Abstract

This meta-analysis investigated the normative development of domain-specific self-evaluations (also referred to as self-concept or domain-specific self-esteem) by synthesizing the available longitudinal data on mean-level change. Eight domains of self-evaluations were assessed: academic abilities, athletic abilities, physical appearance, morality, romantic relationships, social acceptance, mathematics, and verbal abilities. Analyses were based on data from 143 independent samples which included 112,204 participants. As the effect size measure, we used the standardized mean change d per year. The mean age associated with effect sizes ranged from 5 to 28 years. Overall, developmental trajectories of self-evaluations were positive in the domains of academic abilities, social acceptance, and romantic relationships. In contrast, self-evaluations showed negative developmental trajectories in the domains of morality, mathematics, and verbal abilities. Little mean-level change was observed for self-evaluations of physical appearance and athletic abilities. Moderator analyses were conducted for the full set of samples and for the subset of samples between ages 10 and 16 years. The moderator analyses indicated that the pattern of findings held across demographic characteristics of the samples, including gender and birth cohort. The meta-analytic dataset consisted largely of Western and White/European samples, pointing to the need of conducting more research with Non-Western and ethnically diverse samples. The meta-analytic findings suggest that the notion that self-evaluations generally show a substantial decline in the transition from early to middle childhood should be revised. Also, the findings did not support the notion that self-evaluations reach a critical low point in many domains in early adolescence.

Keywords: domain-specific self-evaluations, self-esteem, development, longitudinal studies, meta-analysis

Development of Domain-Specific Self-Evaluations:
A Meta-Analysis of Longitudinal Studies

When people think about whether they are satisfied with their competences and personal characteristics, they may come to very different conclusions. Some individuals may be pleased with their competences in some domains (e.g., school or work), but dissatisfied with other domains (e.g., attractiveness). Others may feel that they do reasonably well with regard to many criteria, but that there is no single domain in which they really excel. Still others may have very positive self-views across the board. Notwithstanding these interindividual differences, it is possible that the average positivity of self-evaluations follows a systematic, normative trajectory across childhood, adolescence, and adulthood. Moreover, the normative developmental trajectory might be domain-specific; that is, the trajectory might depend on whether self-evaluations refer to the academic domain, social relationships, sports, or physical appearance.

Many studies examined developmental trajectories of domain-specific self-evaluations, both decades ago (e.g., Cairns, McWhirter, Duffy, & Barry, 1990; Cole et al., 2001; Eccles et al., 1989; Marsh, 1989) and more recently (e.g., Esnaola, Sesé, Antonio-Agirre, & Azpiazu, 2020; Harris, Wetzel, Robins, Donnellan, & Trzesniewski, 2018; Kuzucu, Bontempo, Hofer, Stallings, & Piccinin, 2014). However, despite the large body of evidence that has been accumulated, the findings have been inconsistent and have not yet led to any agreement on the normative development of domain-specific self-evaluations. In fact, the inconsistent pattern of findings in the literature has been emphasized by the authors of many previous studies on the topic (e.g., Cole et al., 2001; Harris et al., 2018; Kuzucu et al., 2014; von Soest, Wichstrom, & Kvaalem, 2016). In this situation, meta-analytic methods are ideally suited to gain more robust insights into developmental patterns, by aggregating the evidence across a large number of studies. Therefore,

the goal of the present research was to synthesize the available data on how and whether domain-specific self-evaluations change as a function of age.

Understanding the development of domain-specific self-evaluations is important because research suggests that self-evaluations prospectively predict outcomes in important life domains, such as education, work, and health (Marsh & Craven, 2006; Spilt, van Lier, Leflot, Onghena, & Colpin, 2014; Steiger, Allemand, Robins, & Fend, 2014; Valentine, DuBois, & Cooper, 2004; von Soest et al., 2016). For example, favorable self-evaluations in the domain of academic abilities predict better academic achievement, when prior levels of achievement are controlled for (Marsh & Craven, 2006; Marsh & Yeung, 1997). Also, understanding the development of domain-specific self-evaluations may contribute to a better understanding of the development of global self-esteem (Orth & Robins, 2019).

