14 ABSTRACT. The Arctic is one of the most rapidly changing places on Earth and it is a sentinel  
15 region for understanding the range and magnitude of planetary changes, and their impacts on  
16 ecosystems. However, our understanding of arctic coastal ecosystems remains limited, and the  
17 impacts of ongoing and future climate change on them are largely unexplored. Kelp forests are  
18 the dominant habitat along many rocky Arctic coastlines, providing structure and food for  
19 economically and ecologically important species. Here we synthesize existing information on  
20 the distribution and diversity of arctic kelp forests and assess how ongoing changes in  
21 environmental conditions could impact the extent, productivity, and resilience of these  
22 important ecosystems. We identify regions where the range and growth of arctic kelp are likely  
23 to undergo rapid short-term increase due to reduced sea ice cover, increased light, and warming.  
24 However, we also describe areas where kelp could be negatively impacted by rising freshwater  
25 input and coastal erosion due to receding sea ice and melting permafrost. In some regions,  
26 arctic kelp forests have undergone sudden regime shifts due to altered ecological interactions  
27 or changing environmental conditions. Key knowledge gaps for arctic kelp forests include  
28 measures of extent and diversity of kelp communities (especially northern Canada and  
29 northeastern Russia), the faunal communities supported by many of these habitats, and the role  
30 of arctic kelp forests in structuring nearby pelagic and benthic food webs. Filling in these gaps  
31 and strategically prioritizing research in areas of rapid environmental change will enable more  
32 effective management of these important habitats, and better predictions of future changes in  
33 the coastal ecosystems they support and the services that they provide.

## 36 1.1. INTRODUCTION

37 The effects of humans are pervasive and are transforming natural ecosystems and  
38 biogeochemical cycles on global scales (Halpern et al. 2008; Waters et al. 2016). There is,  
39 however, great regional variation in the nature, magnitude, and direction of these changes  
40 (Burrows et al. 2011; Krumhansl et al. 2016), and it is only by understanding these  
41 geographical intricacies that we can begin to grasp the full extent of our footprint on the planet.  
42 Currently, the Arctic is warming 2 – 4 times faster than the global average and is now one of  
43 the most rapidly changing regions in the world (IPCC 2014). Marine ecosystems along Arctic  
44 coasts are experiencing increases in sea temperatures, dramatic declines in sea ice, and  
45 increased input of freshwater (Wassmann and Reigstad 2011; Coupel et al. 2015; Acosta  
46 Navarro et al. 2016; Ding et al. 2017). These changes are altering carbon cycling, affecting the  
47 timing and magnitude of primary production, and driving shifts in the structure and function of  
48 marine communities (Grebmeier et al. 2006; Nelson et al. 2014). As a result, the entire Arctic  
49 region has been designated an ocean warming hotspot (Hobday and Pecl 2014). Impacts of  
50 rapid environmental change on arctic ecosystems has broad significance due to both the global  
51 uniqueness and large geographic extent of the region, and because it may act as a sentinel for  
52 other ecosystems experiencing slower rates of change (Pecl et al. 2014; Hobday and Pecl 2014).  
53 Despite this, most Arctic coasts remain relatively unexplored, and the extent and resilience of  
54 coastal ecosystems are poorly understood, as are the ongoing and future impacts of climate  
55 change on them. Understanding changes to arctic ecosystems is especially critical because  
56 borealization (i.e., the northward shift of temperate communities) could squeeze out high arctic  
57 ecosystems altogether, resulting in the planetary loss of an entire climate zone (Fossheim et al.  
58 2015; Kortsch et al. 2015).

59 Kelp are large brown seaweeds that occur on rocky coasts throughout the Arctic  
60 (Wernberg et al. 2018). Many (or most) kelps are important foundation species that create

61 habitat (forests) for numerous fish and invertebrates (Christie et al. 2009; Norderhaug and  
62 Christie 2011; Teagle et al. 2017), provide food to marine communities through high  
63 production and export of detritus and dissolved organic material (Krumhansl and Scheibling  
64 2012; Renaud et al. 2015; Abdullah et al. 2017; Filbee-Dexter et al. 2018 in press), and store  
65 and sequester carbon (Krause-Jensen and Duarte 2016). Currently, information on the  
66 distribution, diversity, stability, and function of kelp forests is missing for large portions of the  
67 Arctic (Wiencke and Clayton 2009; Krumhansl et al. 2016; Wilce 2016).

68         A recent global analysis of records of kelp abundance over the past 5 decades showed  
69 that kelp forests are changing in many regions of the world (Krumhansl et al. 2016). At the  
70 warmest edges of their range, sudden shifts from kelp forests to reefs dominated by low-lying  
71 turf-forming algae have been increasingly documented over the last decade (Filbee-Dexter and  
72 Wernberg 2018). Along other temperate coasts, native kelps are being replaced by invasive  
73 kelps or other seaweeds (Wernberg et al. 2018), or are being heavily overgrazed by sea urchins  
74 (Filbee-Dexter and Scheibling 2014). In many of these regions, declines in kelp abundance are  
75 partly explained by the direct and indirect effects of warming sea temperatures (Ling et al.  
76 2009; Catton 2016; Filbee-Dexter et al. 2016; Wernberg et al. 2016). Considering the  
77 widespread changes throughout the temperate and tropical range of kelp and the ongoing  
78 environmental changes occurring in the Arctic, the fate of arctic kelps in this era of rapid  
79 change is a critical gap in our knowledge of arctic marine ecosystems.

80         Here we synthesize existing information on the distribution, biomass, and dominant  
81 species of arctic kelp forests. We explore some of the services provided by arctic kelps and  
82 identify missing baseline measures of their extent. We analyze changes in the sea ice extent  
83 and temperature conditions for known locations of kelp, and explore how recent and future  
84 changes in these and other conditions could impact their growth, reproduction, and survival.

85 Finally, we highlight key gaps in our understanding of these ecosystems, and suggest strategies  
86 for future research.

87

## 88 1.2. HIDDEN BLUE FORESTS OF THE ARCTIC

### 89 1.2.1. Bounds of arctic marine ecosystems

90 Arctic and temperate marine ecosystems are separated by a moving boundary, generally  
91 defined by latitude, sea ice cover, light variability, and the locations of the polar front and other  
92 ocean currents (Piepenburg 2005). The locations of these boundaries can be seasonal,  
93 unpredictable, and can shift with climate change. A precise and universally accepted  
94 geographical definition of ‘Arctic marine ecosystems’ therefore does not exist, and different  
95 southern limits for arctic marine ecosystems are used in the literature (Zenkevitch 1963;  
96 Piepenburg 2005; Gattuso et al. 2006; Wilce 2016). For example, so called ‘Arctic conditions’  
97 (ice scoured intertidal zones, ocean temperatures  $< 0^{\circ}\text{C}$ , and months with little to no daylight)  
98 extend below the Arctic circle along the coasts of Greenland and Eastern Canada, which are  
99 influenced by the cold southward moving Labrador and Greenland currents, but are restricted  
100 to above the Arctic circle along the coasts of northern Norway, Iceland and in the southern  
101 Bering sea, which are influenced by the warmer northward moving Gulf Stream and North  
102 Pacific currents, respectively (Wilce 2016). The convergence of cool waters from the Arctic  
103 Ocean and warm waters from the Atlantic and Pacific Oceans occurs around  $65^{\circ}\text{N}$  on the east  
104 coast of Greenland,  $80^{\circ}\text{N}$  west of Svalbard,  $76^{\circ}\text{C}$  in the Barents Sea, in the Bering Strait,  $63^{\circ}\text{N}$   
105 in the eastern Canadian Arctic Archipelago, and then slightly north between Baffin Island and  
106 the west coast of Greenland (AMAP 1998). However, other factors such as sea ice, light, and  
107 glacial run-off also create Arctic conditions south of these limits (AMAP 1998). Here we define  
108 ‘arctic kelps’ as kelps occurring within the boundaries defined by the Arctic Monitoring and  
109 Assessment Program (AMAP). AMAP originally defined Arctic boundaries in 1991 as regions

110 north of the 10°C July isotherm. These boundaries have since been expanded to include some  
111 areas that correspond to political boundaries of member nations of the Arctic Council (e.g.,  
112 coastal shelf of Iceland, Norwegian northwest coast, Hudson Bay, and the Aleutian Islands)  
113 (AMAP 2017). We used this definition because monitoring programs, assessments and  
114 decision-making on pollution and climate change in Arctic regions often use AMAP  
115 boundaries. However, despite our inclusive definition of the Arctic, much of this manuscript  
116 focuses on kelp forests at higher latitudes within the AMAP region where kelps face the most  
117 extreme Arctic conditions and where globally unique species compositions are found.

