**R**ecently, various augmentation procedures (e.g., onlay bone grafting and the maxillary sinus lift procedure) were performed for severely resorbed residual ridges and alveolar crests close to the maxillary sinus floor for implant treatment.<sup>1–5</sup> A critical review of the findings showed variations in the implant survival rates.<sup>4,6–8</sup> Lekholm *et al*<sup>4</sup> reported a 3-year retrospective study of bone grafting with implant placement that showed an overall implant survival rate of approximately 80%. Keller *et al*<sup>6</sup> showed that the survival rate for endosseous implants with maxillary antral-nasal inlay autogenous bone grafting was 87%. Widmark *et al*<sup>7</sup> reported that a life table analysis showed a cumulative success rate of 74% in the graft group and 87% in the trial group at the final examination after 3–5 years. These results corroborated previous findings that patients with severely resorbed maxillae have an in-

*Various ridge augmentation and sinus lift procedures were performed in severely resorbed alveolar crests of a maxilla to provide some volume for implant treatment. It was reported that the outcome of maxillary sinus lift procedures was evaluated with conventional tomography or computerized tomography, and that grafted bone around implants markedly progressed in resorption, particularly at the implant apex. However, veneer bone grafting with implant placement has not been evaluated after treatment with imaging techniques. Therefore, the purpose of this study was to assess veneer bone grafting after maxillary anterior implant treatment. Seven patients with a mean age of 24 years, with implants placed in the maxillary anterior region with or without autogenous veneer bone grafting were postoperatively examined using con-*

*ventional tomography. On tomograms, the ratio of bone-to-implant contact and the area of bone were measured in labial bones with bone grafts, and they were compared with the values without bone grafts. In cases with bone grafting, the average ratio of bone-to-implant contact was 63.6%, whereas 81.8% was formed in cases without bone grafting. The average area of bone was 12.9 mm<sup>2</sup> and 23.4 mm<sup>2</sup> in patients with and without bone grafting, respectively. No significant difference was found between the implants with and without bone grafts. Resorbed labial bone was observed in the maxillary anterior region with and without veneer bone grafting.* (*Implant Dent* 2005;14:301–307)

creased risk of implant failure in comparison to those with good bone quantity and quality. Moreover, maxillary sinus lift procedures were evaluated using computerized tomography (CT). It was found that grafted bone surrounding the implants severely progressed in resorption, particularly at the implant apex.<sup>9–11</sup> However, veneer bone grafting with implant treatment has not been evaluated using postoperative imaging. Therefore, veneer bone grafting after maxillary anterior implant treatment was assessed and

compared with the findings without bone grafting.

## MATERIALS AND METHODS

In 7 patients (4 males and 3 females) with a mean age of 24 years (range 15–40), implants were placed in the maxillary anterior region with or without autogenous veneer bone grafting and postoperatively examined using conventional tomography. All treatments, bone grafts, implant placements, and tomography were performed in the Dental Hospital

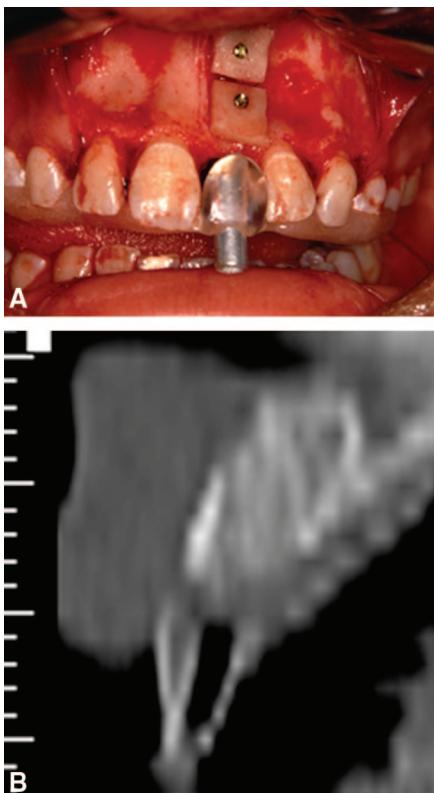

**Fig. 1.** CT before bone grafting. A narrow alveolar bone in the buccolingual plane of the maxillary anterior region is shown.

of Aichi-Gakuin University. Tooth loss was caused by traumatic injury in 5 of the 7 patients, congenitally missing in 1, and periodontal disease in 1.