In this article, we use the term domain-specific self-evaluations, rather than self-concept or domain-specific self-esteem, to denote children's and adults' self-perceptions in domains such as academic abilities, athletic abilities, physical appearance, and social acceptance. We decided to use the term self-evaluations because the relevant measures assess the individual's evaluative beliefs about their abilities or other favorable characteristics, that is, self-evaluations on a continuous dimension ranging from bad (or low, weak) to good (or high, strong). In contrast, the term self-concept also includes non-evaluative beliefs about the self and the term self-esteem is often understood as a person's general level of self-acceptance. However, it is important to note that domain-specific self-evaluations, self-concept, and domain-specific self-esteem are established terms for the same construct, so in the literature summarized in this meta-analysis, all three terms are often used synonymously.

Theoretical Perspectives on the Development of Domain-Specific Self-Evaluations

In the following sections, we review theoretical perspectives on normative change in domain-specific self-evaluations from childhood to adulthood, on similarity to normative change in global self-esteem, and on moderators of change in domain-specific self-evaluations.

Declines in the Transition From Early to Middle Childhood

Theory suggests that average levels of self-evaluations decline in the transition from early to middle childhood (i.e., from about age 5 to 8 years), resulting from a number of social-cognitive advances (Harter, 2006b, 2006c; Robins, Trzesniewski, Tracy, Gosling, & Potter, 2002). For example, children at age 4 or 5 years view their self in an overly positive light because they cannot yet discriminate between their actual and their ideal self (Harter, 2006b). In later years, when children learn to distinguish between actual and ideal characteristics, this process leads to less positive self-evaluations in most children. Another social-cognitive advance in this period is that children learn to use social comparison information when evaluating themselves (Gore & Cross, 2014; Harter, 2006b; Ruble, Boggiano, Feldman, & Loebel, 1980). At age 4 or 5 years, children predominantly make temporal comparisons (i.e., comparing their present competences with their competences a few months earlier, typically leading to positive self-evaluation; Harter, 2006c). However, after entering primary school—a transition that occurs in many countries at about age 6 years—they begin to compare their competences with those of their classmates and peers, which leads to reduced positivity in self-evaluations in most children. Another social-cognitive change emphasized by Harter (2006a) is the improvement in perspective-taking skills. During the transition from early to middle childhood, children typically make substantial progress in social perspective taking, which allows them to infer how the self is evaluated by others (e.g., peers, parents, and teachers). Again, this process causes gradual negative changes in self-evaluations in this period, because children learn, for example, that not

all classmates view their social, athletic, and academic competences positively. In addition to these social-cognitive changes, Harter (2006a) stresses that most parents increase their expectations for their children in this period, for example with regard to behavioral conduct and social competences. If children internalize these raised expectations in their self-concept, this leads to further declines in their self-evaluations.

In sum, the literature suggests that mean levels of self-evaluations decline in the transition from early to middle childhood, in particular because social-cognitive advances reduce the unrealistically positive self-perceptions that are characteristic of very young children at age 4 or 5 years (Harter, 2006c). The literature does not advance hypotheses that are specific to different domains of self-evaluations. Rather, the theoretical perspectives described in this section suggest that the decline applies to all domains of self-evaluation.

Low Point in Early Adolescence

Theory also suggests that individuals typically experience a low point in their self-evaluations in early adolescence (i.e., from about age 10 to 14 years), resulting from developmental changes related to puberty and to the transition from primary to secondary school (Harter, 2006c). Puberty could challenge adolescents' self-evaluations because of the many biological, cognitive, emotional, and social changes in this period (Harter, 2006c; Simmons, Blyth, Van Cleave, & Bush, 1979; Wigfield, Eccles, Mac Iver, Reuman, & Midgley, 1991). In addition, the transition from primary to secondary school could lead to normative declines in self-evaluations because it involves stricter grading standards and greater emphasis on evaluation, less personal attention by teachers, greater social comparison among adolescents, and a disruption in the adolescent's social network (Becker & Neumann, 2018; Cantin & Boivin, 2004; Eccles, Midgley, & Adler, 1984; Fenzel, 2000; Gniewosz, Eccles, & Noack, 2012;

Wigfield et al., 1991). In fact, several studies suggest that self-evaluations become more negative in early adolescence, in particular in the domains of academic abilities and physical appearance (Eccles et al., 1984; Marsh, 1989; Wigfield et al., 1991). The hypothesis that self-evaluations are relatively low in early adolescence is also consistent with research on personality development, which suggests that adaptive traits such as conscientiousness, agreeableness, and emotional stability decline and reach their low points in early adolescence (Göllner et al., 2017; Soto, 2016; Soto, John, Gosling, & Potter, 2011; Soto & Tackett, 2015).