118

### 119 1.2.2. Distribution, growth forms and evolution of arctic kelps

120 Although kelps range along most Arctic coasts, sparse records of kelp in some parts of the  
121 Arctic have been attributed to a lack of hard substrata (Kjellman 1883; Wilce 2016). Only about  
122 35% of the Arctic basin is rocky substrate and shallow coastal areas and inner Arctic fjords are  
123 often dominated by sediment due to glacial run off and river deposition (Leont'yev 2003;  
124 Lantuit et al. 2012), which limits the presence of kelp. In areas with suitable substrate, dense  
125 kelp forests can extend from the intertidal zone down to depths of 30 – 40 m depending on light  
126 conditions, wave regime, and grazing intensity (Wernberg et al. 2018). The deepest recorded  
127 kelp was observed at 60 m depth in Disko Bay, Greenland (Boertmann et al. 2013). In high  
128 Arctic regions, available light and sea ice further restrict this depth range and the upper  
129 sublittoral zone is a barren, low salinity environment that is constantly impacted by sea ice and  
130 meltwater (Wiencke and Clayton 2011).

131         The diversity of kelp in the high Arctic tends to be lower than in temperate kelp forests  
132 (Wiencke and Clayton 2011). Genetic evidence indicates that most kelps reinvaded the Arctic  
133 from the Atlantic Ocean ~8,000 years ago following the last ice age, which eliminated benthic  
134 flora from most current Arctic subtidal regions (Wulff et al. 2011). As a result, most arctic

135 kelps have optimal growth temperatures that exceed those experienced during the Arctic  
136 summer and many of these species therefore also thrive along warmer, temperate coasts  
137 (Wiencke and Amsler 2012). In the high Arctic especially, kelps tend to be morphologically  
138 smaller compared to their southern range limits (e.g., Kuznetsov et al. 1994; Kuznetsov and  
139 Shoshina 2003; but see Borum et al. 2002). However, kelps still form dense canopies in some  
140 regions (e.g., western Alaska and northern Norway) and provide most of the algal biomass and  
141 the largest three-dimensional biogenic structure on rocky coasts in Arctic regions (Wiencke  
142 and Amsler 2012). In fact, these lush underwater forests are particularly striking in the Arctic,  
143 where terrestrial coasts are barren and ice scoured with little three-dimensional structure.

144  
145 Fig 1. Photographs of select kelps from high Arctic regions: a) *Laminaria solidungula*, b)  
146 *Alaria elliptica*, c) *Saccharina longicruris*, d) *Saccharina nigripes*, and e) *Saccorhiza*  
147 *dermatodea* (Guiry and Guiry 2017).

148  
149 The species pool is relatively young, with only one truly arctic endemic kelp, *Laminaria*  
150 *solidungula* (Kjellman 1883; Zenkevitch 1963; Wilce and Dunton 2014). All other kelp species  
151 found in Arctic regions also extend into sub-arctic and northern temperate waters and include  
152 *Alaria esculenta*, *Agarum clathratum*, *Eualaria fistulosa*, *Laminaria digitata*, *Laminaria*

153 *hyperborea*, *Nereocystis luetkeana*, *Saccharina latissima*, *Saccharina longicuris*, *Saccharina*  
154 *nigripes*, *Saccorhiza dermatodea*, *Alaria elliptica*, and *Alaria oblonga* (the latter 2 are only  
155 found in Russia) (Fig 1, Table 1). There is currently taxonomic confusion regarding some arctic  
156 species; *S. nigripes*, for example, has often been misidentified as *L. digitata*, and appears to be  
157 restricted to Arctic or subarctic conditions, although more information on its distribution is  
158 needed (McDevit and Saunders 2010). In 2006 a new species of kelp *Aureophycus aleuticus*  
159 was collected from Kagamil Island, Aleutian Islands, but its classification within the order  
160 Laminariales is still unclear (Kawai et al. 2013). New DNA barcoding techniques show  
161 promise for clearing up misidentifications caused by diverse growth morphologies of kelps in  
162 arctic conditions (McDevit and Saunders 2010; Bringloe et al. 2017).

163

#### 164 1.2.1. Adaptations to Arctic conditions

165 Kelps in arctic environments are challenged by extremely low water temperatures, periods of  
166 low salinity, and extreme variability in light caused by large annual variations in day length,  
167 light intensity, and sea ice cover. In their northernmost range, kelps live in temperatures at the  
168 point of freezing sea water during polar nights (e.g., NE Greenland, Borum et al. 2002; Franz  
169 Joseph Land, Shoshina et al. 2016). Day-length ranges from 24-hour sunlight in mid-summer  
170 to several months of total darkness during winter (Hanelt 1998). The low angle of the sun and  
171 periods of complete darkness mean that high Arctic areas only receive 30 – 40 % of the light  
172 received in the tropics on an annual basis. The long period of darkness during winter is further  
173 extended in areas with partial or complete sea ice cover, especially if the ice is thick or covered  
174 by snow (Mundy et al. 2007). Subtidal habitats in the Arctic can therefore be without light for  
175 much of the year. Studies from NE Greenland illustrates this; the annual surface irradiance  
176 (PAR) in Young Sound (74° 18' N) amounts to ca. 6100 mol photons m<sup>-2</sup>, but the ice-free

177 period is limited to August and September so that the amount of available light at 10 and 20 m  
178 depth is only 234 and 40 mol photons m<sup>-2</sup> yr<sup>-1</sup>, respectively (Borum et al. 2002).

179         The marked seasonal variation in light availability in the Arctic concentrates primary  
180 production into a short period and creates strong seasonality in the growth of kelp (Chapman  
181 and Lindley 1980; Dunton and Jodwalis 1988; Borum et al. 2002; Makarov et al. 2008). Arctic  
182 kelps are well adapted to these long periods of darkness or low light conditions. Studies on *S.*  
183 *latissima* and *L. solidungula* show that these species store most of the carbon obtained during  
184 the short summer period and subsequently use these reserves to form new blades during the  
185 succeeding period of almost darkness (Chapman and Lindley 1980; Dunton and Jodwalis 1988;  
186 Borum et al. 2002). Remarkably, the peak growth period for Alaskan *L. solidungula* was from  
187 February to April under full ice cover (Dunton 1985), and the production of new lamina in *S.*  
188 *latissima* from Young Sound (NE Greenland) occurred under ice cover and in complete  
189 darkness, likely based on re-allocation of C from the old lamina or stipe (Borum et al. 2002).