#### Bone Grafts and Implant Placements

Autogenous veneer bone grafts were performed at the site of the planned implant, diagnosed as narrow alveolar bone width using preoperative imaging, a few months before implant placement (Fig. 1). During the presurgical imaging diagnosis, when a thickness of labial bone over a planned implant is <1 mm along a planned implant, bone grafts were scheduled. In addition, the thickness of bone graft was >1 mm, except in cases of an expected resorbed thickness (1 mm) along a labial side of a planned implant. In all cases, the bone grafts used were corticocancellous bone blocks harvested from the chin. The cancellous bone surface of the bone blocks was placed on labial maxillary cortical bone with a screw(s) (Fig. 2). The bone surface was then covered by a healthy periosteum.

Implant placement was performed in accordance with surgery methods reported by Naitoh *et al.*<sup>12</sup> Nine implants with bone grafting (7 in the central incisor region, 1 in the lateral incisor region, and 1 in the canine region) and 4 implants without bone grafting (all at the central incisor region) were placed. All implants were from the Bränemark System implant (Nobel Biocare, Göteborg, Sweden).

**Fig. 2.** **A**, Autogenous veneer bone graft was performed at the site of the planned implant site diagnosed as a narrow alveolar bone width. **B**, CT after bone grafting.

No perforation of the implant on the labial or palatal side of the nasal floor was observed during implant placement. Bone blocks of bone grafting were fixed tightly to maxillary bone. The time between bone grafting and implant placement, and between implant placement and abutment connection is shown in Table 1.

#### Tomographic Imaging

Cross-sectional linear tomography was performed after some months of abutment connection using a panoramic unit (AZ3000DLP, Asahi

**Table 1.** Duration of Implant Treatments

	With Bone Grafting	Without Bone Grafting
Mean time between bone graft and implant placement (range)	79.0 (59–101)	
Mean time between implant placement and abutment connection (range)	198.8 (149–310)	267.5 (166–330)
Mean time between implant placement and tomography (range)	343.7 (269–425)	794.5 (316–1255)

Units are in days.

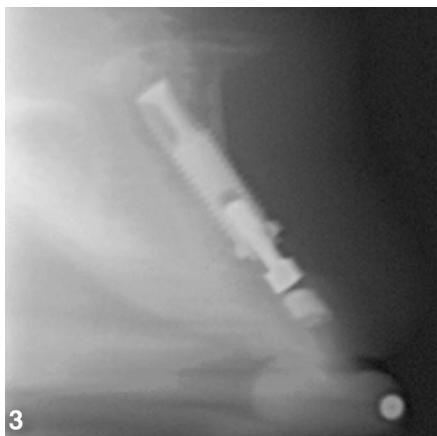

Roentgen Ind. Co., Kyoto, Japan). Mean time between the implant placement and tomography was 343.7 days for implants with bone grafting and 794.5 days without bone grafting (Table 1). The exposure settings were selected for 68 kVp and 6 mA, with a 40-degree tomographic projection angle. Obtained tomograms were printed on film at absolute size using a CR system (FCR9000 HQ, HI-654, CR-LPD, Fuji Medical System Co, Tokyo, Japan). The films were converted to digital images using a film digitizer with 150 dpi (VXR-12 plus, Vidar Systems Co., Herndon, VA) (Figs. 3 and 4) and were measured using image editing software (Photoshop version 5.5, Adobe Systems Inc., San Jose, CA). First, the x and y coordinates of the superior and inferior points of the implants covered by labial bone were recorded. The superior point ( $X_2, Y_2$ ) was regarded as a labial apex of implant, and the inferior point ( $X_1, Y_1$ ) was regarded as a crest of alveolar bone attached to implant (Fig. 5). The ratio of bone-to-implant contact was obtained using the following equation.

The length of implant covered by labial bone was calculated by

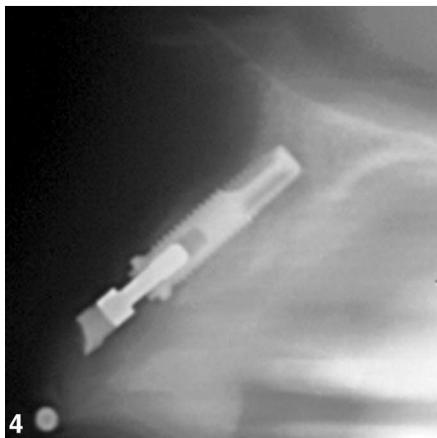

$$\sqrt{(X_2 - X_1)^2 + (Y_2 - Y_1)^2} \times \text{pixel size.}$$

The ratio of bone-to-implant contact was calculated by the length of implant covered by labial bone/the real length of the implant.