In sum, even if early adolescence is no longer considered a period of inevitable storm and stress (Arnett, 1999; Hollenstein & Loughheed, 2013), the literature suggests that mean levels of self-evaluations reach a nadir in early adolescence. The perspectives reviewed above suggest that the low point might be particularly pronounced with regard to self-evaluations of academic abilities, social acceptance, and physical appearance.

Increases in Late Adolescence and Young Adulthood

The literature proposes that mean levels of self-evaluations begin to increase in late adolescence (i.e., from about age 16 years) and continue to increase in young adulthood, because in these developmental periods most personality characteristics develop in the direction of greater maturity (Harter, 2006b). In fact, a large number of studies suggest that people typically become more conscientious (including behaviors such as delaying gratification, following rules, and planning), agreeable (showing more prosocial behavior, trust, and modesty), and emotionally stable (being more even-tempered and experiencing less negative affect) as they move through late adolescence and young adulthood (Lucas & Donnellan, 2011; Roberts, Walton, & Viechtbauer, 2006; Roberts, Wood, & Caspi, 2008; Terracciano, McCrae, Brant, & Costa, 2005), a pattern that has been labeled the maturity principle of personality development (Roberts &

Wood, 2006; Roberts et al., 2008). Given that conscientiousness, agreeableness, and emotional stability contribute to adaptive functioning in social relationships, educational contexts, and the work domain (Mund & Neyer, 2014; Neyer & Asendorpf, 2001; Nettle & Robins, 2007; Roberts, Caspi, & Moffitt, 2003), the maturity principle suggests that people's social, academic, and job-related competences increase as a consequence of personality development. Ultimately, then, objective improvements in these competences could lead to more positive self-evaluations in these domains. Moreover, conscientiousness is also a key predictor of health behavior and exercising (Shanahan, Hill, Roberts, Eccles, & Friedman, 2014). Again, the normative increase in conscientiousness during late adolescence and young adulthood could lead to more positive self-evaluations with regard to athletic abilities and physical appearance, mediated by improved behavior with regard to exercise, diet, sleep, and personal hygiene. An additional reason for increasing levels of self-evaluations is related to possible changes in the relevant reference groups. During late adolescence and young adulthood, individuals gain more autonomy and control in selecting social, educational, and work contexts that match their personality, interests, and abilities (Harter, 2006c; Roberts et al., 2008). Thus, individuals may seek and enter environments in which their competences are more appreciated than in other environments (i.e., niche picking). The corresponding changes in the person's reference groups may lead to favorable changes in self-evaluations (Harter, 2006b).

In sum, there is reason to expect that mean levels of domain-specific self-evaluations increase in late adolescence and young adulthood. The literature on personality development suggests that these improvements might be particularly pronounced with regard to domains that are influenced by maturation of personality, such as academic abilities, social acceptance, and romantic relationships.

Similarity to the Trajectory of Global Self-Esteem

The literature also suggests that in some domains self-evaluations show trajectories that are similar to the trajectory of global self-esteem, whereas in other domains the trajectories differ from it more strongly (e.g., Harris et al., 2018; Marsh, 1989; von Soest et al., 2016). Over the past decade, many longitudinal studies have focused on the development of global self-esteem (e.g., Chung et al., 2014; Orth, Trzesniewski, & Robins, 2010; Wagner, Lüdtke, Jonkmann, & Trautwein, 2013; for a review, see Orth & Robins, 2019). A recent meta-analysis suggested that global self-esteem, on average, increases in early and middle childhood, remains stable in adolescence, increases strongly in young and middle adulthood, and declines in old age (Orth, Erol, & Luciano, 2018). This pattern of findings held across gender, country, ethnicity, and birth cohort.

