genomics Workbench software (CLC
316 bio, Hilden, Germany). After trimming low-quality reads, remaining reads were *de novo* assembled with

317 the default settings. The obtained contigs were analyzed via local BLAST against the virus reference
318 downloaded from the NCBI database. Consensus sequences obtained by mapping to the reference
319 sequences of other known MRVs were aligned with MRV contigs obtained via *de novo* assembly. Finally,
320 all trimmed reads were re-mapped to the aligned sequences and consensus sequences. Additionally, the 5'-
321 and the 3'-terminal regions of each MRV segment were amplified by RACE (Table S1). The RACE method
322 was performed using a SMARTer RACE cDNA Amplification Kit (Takara) according to the manufacturer's
323 protocol. PCR products were subjected to direct sequencing using a Big Dye Terminator v3.1 Cycle
324 Sequencing kit.

325 **Genetic comparison and phylogenetic analysis**

326 The open-reading frame positions and encoded proteins were predicted via comparisons with other
327 known MRV strains. Bioinformatic analyses were performed using various MRV sequences deposited in
328 the DDBJ/EMBL-Bank/GenBank databases (Table S2). Global homology analyses were conducted among
329 Zambian MRV strains using GENETYX version 12 (GENETYX Corporation, Tokyo, Japan). The highest
330 nucleotide identities for each viral segment of Zambian MRVs were identified via BLAST analyses.
331 Phylogenetic analyses based on the nucleotide sequence of each viral segment were performed using
332 MEGA7 [50]. The MUSCLE protocol was used to align the sequences, and phylogenetic trees were
333 constructed using the maximum likelihood method based on the Tamura–Nei model with 1000 bootstrap
334 replicates.

335 **Recombination analyses**

336 Homologous recombination within each genome segment among Zambian MRVs and other MRVs
337 was analyzed. Putative reassortant MRVs were preliminary identified by topological incongruity among
338 phylogenies of different segments. Such incongruities were further investigated using a dataset of MRVs
339 composed of the sequences of Zambian MRVs ($n = 3$) and other MRVs ($n = 27$) with complete genomic
340 sequences available in the reference list (Table S2). Alignments for each viral segment were analyzed

341 using the similarity and Bootscan methods as implemented in SimPlot software version 3.5.1 [51].

342 **Statistical analysis**

343 Differences in the rates of MRV isolation in the presence and absence of trypsin were analyzed using
344 the chi-squared test. $p < 0.05$ denoted statistical significance.

345 **Funding information**

346 This work was supported by grants for Scientific Research (B) from the Ministry of Education, Culture,
347 Sports, Science and Technology, Japan (MEXT)/Japan Society for the Promotion of Science (JSPS)
348 KAKENHI (JP16H05805), the Scientific Research on Innovative Areas and International Group from
349 MEXT/JSPS KAKENHI (JP16H06431, JP16H06429, JP16K21723), the Japan Initiative for Global
350 Research Network of Infectious Diseases (J-GRID) from the Japan Agency for Medical Research and
351 Development (AMED) (JP19fm0108008), and AMED and the Japan International Cooperation Agency
352 (JICA) within the framework of the Science and Technology Research Partnership for Sustainable
353 Development (SATREPS) (JP19jm0110019).

354 **Acknowledgments**

355 We would like to thank Ladslav Moonga, Evans Mulenga, Kapila Penjaninge, Joseph Ndebe,
356 Chembesonfu Mwelwa, and the veterinary staffs at Ministry of Fisheries and Livestock (MFL) for
357 collecting samples. One of the co-author of this manuscript, Prof. Aaron S. Mweene who has passed away
358 on April 27th, 2019, coordinated the epidemiological research in Zambia for this manuscript.

506 Abbreviation: nt, nucleotide sequence; aa, amino acid sequence

507

508 **Figure legends**

509 **Fig. 1.** Electrophoresis analysis of the genome of mammalian orthoreoviruses (MRVs) isolated from fecal
510 samples of pigs. Electropherotypes of viral double-stranded RNAs isolated from MRV strains (MRV-85,
511 MRV-96, and MRV-117) were observed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis
512 using 4–15% gradient gel. The locations of three large segments (L1–L3), three medium segments (M1–
513 M3), and four small segments (S1–S4) are indicated. The L2 and L3 segments and the M1 and M2 are
514 considered to have co-migrated, forming single bands (*).

515

516 **Fig. 2.** Phylogenetic analysis of the S1, M3, and S3 segments. Phylogenetic trees based on the nucleotide
517 sequence of the complete S1 (A), M3 (B), and S3 (C) segments were constructed using the maximum
518 likelihood method with 1000 bootstrap replicates. Bootstrap values greater than 70% are shown on the
519 interior branch nodes, and the scale bar indicates the number of substitutions per site. Group names (MRV1,
520 MRV2, MRV3, and MRV4) and cluster names are indicated on the tree. Black circles represent isolated
521 MRVs in this study. MRV, mammalian orthoreovirus.

522

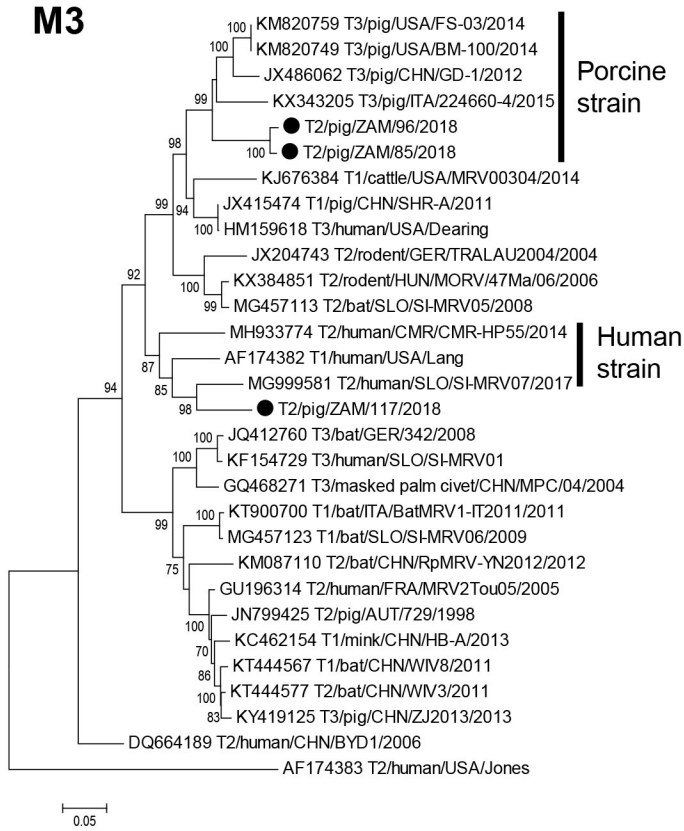

523 **Fig. 3.** Recombination analysis of mammalian orthoreovirus (MRV). Similarity plot (A and D) and
524 Bootscan analyses (B and E) based on the sequences of each viral segment were conducted using SimPlot
525 software v3.5.1. Two putative reassortant viruses, namely MRV-96 (A and B) and MRV-117 (D and E) were
526 analyzed. (C) Schematic diagram of the each MRV genome segments. Window and step sizes of 800 and
527 200 bp, respectively, were used for the similarity plot and Bootscan analyses. Compared sequences and
528 color coding are specified on the top of panels A and D.