Second, regions of interest were visually set at whole bone on the labial side of the implant, and the number of pixels in the area of regions of interest was quantitated. The area of bone was calculated by the number of bone pixels  $\times$  pixel square. A surface of the implant was let a straight lined threads of implant, although a shape of the implant was screw. Postoperative

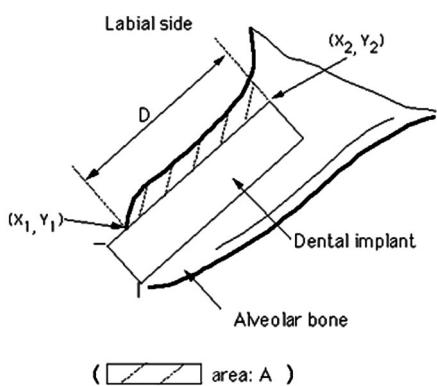

3

**Fig. 3.** Tomographic image of implant site with bone grafting. The resorbed labial bone of the implant is shown.

**Fig. 4.** Tomographic image of implant site without bone grafting. The labial bone of the implant is shown from the neck of the implant to the apex.

**Fig. 5.** Schematic drawing of tomographic measurements. The length of implant covered by labial bone (D) and the number of labial bone pixels (A) were measured.

labial bone with bone grafts was assessed from the ratio of bone-to-implant contact and the area of bone. The values were compared with values

**Table 2.** Tomographic Measurements

	With Bone Grafting	Without Bone Grafting
Ratio of bone contact (%)		
Range	25.2–94.4	53.9–93.4
Mean	63.6	81.8
SD	24.0	18.8
Area of bone ( $\text{mm}^2$ )		
Range	1.1–28.6	11.3–47.7
Mean	12.9	23.4
SD	10.0	17.2

$P < 0.01$ .

from sites without bone grafts calculated in the same way.

#### Statistical Analysis

The difference between the obtained values with and without bone graft was evaluated using the Mann-Whitney *U* test. Testing was considered significant if  $P < 0.01$ .

#### RESULTS

Results from sites with bone graft are shown in Table 2. The ratio of bone-to-implant contact ranged from 25.2% to 94.4%, and the average was 63.6% (standard deviation [SD] 24.0). The area of bone ranged between 1.1 and 28.6  $\text{mm}^2$ , and the average was 12.9  $\text{mm}^2$  (SD 10.0). The results from sites without bone graft are also shown in Table 2. The ratio of bone-to-implant contact ranged from 53.9% to 93.4%, and the average was 81.8% (SD 18.8). The area of bone ranged between 11.3 and 47.7  $\text{mm}^2$ , and the average was 23.4  $\text{mm}^2$  (SD 17.2).

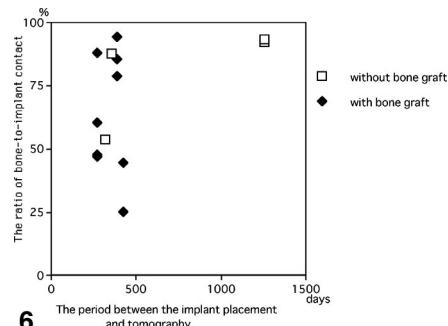

#### Comparison Between Values With and Without Bone Grafts

No significant difference in the ratio of bone-to-implant contact and the area of bone was found between the implant with and without bone grafts ( $P = 0.16$  for the ratio of bone-to-implant contact and  $P = 0.35$  for the area of bone). No correlation between the period between the implant placement and tomography, and the ratio of bone-to-implant contact or the area of bone was clearly found in cases with bone graft and without bone graft (Figs. 6 and 7).