There is reason to expect that domain-specific self-evaluations that correlate more strongly (versus less strongly) with global self-esteem show developmental trajectories that are more similar (versus less similar) to the trajectory of global self-esteem. Although all domain-specific self-evaluations typically show positive correlations with global self-esteem, the domains differ in the strength of their association with it (Donnellan, Trzesniewski, Conger, & Conger, 2007; Esnaola et al., 2020; Harris et al., 2018; Marsh, 1986; von Soest et al., 2016). Across studies, the strongest correlations emerged for self-evaluations in the domains of physical appearance, academic abilities, and social acceptance. In contrast, lower correlations are typically reported for self-evaluations of athletic abilities, behavioral conduct, and specific academic subjects such as mathematics. These correlational findings raise the possibility that self-evaluations in the appearance, academic, and social domain show average trajectories that

are relatively similar to the trajectory of global self-esteem, whereas the average trajectories of other domain-specific measures differ more strongly from global self-esteem.

Sociometer theory (Leary, 2012; Leary & Baumeister, 2000) suggests that self-evaluations in the social domain should show mean-level trends that are especially similar to global self-esteem. More precisely, this theory proposes that global self-esteem reflects an individual's relational value (i.e., with regard to inclusion in close relationships and small groups), as subjectively perceived by the individual him- or herself. In fact, research has documented strong associations between global self-esteem and inclusion in social relationships (Denissen, Penke, Schmitt, & Van Aken, 2008; Leary, Haupt, Strausser, & Chokel, 1998; Murray, Griffin, Rose, & Bellavia, 2003), supporting this central proposition of sociometer theory. Thus, this perspective suggests that the normative trajectory of self-evaluations with regard to social acceptance and romantic relationships could match the trajectory of global self-esteem relatively closely.

Moderators of Mean-Level Change in Domain-Specific Self-Evaluations

Finally, an important theme in the literature is the search for moderators of the trajectories of domain-specific self-evaluations. Many studies have examined the role of gender. In fact, meta-analyses have documented cross-sectional gender differences that largely correspond to gender stereotypes about self-evaluations (Gentile et al., 2009; Wilgenbusch & Merrell, 1999). The meta-analytic findings suggest that girls and women show more positive self-evaluations with regard to morality and verbal abilities, whereas boys and men show more positive self-evaluations with regard to athletic abilities, physical appearance, and mathematics (all of these effects were of small to medium size, i.e., absolute d values ranged from about .20 to .40). With regard to self-evaluations of general academic abilities and social acceptance, the

gender differences were nonsignificant and close to zero (Gentile et al., 2009; Wilgenbusch & Merrell, 1999). However, although there is robust evidence for cross-sectional gender differences in domain-specific self-evaluations (i.e., in the average level of self-evaluations), the evidence on gender differences in mean-level change (i.e., in the average slope of trajectories) is less clear. For example, in the study by von Soest et al. (2016), gender differences in the intercepts of trajectories largely corresponded to the meta-analytic findings described above, but gender differences in the slopes of trajectories were much closer to zero and mostly nonsignificant (for similar results see Cole et al., 2001; Kuzucu et al., 2014; Marsh, 1989). Thus, the literature does not advance hypotheses about gender differences in normative *change* in specific domains.

Birth cohort membership is another factor that might explain individual differences in the trajectory of self-evaluations. Some studies have suggested that more recent generations show greater positivity in their self-concept and even unrealistically positive self-evaluations (Gentile, Twenge, & Campbell, 2010; Twenge & Campbell, 2001, 2008; Twenge, Konrath, Foster, Campbell, & Bushman, 2008). If so, then the normative trajectories of self-evaluations in members of more recent generations might be characterized by steeper increases (or less negative declines). Researchers have argued that sociocultural changes, such as a greater emphasis on children's self-esteem by parents and teachers, grade inflation in educational systems, and increased possibilities for self-presentation through social media, have influenced the way in which children and adolescents perceive and evaluate themselves (Gentile et al., 2010; Twenge & Campbell, 2001, 2010). In Western countries such as the United States, there is empirical evidence for the above-mentioned sociocultural changes (Twenge & Campbell, 2010), so it is possible that these changes have influenced the development of self-views in children and adolescents. In addition to these substantive considerations, testing for cohort differences is also

important for methodological reasons. If mean-level change in self-evaluations differs across birth cohorts (with age held constant), then conclusions about normative development cannot be generalized across generations. Nevertheless, we note that a number of studies did not support the hypothesis that there have been generational changes in the positivity of self-perceptions (Trzesniewski & Donnellan, 2009, 2010; Trzesniewski, Donnellan, & Robins, 2008). Moreover, with regard to global self-esteem, cohort-sequential longitudinal studies suggest that the normative trajectory did not significantly change across the generations born in the 20th century (Erol & Orth, 2011; Orth, Robins, & Widaman, 2012; Orth et al., 2010; but see Twenge, Carter, & Campbell, 2017).