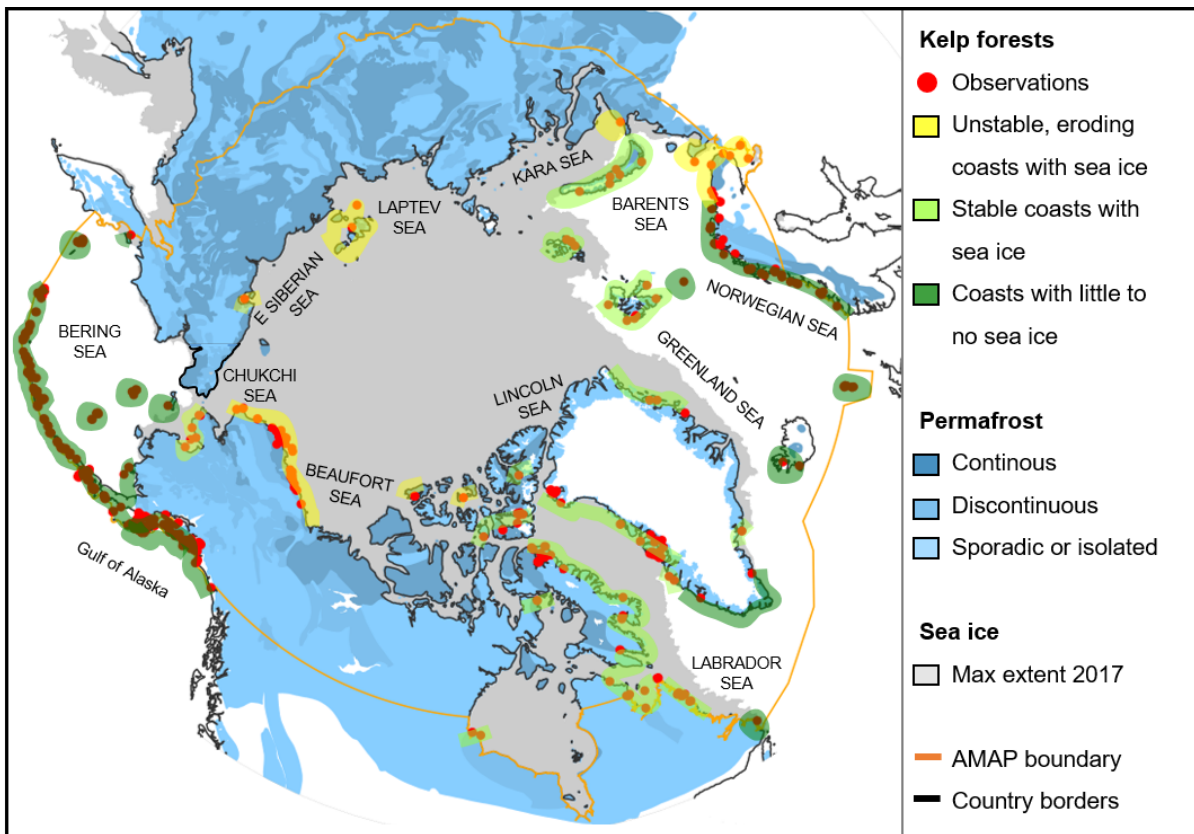

190         Many kelp species can also cope with multi-year sea ice, which can cause severe  
191 mechanical damage to benthic organisms in the intertidal and upper subtidal zone (Krause-  
192 Jensen et al. 2012; Dayton 2013; Shoshina et al. 2016). Most kelp forests recover from sea ice  
193 damage through high reproduction and recolonization of the scoured substrate. Keats et al.  
194 (1985) found, for example, that populations of *A. esculenta* recovered within a few years after  
195 having been removed by ice-scour in the uppermost reaches of its range. However, Konar  
196 (2013) found slow recolonization in clearing experiments on kelps in the Boulder Patch (< 10  
197 % recolonization after 7 years), which is much slower than rates in many temperate kelp forests.

198

### 199 1.3. KNOWN LOCATIONS OF ARCTIC KELPS

200 Data on the current extent and distribution of kelps in the Arctic is not available. To overview  
201 the observational data record of kelp in subarctic and Arctic seas we compiled records of kelp

202 over the last 2 centuries, within the AMAP boundaries, from primary literature, museum  
203 collections, dive logs, Arctic expeditions, coastal monitoring, and local ecological knowledge  
204 from Inuit and northern communities (N = 1179 records, Fig 3). The spatial extent of these  
205 ecosystems ranged from 100s of km<sup>2</sup> of kelp forests to small patches of kelp within inner fjords  
206 and boulder patches along sedimentary coasts. The number of kelp records decreased with  
207 latitude, with the northernmost observations of kelp forests > 80° N at Svalbard, Norway and  
208 Franz Joseph Land, Russia (Shoshina et al. 1997; Bartsch et al. 2016). Most records were from  
209 northern Norway, western Greenland, eastern Canada, and northwestern USA. The earliest  
210 records of arctic kelp were from the Canadian high Arctic during expeditions in search of the  
211 Northwest passage (Lee 1980). Other early records come from Kjellman (1883), who published  
212 the first comprehensive review of polar benthic algae based on expeditions from Sweden via  
213 Norway to Novaya Zemlya, and into the Siberian sea, Russia, and Rosenvinge (1893, 1899),  
214 who described the algal flora in Greenland a decade later. Dive research on arctic kelp forests  
215 was first conducted in Greenland, Canada and USA by Wilce (1963), Chapman and Lindley  
216 (1980), and Dunton et al. (1982). It is worth noting that these historical records represent a  
217 baseline and may not reflect current kelp distributions.

218

219 Fig. 2. Kelp locations (red) within AMAP Arctic boundary line (orange). Gray shading shows  
 220 maximum sea ice extent, blue shading shows continuous permafrost (90 - 100 % cover),  
 221 discontinuous permafrost (50-90 %), and sporadic and isolated patches of permafrost (< 50 %)  
 222 (2016 National Snow and Ice Data Centre,  
 223 [https://nsidc.org/data/docs/fgdc/ggd318\\_map\\_circumarctic/](https://nsidc.org/data/docs/fgdc/ggd318_map_circumarctic/)). Eroding coasts (yellow) and  
 224 stable coasts (light green) in regions with sea ice were differentiated according to the Arctic  
 225 coastal classification scheme developed by Lantuit et al. (2012).

226

227 Extreme variation in environmental conditions occur within the AMAP arctic  
 228 boundaries. Large regional differences in coastal conditions are strongly driven by the cover of  
 229 sea ice and the presence of permafrost (frozen soil, rock, or sediment) (Lantuit et al. 2012). To  
 230 capture this variability in our description of arctic kelps, we grouped information from our

231 observational data into 3 general categories: (1) kelps on stable coasts with sea ice, (2) kelps  
232 on unstable, eroding coasts with sea ice, and (3) kelps on coasts with little to no sea ice.

233

234 Fig 3. Photographs show examples of arctic kelp forests: (A) *Laminaria solidungula* in the  
235 Beaufort Sea, Alaska, USA (Ken Dunton), (B and C) *Laminaria hyperborea* in Malangen fjord,  
236 Norway (Thomas Wernberg, Karen Filbee-Dexter), (D) *Eularia fistulosa* Aleutian Islands,  
237 Alaska (Pike Spector), (E) *Saccharina latissima* under sea ice in Kangiqsujuaq, Canada (PBS,  
238 2017), (F) *Laminaria digitata* in Svalbard, Norway (Max Schwanitz), (G) *Saccharina*  
239 *latissima*, *S. longicuris*, *Alaria esculenta*, *Laminaria solidungula* in northern Baffin Island,  
240 Canada (Frithjof Küpper), and (H) *Laminaria hyperborea* along the Murmansk coast, Russia  
241 (Dalnie Zelentsy).

242

### 243 1.3.1 Kelps on stable Arctic coasts with sea ice

244 Stable, rock bound coasts and fjord systems in Arctic areas with seasonal cover of sea ice can  
245 support luxurious kelp forests, although their vertical distribution is limited by ice scour  
246 (shallow) and light. These areas are expected to experience pronounced changes in  
247 environmental conditions when sea ice retreats. Although this should increase overall primary  
248 productivity along these coasts, the species composition of algae currently found in these Arctic

249 regions may be lost permanently if more temperate-adapted algal communities push northward  
250 and outcompete kelps that are adapted to seasonal sea ice (Krause-Jensen and Duarte 2014).

251 In the northern Barents Sea, kelp forests of mixed *A. esculenta*, *L. digitata* and *S.*  
252 *latissima* occur within high latitude fjords off Svalbard, the western White Sea, and Franz  
253 Joseph Land (Kuznetsov et al. 1994; Cooper et al. 1998; Bartsch et al. 2016; Fig 3fh). Luxuriant  
254 stands of *L. digitata*, *L. solidungula*, *S. dermatodea*, and *A. clathratum* were observed within  
255 fjords in western Novaya Zemlya (Shoshina and Anisimova 2013). In the northernmost regions  
256 around Svalbard and Novaya Zemlya, the arctic endemic kelp *L. solidungula* is found in inner  
257 fjords and areas that receive cold polar currents (Svendsen 1959; Hop et al. 2012; Shoshina  
258 and Anisimova 2013).