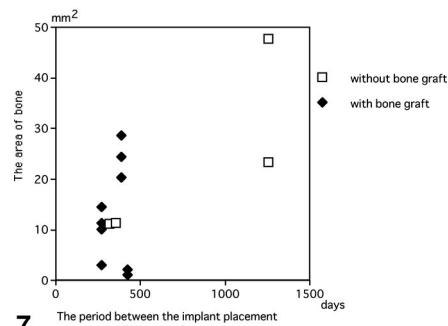

#### DISCUSSION

Various bone grafting methods and implantation times have been reported.<sup>1,3–6,11,13,14</sup> In the present

study, autogenous corticocancellous bone grafts were harvested from the chin and placed as veneer bone blocks on the labial side of the alveolar process of the maxilla. Because the bone surface was covered by a healthy periosteum with release incision, no membrane technique was used in all cases. Widmark *et al*<sup>15</sup> reported that bone resorption in the buccal/palatal direction of the anterior maxilla was 25% after 4 months of bone graft and 60% after 10

6

7

**Fig. 6.** Correlation between the period and the ratio of bone-to-implant contact. No correlation between the period between the implant placement and tomography, and the ratio of bone-to-implant contact was found in cases with bone graft and without bone graft.

**Fig. 7.** The correlation between the period and the area of bone. No correlation between the period between the implant placement and tomography, and the area of bone was found in cases with bone graft and without bone graft.

months following bone graft, when a bone graft from the symphyseal region of the mandible was used in the maxillary central incisor region.

For postoperative evaluations of maxillary sinus lift procedures, tomography or CT have been used as imaging techniques. However, after placed dental implant, CT images have a metal artifact from dental implant made of titanium, and correct diagnosis in implant-to-bone interface was not performed. In addition, CT has the partial volume effect showing less points.<sup>16</sup> Tomograms with a direct laser positioning system were used in the present study to observe the labial side of implants.<sup>17</sup> The position of the tomographic plane was set on the basis of the occlusal surface impression, and direction of the tomographic plane was set on the basis of the preoperative CT. Because the dental arch was a curve in the anterior region and the direction of x-rays in the tomography was set tangential to the anterior region, the tomograms showed clearly the bone in the labial side of implant without obstructive shadows on the anterior site. The implant threads could be clearly identified on all tomographic images obtained in this study.

This investigation was conducted as a retrospective study. Because the period between implant placement and tomography was more than 3 years for 2 implant sites without bone graft, mean time between the implant placement and tomography was different in cases with bone graft and without bone graft. However, no correlation between the period between the implant placement and tomography, and the ratio of bone-to-implant contact or the area of bone was clearly found in cases with bone graft and without bone graft.

It was observed that the ratio of bone-to-implant contact was low, and the area of bone was small in many cases with and without bone grafting. We consider the results of the ratio of bone-to-implant contact were more important. These results will influence directly a prognosis of dental implant treatment. In addition, in cases with bone graft, the value in the area of bone will be affected by the volume of bone graft. In the ratio of bone-to-implant contact, mean value with the

bone graft was slightly lower than that without bone grafting, and the SD with bone grafting was slightly higher. All implants were clinically stable without complaint or mobility at tomography. The bone surrounding the implants that were placed with bone augmentation procedures and the bone in maxillary sinus lift procedures have been evaluated using postoperative imaging in some previous studies. Peleg *et al*<sup>10</sup> reported radiologic findings in short-time (8–10 months) CT in a follow-up study for 1-stage maxillary sinus lift procedures. Of the 57 implants placed, 28 had a full bone covering the implants on all sides but did not extend above the apical portion, 20 had bone fully covering the implant, which extended above the apex, and 9 showed incomplete bone coverage.

Block *et al*<sup>9</sup> measured the bone level using tomograms at 5–10 years after simultaneous maxillary sinus graft and implant placement, and the average height of the grafted bone at the implant apex was 3.3 mm (SD 3.1 mm). Nystrom *et al*<sup>18</sup> followed up 20 patients with combined horseshoe-shaped iliac bone grafts and Bråne-mark implants in severely resorbed maxillae. In the results, the mean width of the bone graft was 12.2 mm, which was significantly different from baseline ( $P < 0.001$ ). It was reported that most of the bone width was lost during the first 3 months.

Resorption of bone was observed in the maxillary anterior region with and without veneer bone grafting using tomograms. It can be suggested that similar conditions may occur in cases with thin cortical bone. Even if bone of the labial site appears unclear on tomograms, the labial surroundings of the implant would be covered by thinner bone clinically. In addition, it was suggested that this resorption of bone was influenced by bone quality and tension of the lip. Further studies should evaluate the values in many cases with/without bone graft using no/some membrane techniques, and aim to discover the relationship between the measured bone volume and a prognosis that may be detected from the values.