Trajectories of domain-specific self-evaluations could also differ by country and ethnicity. For example, theory suggests that individuals from Asian and Western cultures develop different self-construal styles, which may influence the typical trajectories of self-evaluations in these cultural contexts (Heine, Lehman, Markus, & Kitayama, 1999; Markus & Kitayama, 1991). More generally, researchers have pointed to the need to assess the degree to which psychological phenomena and processes hold across, or are unique to, different cultural contexts (Arnett, 2008; Henrich, Heine, & Norenzayan, 2010). Although the evidence on self-evaluations is based mostly on Western and White/European samples (Gentile et al., 2009; Wilgenbusch & Merrell, 1999), some studies have examined change in self-evaluations in Non-Western countries (X. Chen, He, & Li, 2004; King & McInerney, 2014; Liu, Wang, & Parkins, 2005; Wu, Watkins, & Hattie, 2010). Moreover, some studies with U.S. samples have tested whether change in self-evaluations differs by ethnicity (Brown et al., 1998) or have tracked the development of self-evaluations in Non-White samples (Diemer, Marchand, McKellar, &

Malanchuk, 2016; Harris et al., 2018). Therefore, we coded studies also with regard to country and ethnicity.

The Present Research

The goal of this research was to synthesize the available longitudinal data on mean-level change in domain-specific self-evaluations. We searched for studies with samples from all ages across the life span (i.e., from early childhood to old age). However, the coding of studies showed that the age in eligible studies was restricted to 5 to 28 years (see below for further information). In the analyses, we first examined the average trajectory of domain-specific self-evaluations, and then tested for moderators of the trajectory, including gender, birth year, country, and ethnicity.

Table 1 shows the eight domains of self-evaluations that were included in this meta-analysis. These domains were selected for the following reasons. First, we included those six domains that are central in theories on self-concept and domain-specific self-evaluations (e.g., Harter, 2012a; Marsh, 1990a; Shavelson, Hubner, & Stanton, 1976) and in key measures, such as Harter's Self-Perception Profiles (e.g., Harter, 2012c) and Marsh's Self-Description Questionnaires (e.g., Marsh, 1990b). Specifically, we included the domains of academic abilities, athletic abilities, physical appearance, social acceptance, morality (or behavioral conduct), and romantic relationships. Second, we included two additional domains, that is, mathematics and verbal abilities. Although these categories are considered subdomains of general self-evaluations in the academic domain (Shavelson et al., 1976), they are explicitly distinguished in some measures such as Marsh's Self-Description Questionnaires. Moreover, many primary studies have focused on mathematics and verbal abilities (e.g., King & McInerney, 2014; Musu-Gillette, Wigfield, Harring, & Eccles, 2015; Nagy et al., 2010). Table 1 provides information about

domain content and synonyms, as well as the corresponding subscales in the measures by Harter and Marsh. Moreover, the first column of Table 1 shows brief terms for the eight domains. We note that the focus of the present research is on trait, not state, domain-specific self-evaluations (for a measure of state self-evaluations, see Heatherton & Polivy, 1991).

The present meta-analysis advances the field by yielding robust insights into the normative trajectories of self-evaluations in important domains (no prior meta-analysis or systematic review is available on the topic). Also, the results will indicate whether domain-specific self-evaluations follow developmental trajectories that are similar to, or different from, the trajectory of global self-esteem (as determined in a recent meta-analysis; see Orth et al., 2018). Moreover, the moderator analyses will provide information about the robustness of the findings and, potentially, about factors that explain heterogeneity in the trajectories of domain-specific self-evaluations.

Method

The present meta-analysis used anonymized data and therefore was exempt from approval by the Ethics Committee of the authors' institution (Faculty of Human Sciences, University of Bern), in accordance with national law. Data, materials, and code are available on the Open Science Framework (<https://osf.io/hnrv5/>).

For the present meta-analysis, we used the same general procedures as in the meta-analysis on the development of global self-esteem reported in Orth et al. (2018). For reasons of clarity and completeness, we provide all relevant information on the present meta-analysis in this Method section, even if some of the information has already been described in Orth et al. (2018).