259 The west coast of Greenland is largely rockbound and dominated by sub-littoral kelp  
260 forests from Cape Farewell in the south (59° N) to Smiths Sound in the north (>80° N,  
261 Rosenvinge 1893, 1899). The western Greenland kelp forests are dominated by *S. longicuris*  
262 north of 62° N and by *S. latissima* south of this latitude, while other species such as *L.*  
263 *solidungula*, *A. esculenta*, *Agarum clathratum*, *S. nigripes* and *S. dermatodea* are present, but  
264 less conspicuous (Rosenvinge 1899; Krause-Jensen et al. 2012). The kelp forests in western  
265 Greenland are narrow and shallow in the north, but become broader, more abundant, and extend  
266 deeper in the south due to less ice cover (Krause-Jensen et al. 2012). In some parts of  
267 Greenland, high densities of sea urchins or a lack of hard bottom restricts the extent of the kelp  
268 forests (Krause-Jensen et al. 2012). The kelp populations in eastern Greenland tend to be  
269 situated deeper, have less biomass per unit area and grow more slowly than those on the west  
270 coast (Borum et al. 2002; Krause-Jensen et al. 2012), which may be due to lower water  
271 temperatures, longer periods with ice-cover, and more heavy scour by pack ice. *S. latissima*  
272 and *A. esculenta* appear to be the dominant species along most of the east coast (recorded as

273 high as Danmarks Havn (75° N)), while *L. solidungula*, *S. nigripes*, *S. longicuris* and *A.*  
274 *clathratum* are present, but less abundant (Rosenvinge 1899).

275 In Hudson Bay and Eastern Canada, sea ice extends below the Arctic circle due to the  
276 influence of the cold Labrador current. *S. latissima*, *A. clathratum*, *A. esculenta*, and *L.*  
277 *solidungula* have been documented between Ellesmere Island and Labrador, and along coasts  
278 in Lancaster Sound, Ungava Bay, Hudson Bay, Baffin Bay, and Resolute Bay (Table 1). These  
279 ecosystems can be highly productive in some areas, with luxuriant beds of 15-m long *S.*  
280 *latissima* observed in Frobisher Bay, and beds containing a biomass of 19 kg wet weight m<sup>-2</sup>  
281 of *A. esculenta* measured in Ungava Bay (Sharp et al. 2008). Kelp forests have also been  
282 documented in eastern Chukchi Sea from Norton Sound to north of the Bering Strait along the  
283 west coast of Alaska (70 and 71° N; Phillips and Reiss 1985).

284

### 285 1.3.2. Kelps on eroding, permafrost bound Arctic coasts with sea ice

286 Scattered low relief, rocky coasts in the eastern Siberian, Laptev, Beaufort, and Chukchi  
287 seas, and the Canadian high Arctic have temperatures and light conditions that should support  
288 kelp (Krumhansl and Scheibling 2012), but observations are rare in these regions (Zenkevitch  
289 1963; Lee 1973; Wilce and Dunton 2014; Wilce 2016). These coasts are more permanently  
290 icebound compared to other Arctic regions— especially in the Beaufort, eastern Siberian, and  
291 Laptev seas – and the seafloor is often covered in sediment due to intense glacial run off. Low  
292 salinity, high levels of sedimentation, and sparse substrate make kelps and other macroalgae  
293 poorly developed (Taylor 1954; Leont'yev 2003; Dayton 2013). As a result, kelps along these  
294 coasts face ‘uniquely Arctic conditions’ such as extensive sea ice scour, long periods of  
295 darkness, variable salinity, turbidity, and low temperatures (Wilce 2016). The associated  
296 macroalgal communities in these regions have distinct species compositions compared to other  
297 regions of the Arctic, possibly because they are less connected to nearby temperate

298 communities due to outflow of polar currents from the north to south along their coasts (Wilce  
299 and Dunton 2014). In the Alaskan Beaufort Sea, kelps are found in scattered rocky habitats in  
300 shallow waters (5 – 10 m depth) along the mainly sedimentary coast. Research on kelps in this  
301 area are from the ‘Boulder Patch’ (71° N), where *L. solidungula* forms beds intermixed with  
302 *A. esculenta* and *S. latissima* on shallow cobbles and boulders (Wilce and Dunton 2014; Fig  
303 3a). These isolated kelp communities contain about half of the 140 macroalgal species found  
304 in the Arctic. The Boulder Patch has been studied since 1978 and revisited in 14 separate years  
305 between 1978 – 2012, over which time the species composition has remained relatively static  
306 (Wilce and Dunton 2014).

307         In the northwestern high Canadian Arctic, low availability of rocky substrate and a  
308 harsher climate support smaller, fragmented kelp forests (Lee 1980). This region of the  
309 Canadian Arctic commonly supports *L. solidungula*, which has been observed as high as 74.5°  
310 N.

311         In northeastern Russia, observations of kelp are limited to a handful of records along  
312 these sedimentary coasts, namely, *S. latissima* off Amderma, mainland Russia, Kotel Nyy  
313 Island (Cooper et al. 1998), and along the Russian coast of Chukchi Sea (Zenkevitch 1963); *L.*  
314 *solidungula* on islands in the Laptev Sea and within bays in the Siberian Sea (Cooper et al.  
315 1998), and *S. latissima*, *L. solidungula*, *S. nigripes*, *A. elliptica* and *A. oblonga* in the Kara sea  
316 (Zenkevitch 1963; Guiry and Guiry 2017).

317

### 318 1.3.3. Kelps in Arctic regions with little to no sea ice

319         Kelp forests in the Norwegian Sea, the Barents Sea, and the northern Pacific (Aleutian  
320 Islands and northern Gulf of Alaska) have high upper limits of biomass compared to other  
321 arctic kelp forests (Table 1; Fig 3bcd). These regions have little to no sea ice and ocean  
322 temperatures that are warmer than other Arctic regions due to the influence of the Gulf Stream

323 or the Pacific Current. Kelp forests in some of these regions (e.g., the Gulf of Alaska) are highly  
324 influenced by environmental conditions on land, namely high freshwater inputs from melting  
325 permafrost and melting glaciers that creates strong clines in salinity in coastal areas (Spurkland  
326 and Iken 2011; Lind and Konar 2017). Kelp in other regions with little to no sea ice appear to  
327 be more influenced by biological factors than by environmental conditions. Many kelp forests  
328 are strongly influenced by the density of herbivorous sea urchins, which increase with the loss  
329 of higher level predators (e.g., crabs, cod, otters) (Doroff et al. 2003; Filbee-Dexter and  
330 Scheibling 2014). Importantly, kelps currently found in areas with little to no sea ice may  
331 represent future scenarios for other Arctic regions.

332         Along the western and northern coast of Norway, and along low-lying, rock-bounded  
333 coasts within the Murmansk region of Russia, *Laminaria hyperborea* dominates the exposed  
334 coasts (Fig 3bc, Table 1) and kelp forests can obtain biomasses up to 21 kg fresh weight m<sup>-2</sup>  
335 (Fig S1). In the mid-1970s, high densities of the green sea urchin *Strongylocentrotus*  
336 *droebachiensis* destructively grazed kelp forests and created extensive urchin barrens,  
337 restricting the distribution of kelp to exposed regions or shallow surf zones (Leinaas and  
338 Christie 1996). Currently, regional recovery of kelp forests is occurring following decreases in  
339 sea urchin populations due to reduced urchin recruitment in the south (Fagerli et al. 2013) and  
340 increased crab predation in the north (Fagerli et al. 2015).

341         In the North Pacific Ocean, surface canopy forming kelps *Eularia fistulosa* and  
342 *Nereocystis luetkeana* and subsurface kelps (*Agarum clathratum*, *Alaria esculenta*, *Costaria*  
343 *costada*, *Laminaria digitata*, and *Saccharina latissima*) form forests along the Aleutian Island  
344 chain, the northern Gulf of Alaska coast and the northeastern coast of Russia. *Eularia fistulosa*  
345 dominates surface canopies in the Aleutian Islands and *E. fistulosa* and *N. luetkeana* in  
346 southeast Alaska that can grow from > 30 m depth. Subsurface kelps tend to be competitively  
347 dominant in both regions (Duggins 1980, Dayton 1975). Kelp forests in the northern Gulf of

348 Alaska occur within the largest freshwater discharge system in North America, and experience  
349 strong gradients of salinity due to substantial glacial inputs. The amount of glacial melt is  
350 increasing with climate change, further lowering salinity and negatively effecting kelps in these  
351 areas (Lind and Konar 2017). In contrast, kelp forests along the shores of the Aleutian Islands  
352 are more influenced by biotic interactions. These coasts have alternated between kelp forests  
353 and urchin barrens for over a century (Estes et al. 2004). Shifts between these two ecosystem  
354 states are driven by changing abundances of sea otters, which are major predators of the sea  
355 urchin *Strongylocentrotus polyacanthus* (Estes and Duggins 1995). Evidence from the region  
356 suggests that kelp forests established in 1911 after protection of sea otters enabled their  
357 populations to rebound (Estes et al. 1978). The recovered kelp forests (*Eualaria fistulos* and  
358 *Laminaria* spp.) were maintained for decades, until otter populations declined again due to  
359 predation by killer whales in the 1990s (Doroff et al. 2003; Estes et al. 2004), once again  
360 limiting kelp forests to exposed areas and shallow depths, which serves as refuges from grazing  
361 (Konar and Estes 2003).