## CONCLUSIONS

The postoperative findings of veneer bone grafting in maxillary anterior implant treatment were assessed using tomography, and they were compared to the findings without bone grafting. It was clarified that the ratio of bone-to-implant contact was low and the area of bone was small in the maxillary anterior implants with and without bone grafts. The findings of resorbed bone grafts found at the implant apex with the maxillary sinus procedures were also observed on the labial side of the maxillary anterior region with and without veneer bone grafts.

### *Postoperative tomographische Bewertung bei Transplantierungen von Verblendungsknochenmaterialien mit anschließender Implantatsetzung im vorderen Bereich des Oberkiefers*

**ZUSAMMENFASSUNG:** Verschiedene Methoden zur Anreicherung des Kamms und Sinusanhebung wurden in schweren Fällen von resorbierten Alveolarleisten im Oberkiefer zur Bereitstellung eines für eine Implantierungsbehandlung ausreichenden Volumens. Dem Bericht zufolge wurden die Ergebnisse der Sinusanhebungen im Oberkiefer mit entweder konventioneller Tomographie oder Computertomographie zusammengestellt. Außerdem wies das transplantierte Knochengewebe um das Implantat herum einen besonderen Resorptionsanstieg im Bereich der Implantatspitze auf. Allerdings wurde noch keine kombinierte Behandlung mit Transplantation von Verblendungsknochenmaterialien in Verbindung mit Implantatsetzung nach Durchlauf von Bildgebenden Verfahren bewertet. Daher zielt die vorliegende Studie darauf ab, Transplantierung von Verblendungsknochenmaterial nach Implantierungsbehandlung im vorderen Oberkieferbereich zu bewerten. Sieben Patienten mit einem durchschnittlichen Alter von 24 Jahren mit Implantaten in der vorderen Oberkieferregion, die entweder mit oder ohne Transplantation von autogenem Verblendungsknochenmaterial behandelt wurden, wurden postoperativ über konventionelle tomographische Methoden untersucht. In diesen Tomogrammen wurden das Verhältnis von Knochen-Implantat-Kontakt sowie der Bereich des Knochengewebes bei Labialknochen mit Knochengewebstransplantaten gemessen. Diese Ergebnisse wurden mit den Werten bei Auslassung einer Knochengewebstransplantation. Bei den Fällen mit erfolgter Transplantierung von Knochengewebe betrug das durchschnittliche Verhältnis von Knochen-Implantat-Kontakt 63,6%, während in den Fällen ohne Transplantierung 81,8% ermittelt wurden. Der durchschnittliche Knochenbereich betrug 12,9 mm und 23,4 mm bei Patienten entweder mit oder ohne Knochengewebstransplantat. Es konnte kein wesentlicher Unterschied für Implantate mit bzw. ohne Knochentransplantate festgestellt werden. Resorbiertes Labialknochen in der Oberkieferregion lag sowohl mit als auch ohne Transplantation von Verblendungsknochengewebe vor.

## *Evaluación tomográfica postoperatoria de un injerto de veneer de hueso con colocación del implante en la región anterior maxilar*

**ABSTRACTO:** Varios procedimientos de levantamiento del seno y aumento de la cresta se realizaron en crestas alveolares severamente reabsorbidas de una maxila para proporcionar cierto volumen para el tratamiento con un implante. Se informó que el resultado de los procedimientos de levante del seno maxilar se evaluó con tomografía convencional o tomografía computadora y que el hueso injertado alrededor de los implantes progresó marcadamente en la reabsorción, particularmente en la cima del implante. Sin embargo, el injerto con veneer de hueso con la colocación del implante no ha sido evaluada después del tratamiento con técnicas de imágenes. Por lo tanto, el propósito de este estudio fue evaluar el injerto con veneer de hueso después del tratamiento con implante en el maxilar anterior. Siete pacientes con una edad media de 24 años con implantes colocados en la región maxilar anterior con o sin injertos con enchapado de hueso autógeno fueron examinados postquirúrgicamente usando la tomografía convencional. En las tomografías, la relación del contacto del hueso al implante y el área del hueso se midieron en los huesos labiales con injertos de hueso, y se compararon con los valores sin los injertos de hueso. En casos con injertos de hueso, la relación promedio del contacto de hueso al implante fue un 63,6%, mientras que un 81,8% se formaron en casos sin un injerto de hueso. La superficie promedio del hueso fue 12,9 mm<sup>2</sup> y 23,4 mm<sup>2</sup> en pacientes con y sin el injerto de hueso, respectivamente. No se encontró una diferencia notable entre los implantes con y sin los injertos de hueso. Se observó hueso labial reabsorbido en la región maxilar anterior con y sin un injerto con veneer de hueso.