Table 1

Domains of Self-Evaluations and Corresponding Subscales in the Measures by Harter and Marsh

Domain	Content and synonyms	Subscales in measures by Harter	Subscales in measures by Marsh
Academic	Academic abilities, scholastic competence, intellectual abilities	PS: Cognitive Competence SPPC: Scholastic Competence SPPA: Scholastic Competence SPPCS: Scholastic Competence SPP-Adults: Intelligence	SDQ-I: General School SDQ-II: General School SDQ-III: Academic

Note. Information on Harter's and Marsh's measures is provided in the following sources: PS = Pictorial Scale of Perceived Competence and Social Acceptance for Young Children (Harter & Pike, 1984); SPPC = Self-Perception Profile for Children (Harter, 1982); SPPA = Self-Perception Profile for Adolescents (Harter, 2012b); SPPCS = Self-Perception Profile for College Students (Neemann & Harter, 2012); SPP-Adults = Self-Perception Profile for Adults (Messer & Harter, 2012); SDQ-I = Self-Description Questionnaire I (Marsh, Barnes, Cairns, & Tidman, 1984); SDQ-II = Self-Description Questionnaire II (Marsh, Ellis, Parada, Richards, & Heubeck, 2005); SDQ-III = Self-Description Questionnaire III (Marsh & O'Neill, 1984).

Selection of Studies

To search for relevant studies, we used three strategies. First, English-language journal articles, books, book chapters, and dissertations were searched in the database PsycINFO. A first search was conducted in September 2015 together with a search for articles on global self-esteem (Orth et al., 2018), which is the reason why we did not restrict the search to domain-specific measures of self-evaluations. We complemented the set of potentially relevant articles with a second search in October 2018 (i.e., by identifying articles included in PsycINFO after September 2015). Thus, the search of studies covered all entries in PsycINFO from 1806 to October 2018. We used the following search terms: *self-esteem*, *self-worth*, *self-concept*, *self-liking*, *self-respect*, *self-regard*, *self-acceptance*, *self-view**, and *self-image**. The asterisk (i.e., the truncation symbol) allowed for the inclusion of alternate word endings of the search term (e.g., *self-view** yielded entries containing the term “self-view” but also “self-views”). We restricted the search to empirical-quantitative and longitudinal studies, by using the limitation options “empirical study,” “quantitative study,” and “longitudinal study” in PsycINFO. This search yielded 2,156 articles. Second, we examined the references cited in four narrative reviews of research on self-esteem development (Orth, 2017; Orth & Robins, 2014; Robins & Trzesniewski, 2005; Trzesniewski, Donnellan, & Robins, 2013) and cited in three meta-analyses using longitudinal data on self-esteem (Huang, 2010; Sowislo & Orth, 2013; Trzesniewski, Donnellan, & Robins, 2003). This search resulted in 77 additional potentially relevant articles. Third, we included all other relevant articles that we were aware of, resulting in 3 additional articles. Thus, overall, there were 2,236 potentially relevant articles.

To decide on the eligibility of studies, all articles were assessed in full text by the second, third, fourth, or fifth author.¹ In addition, 120 studies were rated by two of the authors to obtain

estimates of interrater agreement. The interrater agreement on inclusion or exclusion in the meta-analysis was high ($\kappa \geq .95$) and all diverging assessments were discussed until consensus was reached.

We included dissertations in the meta-analysis because dissertations are a category of the “gray” literature, providing a promising way to examine publication bias (Ferguson & Brannick, 2012; B. D. McLeod & Weisz, 2004). Although dissertations are publicly available and indexed in databases, Ferguson and Brannick (2012) argue that publication bias is less of an issue in dissertations because dissertations are typically submitted to dissertation committees regardless of whether the findings are statistically significant or not. Consistent with this reasoning, Ferguson and Brannick (2012) reported that effect sizes from dissertations typically yield effect sizes that differ more strongly from effect sizes from peer-reviewed journal articles than do effect sizes from unpublished manuscripts.