362

#### 363 1.4. ECOSYSTEM SERVICES PROVIDED BY ARCTIC KELP

364 Kelps can provide extensive substrate for colonizing organisms, and their canopies create  
365 habitat for a number of marine plants, fish, and invertebrates (Teagle et al. 2017). The flora in  
366 arctic kelp forests can be diverse and has been described in detail for some high Arctic regions  
367 (e.g., Wilce and Dunton 2014; Küpper et al. 2016). Diverse fish, invertebrate and epiphytic  
368 communities are found in kelp forests in Svalbard, Norway, the Aleutian Islands, the Gulf of  
369 Alaska, and the Boulder Patch, USA (Hamilton and Brenda 2007; Włodarska-Kowalczyk et al.  
370 2009; Wilce and Dunton 2014). Kelp canopies can create favourable conditions for some  
371 understory species and were shown to provide predation refuge for juvenile cod in  
372 Newfoundland, Canada (Gotceitas et al. 1995) and rockfish and ronquils in the Gulf of Alaska

373 (Dean et al. 2000b). Traditional knowledge from northern communities in Greenland reported  
374 higher arctic cod catches in areas near kelp forests compared to other areas (Krause-Jensen and  
375 Duarte 2014). Despite these reports, the smaller size and patchy nature of kelps in some Arctic  
376 regions may reduce their importance as habitat forming species compared to temperate forests.  
377 Kelp also has cultural value for northern peoples and features in their traditions and stories. It  
378 is a traditional food for Inuit, who harvest it from under sea ice during low tide (Wein et al.  
379 1996) and can be used by farmers as fertilizer or to cattle feed (Reedy and Katherine 2016).

380 Kelp-derived organic material constitutes a significant component of coastal primary  
381 production, often forming the base of benthic food webs in nearby habitats (Dunton and Schell  
382 1987; Fredriksen 2003; Krumhansl and Scheibling 2012). Direct consumption rates on most  
383 high arctic kelps are unknown, but are likely lower than those along temperate and subarctic  
384 coasts, as herbivores tend to be less abundant and the digestion of algae hypothesized to be less  
385 energy efficient in colder ecosystems compared to warmer ecosystems (Floeter et al. 2005;  
386 Konar 2013; Wilce 2016). Konar (2007) deployed grazer exclusion cages in experimental  
387 clearings in kelp forests in the Beaufort Sea, Alaska, and found that the overall increase in algal  
388 recruitment due to grazing was < 1% of the total area cleared. Similarly, the sea urchin  
389 *Strongylocentrotus droebachiensis*, a key grazer of kelps along temperate coasts in the North  
390 Atlantic (Filbee-Dexter and Scheibling 2014), is confined to shallow waters in the south  
391 western Barents Sea (Murman coast), localized patches in Jan Mayen (Gulliksen et al. 1980),  
392 Novaya Zemlya (Nordenskiöld 1880) and southern parts of Svalbard (Gulliksen and Sandnes  
393 1980), and is rare or absent around Franz Josefs Land and the Laptev and Kara Sea (Levin et  
394 al. 1998). Clear exceptions to this pattern of low grazing pressure at higher latitudes include  
395 kelp forests in the Aleutian islands and northern Norway, where high consumption rates by sea  
396 urchins have been recorded (Estes and Duggins 1995; Leinaas and Christie 1996).

397 Kelp carbon contributions to marine organisms in coastal environments can be  
398 substantial. On average, around 80% of the kelp production globally (91% for the Boulder  
399 Patch in the Beaufort Sea) enters coastal food webs as detritus, through detachment or  
400 exudation of dissolved organic carbon, which is exported to adjacent ecosystems on beaches  
401 and deeper offshore areas (Krumhansl and Scheibling 2012). Macroalgal-derived carbon can  
402 be used by benthic herbivores and predators, while upper trophic level fishes and marine  
403 mammals generally use phytoplankton-derived carbon (McMeans et al. 2013). Stable isotope  
404 analyses show kelp carbon contributed 57% to nearshore fish populations in the Gulf of Alaska  
405 (von Biela et al. 2016), 15 to 75% to rock greenling, predatory sea stars, and cormorants in the  
406 Aleutian Islands (Duggin et al. 1989), 0 to 42% for diverse marine predators in Baffin Island,  
407 Canada (McMeans et al. 2013), and 50% to mysid crustaceans in the Beaufort Sea (Dunton and  
408 Schell 1987). The latter predatory snails are a critical food source for higher trophic levels such  
409 as fish, whales, and birds, indicating the high importance of kelp as a primary producer (Dunton  
410 and Schell 1987).

411 A comprehensive understanding of the nature and extent of kelp subsidy to other arctic  
412 benthic, pelagic, and terrestrial ecosystems is still lacking, and the magnitude and importance  
413 of kelp exported from shallow coasts to deeper habitats is a debated topic of on-going research  
414 (Renaud et al. 2015). In the subarctic and Arctic regions, most research has focused on the  
415 vertical influx of phytoplankton- or zooplankton-derived organic matter as the main source of  
416 carbon in benthic systems. In Greenland, Krause-Jensen et al. (2007) showed that primary  
417 production of kelps and other benthic algae can contribute to > 20% of the total primary  
418 production in shallow coastal areas. However, at depths > 15 m this production was largely  
419 insignificant compared to that of phytoplankton and benthic microalgae (Krause-Jensen et al.  
420 2007). The magnitude of, and timing by which, kelp-derived carbon enters arctic ecosystems  
421 is especially interesting because climate change is triggering earlier phytoplankton blooms in

422 the Arctic, creating temporal mismatch between pelagic primary production and some higher  
423 trophic level species that synchronize their life cycle or behaviour to this pulsed source of  
424 energy (van Leeuwe et al. 2018). In light of this mismatch, understanding other sources of  
425 arctic primary production during food-limited periods is becoming critical.

426         Knowing the residence time of kelp detritus in Arctic environments is important in light  
427 of increased interest in blue carbon sequestration worldwide (Krause-Jensen and Duarte 2016).  
428 In the Canadian High Arctic, large amounts of macroalgal detritus have been observed on the  
429 seafloor in sheltered fjords (Küpper et al. 2016). In northern Norway (70°N), pulses of whole  
430 kelp blades rapidly reached deep-fjord communities (> 400 m depth) during the spring  
431 shedding of old *L. hyperborea* lamina (Filbee-Dexter et al. 2018). If kelp material degrades  
432 slower and remains intact longer in colder arctic environments, it may be more likely to be  
433 sequestered in ocean sediments than kelp carbon produced at lower latitudes.

434

#### 435 1.5. KELPS IN A SENTINAL REGION OF CHANGE

436 Key changes that will influence kelps in the Arctic include elevated temperatures (Najafi et al.  
437 2015; Wang et al. 2017), decreased cover and thickness of sea ice (Arctic Monitoring and  
438 Assessment Programme. 2011; Parkinson and Comiso 2013; Ding et al. 2017), reduced  
439 salinity, and increased turbidity (IPCC 2014; Günther et al. 2015). Other environmental  
440 changes that could impact kelps are altered nutrients levels and increased UV radiation.  
441 Reduced sea ice and warming could also bring in invasive species by increasing shipping traffic  
442 or warm water species migration (Miller and Ruiz 2014), which could impact kelp  
443 communities. The cumulative impact of these stressors will likely affect kelp growth rates and  
444 periods severely, but ultimately depends on their nature and strength, the interactions between  
445 them, and the ways in which different kelp species acclimate and/or adapt to new conditions  
446 (Harley et al. 2012).

447

### 448 1.5.1. Temperature

449 Temperatures in the Arctic are projected to increase by 3 – 4°C by the end of the 21<sup>st</sup> Century  
450 under realistic warming scenarios (IPCC 2014; Huang et al. 2017). Currently, kelps in Arctic  
451 waters experience low temperatures with little seasonal variation. Water temperatures rarely  
452 exceed 5°C in summer in the high Arctic, but may reach 10°C during summer in the southern-  
453 most parts of Arctic or where warm ocean currents affect local climate. Average temperatures  
454 may be below 0° C with a variation as small as  $\pm 1^\circ$  C in high latitude places affected by cold  
455 currents (e.g., Igloolik, Northwest Territories, Canada (Bolton and Lüning 1982); Young  
456 Sound, eastern Greenland (Borum et al. 2002); Franz Joseph Land, Russia (Shoshina et al.  
457 2016)).