**PALABRAS CLAVES:** implante dental, injerto con veneer de hueso, región maxilar anterior, tomografía, conclusiones postquirúrgicas

## *Avaliação Tomográfica Pós-Operatória de Enxerto Ósseo com Uso de Faceta e Colocação de Implante na Região Maxilar Anterior*

**RESUMO:** Vários procedimentos de aumento do rebordo e levantamento do seio foram realizados em cristas alveolares gravemente reabsorvidas de um maxilar para fornecer algum volume para tratamento de implantes. Foi relatado que o resultado de procedimentos de levantamento do seio maxilar foi avaliado com tomografia convencional ou tomografia computadorizada, e que o osso enxertado em torno de implantes progrediram marcadamente em reabsorção particularmente no ápice do implante. Contudo, o enxerto ósseo com uso de faceta e colocação de implante não foi avaliado após o tratamento com técnicas de geração de imagens. Portanto, o propósito deste estudo foi avaliar o enxerto ósseo com uso de faceta após o tratamento de implantes maxilares anteriores. Sete pacientes com idade média de 24 anos com implantes colocados na região maxilar anterior com ou sem enxerto ósseo autógeno com uso de faceta foram examinados pós-operatoriamente usando tomografia convencional. Em tomografias, a razão de contato osso/implante e a área de osso foram medidas em ossos vestibulares com enxertos ósseos, e eles foram comparados com os valores sem enxertos ósseos. Em casos com enxerto ósseo, a razão média de contato osso/implante foi de 63,6%, ao passo que 81,8% foram formados em casos sem enxerto ósseo. A área média de osso foi de 12,9 mm<sup>2</sup> e 23,4 mm<sup>2</sup> em pacientes com e sem enxerto ósseo, respectivamente. Nenhuma diferença significativa foi encontrada entre os implantes com e sem enxertos ósseos. O osso vestibular reabsorvido foi observado na região maxilar anterior com e sem enxerto ósseo com uso de faceta.

**PALAVRAS-CHAVE:** implante dentário, enxerto ósseo com uso de faceta, região maxilar anterior, tomografia, laudos pós-operatórios

## 上顎前部のインプラント装着に伴うVeneer Bone Graftingの手術後の断層写真評価

著者：ムネタカ・ナイトウ、DDS、PhD\*、カール・デュラ、DDS、PhD\*\*、ヤシヒロ・イトウ、DDS、PhD\*\*\*、テツロウ・トヨダ、DDS、PhD#、ケンイチ・クリタ、DDS、PhD##、エイイチロウ・アリジ、DDS、PhD###

**目的：**高度に吸収の進んだ上顎alveolar crestには、インプラント処置に必要な体積を獲得するために各種のridge augmentationと扁骨腔増大法が行われる。上顎副鼻腔増大法が従来の断層写真またはコンピューター断層写真によって評価され、インプラント周辺の移植骨吸収が特にインプラント先端部においてかなり改善されたとの報告はこれまでにもあった。しかし、veneer bone graftingにおける処置後の断層写真評価はまだ行われていない。本研究の目的は、上顎前部のインプラント処置後のveneer bone graftingの評価を行うことであった。

**素材と方法：**Autogenous veneer bone graftingを受けたものと受けなかつたものをともに含む、上顎前部にインプラントを装着された平均年齢24歳の7人の患者が、従来の断層写真によつて手術後に検査された。断層写真では、骨移植を受けた症例のlabial boneのbone-to-implant contact ratioと骨面積が測定され、骨移植を受けなかつた症例と数値的に比較された。

**結果：**Bone-to-implant contact ratio平均値は骨移植を受けた症例では63.6%で、骨移植を受けなかつた症例においては81.8%であった。骨平均面積は、骨移植を受けた症例が12.9mm<sup>2</sup>、受けなかつた症例が23.4mm<sup>2</sup>であった。骨移植を受けた症例と受けなかつた症例のインプラントには、有意な違いが認められなかった。

**結論：**Veneer bone graftingを受けた症例と受けなかつた症例の両者において、上顎前部のlabial bone吸収が認められた。

**キーワード：**デンタルインプラント、veneer bone graft、上顎前部、断層写真、手術後所見