For inclusion in the present meta-analysis, we used the same set of criteria as in the meta-analysis by Orth et al. (2018): (a) the study used an explicit measure of domain-specific self-evaluations; (b) the study used a longitudinal study design (i.e., it included two or more assessments of the same sample); (c) the time lag between the first and last assessment was 6 months or longer (note that if a study included more than two assessments, each interval coded was at least 6 months or longer and intervals coded did not overlap); (d) the measure was identical across assessments (i.e., with regard to number of items, item wording, response scale, etc.); (e) the sample included at least 30 participants; (f) the sample was not a clinical sample; (g) the sample as a whole did not undergo a psychological or psychopharmacological intervention (i.e., the sample was not a treatment group of an intervention study; however, we used information from control groups if the control group did not undergo any alternative treatment);

and (h) enough information was given to compute effect sizes. Moreover, studies were included only if (i) the sample was sufficiently homogeneous with regard to age, as operationalized by a cutoff value of $SD = 5$ years for age at Time 1. This inclusion criterion was needed to ensure that the study can provide a valid estimate of age-related change in domain-specific self-evaluations. These procedures left 103 articles for analysis, providing effect sizes on 143 independent samples.

Coding of Studies

We coded the following data: year of publication, publication type, sample size, sample type, proportion of female participants, country in which sample was collected, ethnicity, year of Time 1 assessment, measure of domain-specific self-evaluations, mean age of participants at Time 1, standard deviation of age at Time 1, time lag between assessments, and effect size information.

If studies provided information that allowed coding of independent subsamples (e.g., female and male participants), we coded subsamples rather than the full sample to increase the precision of moderator analyses. If year of Time 1 assessment was not reported in the article or in other publications or sources of information on the sample, we estimated it using the following formula: Year of Time 1 assessment = publication year – 3 years (assuming that studies were published on average 3 years after the completion of data collection) – interval between first and last assessment (i.e., duration of data collection). If studies did not report the mean age of participants but valid indicators of age were given, we used this information to estimate age. For example, if a study reported that participants were children in 5th grade, we estimated mean age of participants as 11 years (thus, the general rule was adding the value of 6 to the grade). As reported above, studies were excluded if the standard deviation of Time 1 age was greater than 5

years (i.e., if the age variability in the sample was too large). Some studies did not report the standard deviation of age, although all other information needed for including the study was available. We included these studies if other information clearly suggested that the sample was sufficiently homogeneous with regard to age (e.g., if all participants were children in the same grade).

For studies that included more than two assessments, we coded all available assessments if the intervals between assessments were 6 months or longer. Later, in the meta-analytic computations, we ensured that each study provided only one effect size estimate per analysis. Thus, when a study provided more than one effect size for a given age period to be meta-analyzed (e.g., age 10 to 12 years), we first averaged effect sizes within studies (by computing the mean) and then conducted the meta-analytic computations. If a study included more than two assessments, but the intervals between assessments were shorter than 6 months, we used those assessments that provided for consecutive (i.e., non-overlapping) intervals that were at least 6 months long. For example, if a study included 5 assessments with 3-month-intervals, we used the first, third, and fifth assessment to compute effect sizes that were based on 6-month-intervals.

As the effect size measure, we used the standardized mean change d per year, denoted as d_{year} (Orth et al., 2018). We first computed the standardized mean change by subtracting the Time 1 mean from the Time 2 mean and dividing this difference by the Time 1 standard deviation (Morris & DeShon, 2002). Thus, computing standardized mean changes yielded d values (Cohen, 1988), with positive d values indicating an increase in domain-specific self-evaluations and negative d values indicating a decrease. Next, we set the standardized mean change in relation to the observed time interval, by dividing it by the length of the time lag between Time 1 and Time 2. Thus, the effect size measure used in the present meta-analysis is a

change-to-time ratio, with the unit d per year. If information on the means and standard deviations of domain-specific self-evaluations was not given in the article, but d values of mean-level change were reported, we used these to compute d_{year} .

The articles were coded by the second, third, fourth, or fifth author. In addition, 65 studies were coded by two of the authors to obtain estimates of interrater agreement. The interrater agreement was high ($\kappa \geq .97$ for categorical variables and $r \geq .97$ for continuous variables).² All diverging assessments were discussed until consensus was reached.