458 To explore prior and ongoing temperature changes in the vicinity of documented  
459 locations of arctic kelp, we related these to maps of surface temperature for the region. We  
460 calculated average temperature measures from 1986 and 2016 at each of our kelp locations  
461 using historical IPCC temperature maps (IPCC 2014, accessed through  
462 [gisclimatechange.ucar.edu](http://gisclimatechange.ucar.edu)). Around each kelp location we averaged the mean summer (July to  
463 September) temperature over this 20-year period within a buffer radius of 1° latitude, which  
464 corresponded to the spatial error associated with locations of early records. We also calculated  
465 the magnitude and rate of the predicted increase in mean summer temperature at each location  
466 using climate model forecasts for 2016 to 2036 (IPCC 2014). We used the model based on the  
467 conservative greenhouse gas emission scenario B1, which predicted a conservative increase of  
468 1.1 to 2.9 °C by 2090-2099 relative to 1980-1999 (SRES 2000).

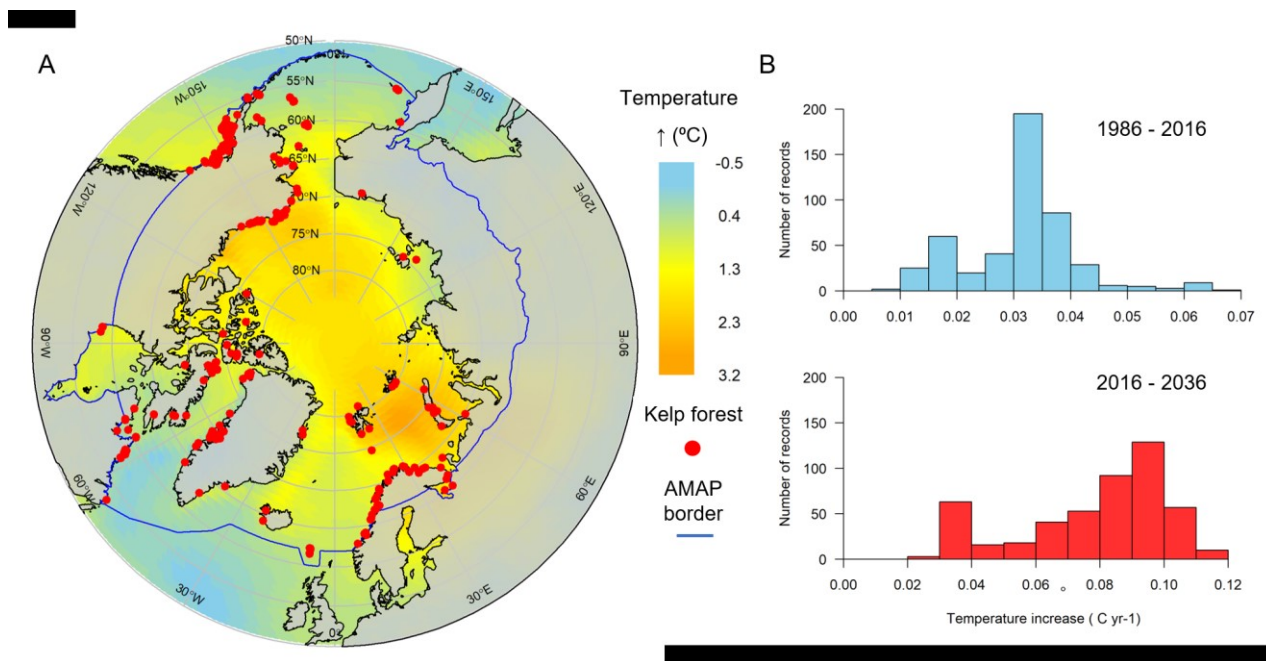

469 The mean summer temperature across all kelp locations has increased by 0.35° C ( $\pm$   
470 0.20) per decade over the period from 1986 to 2016 (Fig. 4a) and is predicted to increase by  
471 1.09° C ( $\pm 0.59$ ) per decade over the next century (Fig 4b). Predicted temperature increases are

472 least pronounced for kelps along the coasts of Greenland and eastern Siberia, and most  
473 pronounced in the Barents Sea, Beaufort Sea, and Canadian High Arctic, suggesting that  
474 changes to kelp forests due to warming will first occur in these regions.

475         Based on temperature tolerance and growth optima of most arctic kelp species, warmer  
476 temperatures should increase growth rates (Müller et al. 2009; Shoshina et al. 2016). The  
477 optimum growth temperature for most arctic and cold-temperate kelp species range from 10 to  
478 15°C (Wiencke and Amsler 2012; Roleda 2016), and growth at 0 to 5°C is typically only 25 –  
479 30% of growth at their optimum temperature (e.g., Bolton and Lüning 1982). Upper  
480 temperature limits on growth of arctic kelps ranges from 16°C to 21°C (Assis et al. 2018),  
481 which are well above conditions found along Arctic coasts. This suggests warming could more  
482 than double kelp production in some regions the next 2 – 3 decades. Warming may also  
483 improve recruitment; for example, germination of spores, fertility (Golikov and Averintsev  
484 1977), and survival of arctic kelp gametophytes are limited by temperatures below -1° C  
485 (Sjötun and Schoschina 2002; Müller et al. 2008; Assis et al. 2018) (Table 2). Such changes  
486 will vary across kelp species and will likely alter their competitive interactions. In the northern  
487 Gulf of Alaska, spore settlement and gametophyte growth of *Eualaria fistulosa* were more  
488 negatively impacted by elevated temperatures and low salinity, than that of the more widely  
489 distributed *N. luetkeana* and *S. latissima* (Lind and Konar 2017). *A. esculenta* is best adapted  
490 to low temperatures and cannot survive in waters warmer than 16°C (Sundene 1962).  
491 Likewise, recruitment of *L. solidungula* becomes limited when temperatures exceed 10° C.  
492 Other, more warm adapted temperate kelps such as *L. hyperborea*, *L. digitata* and *Saccharina*  
493 *polyschides* may extend their range northward, following the trend of boreal species moving  
494 into the Arctic (Fossheim et al. 2015; Hargrave et al. 2017; Stige and Kvile 2017). However,  
495 kelps produce short-lived zoospores that disperse slowly (current patterns of kelp diversity and  
496 structure can still be related to glacial cycles (Neiva et al. 2018), so any temperature-driven

497 northern expansion of temperate kelp species into polar regions is likely to be slow (Konar  
 498 2007; Wilce 2016).

499  
 500 Fig. 4. a) Global trends in predicted increase in mean summer (July 21 to Sept 21) surface  
 501 temperature from 2016 to 2036 according to IPCC models. Kelp locations are shown in red  
 502 within AMAP Arctic boundary line (blue). b) Rate ( $y^{-1}$ ) of historic and c) rate of projected  
 503 warming of peak summer temperature (Aug to Sept) calculated on basis on linear trend analysis  
 504 for all for all  $1^\circ$  latitude radius buffers around each kelp forest record.

505  
 506 1.5.2. Sea ice and light

507 The amount of light reaching the benthos is a defining factor for benthic primary production  
 508 and depends largely on the extent of sea ice cover. Sea ice is rapidly retreating in the Arctic  
 509 (areal loss of 3.5 – 4.5% per decade, Fig 5a). Average sea ice extent ( $\pm$  SD) declined by 3.7%  
 510 between 2006 and 2016 (from  $16.2 \pm 104$  to  $15.6 \pm 105$  M km<sup>2</sup>), and by 23% in 2016 compared  
 511 to average sea ice measures from 1981 to 1989 ( $21.4 \pm 2.4$  M km<sup>2</sup>).

512 To examine ongoing changes in sea ice extent at locations with records of kelp, we  
 513 obtained the position of the ice edge (defined by a threshold of >15% sea ice cover) from NASA

514 satellite images taken weekly from 2006 to 2016 (<http://nsidc.org/>, NOAA, accessed 2017).  
515 We constrained our measures to this period because years prior to 2006 had lower resolution  
516 spatial measures for coastal regions. At each kelp location we calculated the nearest distance  
517 (m) to the sea ice edge each week over the 10-year period. To compare these trends over this  
518 last decade with broader patterns of sea ice loss we obtained daily measures of areal sea ice  
519 extent from NASA satellite data from 1980 to 2016 (Fig 5).

520         Of the total 1179 records of kelp, 2.6% occurred in locations where the ice-free period  
521 was < 1 week in 2006 and 0.12% occurred where the ice-free period was < 1 week in 2016  
522 (mean  $0.55 \pm 0.99$  SD), supporting evidence of survival and growth under extremely low light  
523 conditions (Wilce 2016). On average, the annual mean and minimum distance (km) to sea ice  
524 (mean  $\pm$  SD) were highly variable at kelp locations (mean  $221 \pm 156$  km and minimum  $30 \pm$   
525  $62$  km in 2006, and mean  $274 \pm 341$  km and minimum  $49 \pm 138$  km in 2016; Fig. S2). For  
526 records that were under sea ice for at least 1 week during this period, the mean distance to the  
527 sea ice edge increased from  $45 \pm 24$  km to  $88 \pm 72$  km and the minimum distance to sea ice  
528 edge increased from  $0.53 \pm 1.52$  km to  $0.59 \pm 1.88$  km from 2006 to 2016. Increases in distance  
529 to sea ice were largest in the White Sea and Novaya Zemlya, Russia and southeastern  
530 Greenland, and lowest in northern Canada and northeastern Russia (Fig. 5b).

531         Available evidence indicates that the loss of sea ice currently occurring in the Arctic  
532 will lead to the northward expansion of kelps (Müller et al. 2009), and an increase in the depth  
533 range and productivity of these habitats due to increased light and reduced scour in the surf  
534 zone, which narrows the vertical distribution of kelp (Krause-Jensen et al. 2012; Krause-Jensen  
535 and Duarte 2014). Kelps cannot exist in areas with permanent sea ice (Shoshina et al. 2016),  
536 so ice loss may open new habitats in the high Arctic. The effect of sea ice loss on kelps may  
537 even be stronger than anticipated because day length increases rapidly during the period of ice  
538 break-up (Clark et al. 2013), implying a slight reduction in ice cover will result in a

539 disproportionately large increase in the amount of light reaching kelp. These expectations are  
 540 supported by correlative studies from along the west coast of Greenland showing that the extent  
 541 of sea ice cover explained 92% of the variation in maximum depth distribution and 80% of the  
 542 variation in kelp growth (Krause-Jensen et al. 2012). Hop et al. (2012) monitored the biomass  
 543 and depth range of kelps in Svalbard, Norway between 1996 and 2014 and found that kelp  
 544 biomass (mainly *L. digitata*) recently increased 2 – 4 fold in the shallow zone (2.5 m depth).  
 545 They ascribed these changes to reductions in sea ice cover (Bartsch et al. 2016).  
 546  
 547

548  
 549 Fig 5. A) Daily sea ice extent in millions of km for entire Arctic region between 1981 and 2010.  
 550 B) Change in mean distance to sea ice edge (km) between 2006 and 2016, for locations of kelp  
 551 that occurred under ice for at least 1 week over this period.

552  
 553 1.5.3. Salinity and turbidity

554 As a consequence of reduced sea ice and melting permafrost, many Arctic coastlines are  
 555 breaking apart and eroding into the sea. These traditionally icebound coasts can be fragile  
 556 because ice provides protection from storms and waves, and its loss can expose the ground to

557 the elements and make it unstable (Lantuit et al. 2012). Coastal environments near these  
558 eroding regions are receiving higher amounts of sediment loading and freshwater inputs,  
559 resulting in longer and more extreme periods of low salinity and intense turbidity and  
560 sedimentation (Lantuit et al. 2012; McClelland et al. 2012; Fritz et al. 2017). Since 2000,  
561 average erosion rate of permafrost-bound coasts was  $0.5 \text{ m yr}^{-1}$ , and reached  $10 \text{ m per yr}^{-1}$  along  
562 some segments. Inputs of sediment and particulate organic carbon (POC) from coastal erosion  
563 are currently entering the Arctic ocean at rates  $\sim 430 \text{ Tg yr}^{-1}$  sediment and  $4.9 - 14 \text{ Tg yr}^{-1}$  POC  
564 (Fritz et al. 2017). Coastal erosion is most severe along the shallow coasts of the Laptev, East  
565 Siberian and Beaufort Seas (Lantuit et al. 2012), but increased turbidity from melting ice can  
566 also be pronounced near the heads of Arctic fjords (Bartsch et al. 2016) and in areas receiving  
567 glacial discharge (Traiger and Konar 2018).

568         Increased turbidity and reduced salinity is expected to reduce the performance and  
569 lower depth limit of kelp by reducing light penetration and restricting photosynthesis (Aumack  
570 et al. 2007; Fredersdorf et al. 2009; Spurkland and Iken 2011; Wiencke and Amsler 2012;  
571 Traiger and Konar 2018) (Fig 6). Variable salinity reduced photosynthetic efficiency of *L.*  
572 *solidungula*, *S. dermatodea*, *L. digitata*, *A. esculenta* and *S. latissima* (Karsten 2007).  
573 Laboratory experiments on kelps collected from Svalbard, Norway found that sediment from  
574 melting ice negatively impacted their recruitment (Zacher et al. 2016). Manipulative field  
575 experiments on kelp forests in Alaska and found that glacier run-off reduced kelp settlement  
576 and recruitment by increasing sedimentation in the coastal zone (Traiger and Konar 2018).  
577 Research from Kola bay and anecdotal reports from areas along the Siberian shelf in Russia  
578 describe declines in the lower depth limit of kelp forests due to low transparency of water ( $< 3$   
579 m visibility) caused by domestic pollution, sediment plumes and agricultural run-off  
580 (Malavenda and Malavenda 2012). These negative impacts may offset the possible positive  
581 effects of warming and increased light on kelp growth in some Arctic regions. This was evident

582 in the Beaufort Sea, where long-term records of annual growth of *L. solidungula* kelps showed  
 583 no change in productivity since 1979, despite earlier sea ice break-up and a longer ice-free  
 584 period in recent years (Bonsell and Dunton 2018). This pattern was explained by increasing  
 585 resuspension of sediment and larger coastal erosion following sea ice break-up, which counter  
 586 balanced the positive effect of longer ice-free periods.

Effects of climate-driven stressors on life stages of Arctic kelps	Coastal regions			Reproduction Recruitment	Growth	Adult survival
	Unstable eroding coasts with ice	Stable aggrading coasts with ice	Coasts with little to no sea ice			
↓ Sea ice	**	*	x	?	+	+
↑ °C	*	*	*	+	+	0
↑ Turbidity	**	x	x *	-	-	-
↓ Salinity	*	*	x *	-	?	-

587  
 588 Fig 6. Effects of environmental changes on arctic kelps from laboratory and field experiments.  
 589 + is positive, - negative, 0 is no measurable effect, and ? is unknown. Relative importance of  
 590 stressors for 3 different coastal regions (see Fig 2): \*\* = strong impact, \* = moderate impact,  
 591 and 'x' little to no impact. Note increased turbidity and decreased salinity can also occur along  
 592 coasts with no sea ice that receive glacial melt or other freshwater inputs.

593  
 594 1.5.4. Nutrients

595 Nutrient concentrations are predicted to increase and change their seasonal timing along Arctic  
596 coasts with increased (and earlier) spring melts, but the impacts of elevated nutrient richness  
597 on arctic kelps are unclear. Nutrient availability is typically low in most Arctic waters, and  
598 nutrient concentrations tend to increase during winter when primary production is low, but  
599 decrease to extremely low levels during the short Arctic summer. Therefore, pelagic primary  
600 production is therefore often limited by low nutrient availability in late summer.

601         This may not be the case for kelps. In a study of twenty-one different species of arctic  
602 macroalgae (including *Laminaria* spp.), none of them were significantly nitrogen-limited in  
603 July (Gordillo et al. 2006). Kelps may be able to acquire and accumulate nutrients in winter  
604 when nutrient availability is relatively high. Nutrients can be translocated from the blade  
605 towards the meristem (Davison and Stewart 1983) and nutrient reserves can subsequently be  
606 used to support photosynthesis and, thus, prolong blade growth during summer when insolation  
607 is high and nutrient availability is low (Gagne et al. 1982; Henley and Dunton 1997; Pueschel  
608 and Korb 2001). Most kelp species should therefore remain rather unaffected by increasing  
609 nutrient availability, but studies have shown that the growth of at least some species, here *L.*  
610 *solidungula*, decreases significantly in early spring as nutrient concentrations drop (Chapman  
611 and Lindley 1980; Dunton et al. 1982). This suggests that some kelp species and/or kelps in  
612 certain extremely nutrient poor areas can be limited by low nutrient availability, and therefore  
613 would be stimulated by increased nutrient levels.

614         It is important to note that pelagic phytoplankton are more stimulated by increasing  
615 nutrient and light levels compared to benthic algae. Estimates predict thus that the pelagic  
616 production by phytoplankton in some Arctic waters will increase 3-fold within this century due  
617 to longer ice-free periods and increased run-off from land (e.g., Rysgaard and Glud 2007). This  
618 significant increase in phytoplankton biomass and productivity will decrease light penetration

619 in the water column, which will negatively affect kelp biomass and depth limit, possibly  
620 offsetting any benefits that higher nutrient levels could have on some kelp species.

621

#### 622 1.5.5. UV radiation

623 Other changes in environmental conditions that could impact kelps include increased  
624 UV radiation, which is especially pronounced at high latitudes (Garcia-Corral et al. 2014).  
625 Increases in UV radiation negatively impacts photosynthesis of arctic kelps (Roleda et al. 2006;  
626 Müller et al. 2008; Roleda 2016) and reduces their performance (Heinrich et al. 2015).  
627 However, research to date indicates that UV damage will have a minor impact on arctic kelps  
628 compared other environmental changes, and will mainly affect early life stages (Roleda et al.  
629 2006; Wiencke et al. 2006). In laboratory experiments on *L. solidungula* collected from  
630 Svalbard by Roleda (2016), high UV radiation disrupted the life cycle of meiospores and  
631 gametophytes. UV exposure also caused significant declines in photosynthetic efficiency, and  
632 increased transcription of DNA repair genes, but these effects were less pronounced in kelps  
633 collected from the field compared to cultured plants (Heinrich et al. 2015). Fredersdorf et al.  
634 (2009) examined combined effects of different temperatures, salinity, and UV radiation levels  
635 on photosynthesis of *A. esculenta* collected from Svalbard. They found that *A. esculenta*  
636 zoospores were sensitive to synergistic effects of temperature and salinity changes (Fredersdorf  
637 et al. 2009), but that adults *A. esculenta* could tolerate a range of UV conditions.

638

#### 639 1.6. PREDICTING CHANGES TO DISTRIBUTION OF ARCTIC KELPS

640 Predicting changes to arctic kelps under rapidly changing environmental conditions remains  
641 challenging. Assis et al. (2018) developed models that described the current distributions of  
642 *Alaria esculenta*, *L. solidungula*, *L. digitata*, *L. hyperborea*, *S. latissima*, and *S. dermatoda* in  
643 the northern Atlantic according to environmental parameters (mainly sea temperature, sea ice,

644 salinity, upwelling), and used these relationships to predict the impacts of climate change on  
645 their future distribution. These models predicted large northward expansions of these species,  
646 including the expansion of *L. hyperborea* to Svalbard, Norway, and further into the White Sea,  
647 the spread of *S. dermatoadae* and *L. digitata* (or *S. nigripes* depending on source, S. Fredriksen  
648 personal communication) along the northeastern coast of Greenland, and the expansion of *A.*  
649 *esculenta* into the Canadian high Arctic. The models also predicted *L. solidungula* and *S.*  
650 *latissima* would extend northward to cover the northernmost coasts of Greenland, Russia and  
651 Canada, suggesting that all Arctic coasts would have environmental conditions suitable for kelp  
652 forests in the future. Similar range expansions have been predicted for *L. solidungula* and *S.*  
653 *latissima* with models by Müller et al (2009) and for a number of furoid species by Jueterbock  
654 et al. (2013, 2016). However, there is a discrepancy between these predictive models and long-  
655 term field observations of changes to arctic kelps. In Canada, Adey and Hayek (2011) were  
656 unable to identify significant shifts in the distributions of subtidal algal species in the eastern  
657 subarctic or boreal regions over the past 40 years. Likewise, Merzouk & Johnson (2011)  
658 reviewed the distribution of kelp along the northwest Atlantic shores from records dating back  
659 to the 1950s and were unable to document any significant change in dominant kelp species  
660 composition or abundance over that period, despite increasing sea temperature, although, the  
661 lack of sufficient spatially and temporally extensive datasets for this region prevented them  
662 from concluding that no change had occurred. Northward range expansions of kelps may be  
663 limited by extensive gaps between suitable substrate (e.g., from northern Norway to Svalbard)  
664 and low dispersal potential of kelps (Wernberg et al. 2018). It is also possible that the spread  
665 and performance of kelps may be more influenced by changes in turbidity, sea ice cover, and  
666 light penetration compared to relatively small changes in sea temperatures. This suggests that  
667 model predictions may overestimate northern range expansions of kelps, at least in the short-  
668 term.

669

## 670 1.7. CONCLUSIONS

671 The Arctic is at the epicenter of the global climate crisis, and emerging opportunities and  
672 developments have increased international attention on changes to ecosystems in this area.  
673 Long-term research from Greenland and Norway suggests a warmer Arctic with less sea ice  
674 may support higher kelp productivity and biomass and expand the northern range and lower  
675 depth limit of these species. However, the degree to which these changes will positively affect  
676 kelps will vary regionally and depend on the extent that melting sea ice and permafrost  
677 increases turbidity in coastal areas, as well as the available substrate in the lower depth range  
678 (Bartsch et al. 2017; Bonsell and Dunton 2018). Predictive models and laboratory experiments  
679 suggest the ‘borealization’ of arctic kelp forests will occur as temperatures warm, altering the  
680 species composition of existing cold and ice-adapted kelp communities in high Arctic regions.  
681 Although current predictions are highly uncertain, the possible expansion of kelp forests should  
682 provide new habitats for fish and other marine organisms, and a suite of valuable ecosystem  
683 services along Arctic coastlines. Interestingly, where data are available, kelp abundance  
684 appears relatively stable, suggesting these changes are occurring slower than predicted or are  
685 being buffered by other factors. Either way, anticipating these changes, and understanding  
686 these new ecosystems will be a key priority for northern communities.

687         Our understanding of kelp forests is rapidly expanding in many regions of the Arctic.  
688 However, baseline measures of the extent of kelp communities are missing in northern and  
689 eastern Canadian Arctic, Siberia, the east Greenland Shelf, and Russia. This lack of data is not  
690 unique to kelp ecosystems. Despite the fact that over 28% of the world’s coastlines are found  
691 in the Arctic (Lantuit et al. 2012), they remain largely unstudied, which jeopardizes current  
692 strategies to protect or conserve arctic environments and will have consequences for northern  
693 communities that rely on them. Lack of data has already greatly hindered our ability to detect

694 and understand the impacts of climate change on these and other ecosystems (e.g., Merzouk  
695 and Johnson 2011). Exploring effects of ongoing and future climate changes will provide  
696 important insight on the stability of these ecosystems. Maintaining and augmenting current  
697 monitoring initiatives and time series data sets should be a priority. For kelp forests,  
698 understanding how these ecosystems influence the structure and function of coastal arctic food  
699 webs is an important focus for ongoing research. There is also a critical lack of knowledge on  
700 the contribution of kelp forests to carbon cycling in the Arctic. Filling in these gaps and  
701 strategically prioritizing research in areas of rapid environmental variation will enable us to  
702 more effectively understand and conserve these ecosystems.

703 Arctic coasts are in line to become one of the most impacted environments in the world  
704 under changing climate. For this region to act as a sentinel for climate change it is critical to  
705 monitor and understand the impacts of environmental stressors on arctic ecosystems. Kelp  
706 forests provide a key example of the regional diversity of responses to climate change, and  
707 demonstrate the need for a mechanistic understanding of how multiple stressors and diverse  
708 ecological processes influence ecosystem structure and function. Although it is tempting to  
709 make generalized statements about broad-scale climate-driven impacts, the reality is much  
710 more nuanced, regionally specific, and highly uncertain. What is clear is that extensive  
711 ecological changes are likely to occur in these rapidly changing environments, with both  
712 ‘positive’ or ‘negative’ consequences for a range of species.