Meta-Analytic Procedure

The meta-analytic computations were made with R (R Core Team, 2019), using the metafor package (Viechtbauer, 2010). In the effect size analyses, we used random-effects models (for estimating weighted mean effect sizes) and mixed-effects meta-regression models (for testing moderators), following recommendations by Borenstein, Hedges, Higgins, and Rothstein (2009) and Raudenbush (2009). Between-study heterogeneity (i.e., τ^2) was estimated with restricted maximum likelihood estimation, as recommended by Viechtbauer (2005, 2010). Following Borenstein et al. (2009), study weights are given by

$$\omega_i = \left(\frac{1}{v_i + \tau^2} \right),$$

where ω_i is the study weight for study i , v_i is the within-study variance for study i , and τ^2 is the estimate of between-study heterogeneity. When using standardized mean change as effect size, the within-study variance is given by

$$v_i = \frac{2(1 - r_i)}{n_i} + \frac{d_i^2}{2n_i},$$

where d_i is the effect size in study i , n_i is the sample size in study i , and r_i is the correlation between pre- and post-scores in study i (Borenstein et al., 2009). Because this correlation is frequently not reported in primary studies, as in Orth et al. (2018) we used an estimate of .50, based on findings from a meta-analysis on test-retest stability in measures of self-esteem (Trzesniewski et al., 2003).

Results

Description of Studies

The meta-analytic dataset included 143 samples (Table 2 shows basic sample characteristics). Data were drawn from 98 journal articles and 5 dissertations. These 103 articles were published between 1984 and 2018, with the median in 2009. Sample sizes ranged from 36 to 20,644 ($M = 784.6$, $SD = 1,915.4$, $Mdn = 317.0$). In sum, the samples included 112,204 participants. Ninety-two percent of the samples were community samples, 6% were nationally representative, and 2% were samples of college students. The mean proportion of female participants was 54% (range = 0% to 100%, $SD = 33%$, $Mdn = 51%$). Forty percent of the samples were from the United States, 13% from Germany, 9% from Australia, 8% from China, 5% from Canada, 4% from Sweden, 4% from the Netherlands, 3% from Portugal, 3% from Switzerland, 2% from Norway, and the remaining 9% from other countries. Taken together, most samples (90%) were from Western cultural contexts such as the United States, European countries, Australia, and Canada; the remaining samples (10%) were from East and Southeast Asian countries including China, Indonesia, and Singapore; no African, South American, or Central American samples were included. With regard to ethnicity, 66% of the samples were

predominantly White/European (“predominantly” was defined as 80% and more), 11% predominantly Asian, 2% predominantly Black, 2% predominantly Hispanic/Latin American, 2% predominantly Native American, and 18% were other/mixed; the numbers do not add up to 100% because of rounding. Mean age at Time 1 ranged from 4.9 to 26.0 years ($M = 12.0$, $SD = 3.5$; note that some studies included 3 or more waves of data, and that we used the mean age at the center of time intervals for the effect size analyses, so the highest mean age examined was 27.5 years).³ Year of Time 1 assessment ranged from 1966 to 2013 ($M = 1998.3$, $SD = 8.9$). We computed mean year of birth using the variables mean age at Time 1 and year of Time 1 assessment. Mean year of birth ranged from 1950 to 2007 ($M = 1986.3$, $SD = 9.6$). To assess domain-specific self-evaluations, 32% of the studies used one of the scales developed by Harter, 18% one of the scales by Marsh, and 50% another measure (for the scales developed by Harter and Marsh, see Table 1). The other measures included a broad range of measures. Among these, the most frequently used measure (with 7% of the samples) was the Body Esteem Scale for Adolescents and Adults (Mendelson, Mendelson, & White, 2001); all other measures were used in only a few (i.e., 3% or less) of the samples.

As reported in the Method section, one inclusion criterion for studies was that the sample was sufficiently homogeneous with regard to the age of participants (using a cutoff value of $SD = 5$ years for age at Time 1). This criterion was needed to ensure that effect sizes can be mapped with sufficient precision on age. Across samples, the standard deviation of age was relatively small with a mean of 0.74 years, ranging from 0.07 to 2.10 years. Thus, the findings suggest that age variability in the samples was not a concern in this meta-analysis.

Table 2

Descriptive Information on the Studies Included in the Meta-Analysis

Study	Sample size	Mean age at Time 1	SD of age at Time 1	Year of Time 1	Female	Sample type	Country	Ethnicity	Measure

Note. Mean age and standard deviation of age are given in years. As described in the Method section, some studies did not report the standard deviation of age, but other information clearly suggested that the sample was sufficiently homogeneous with regard to age (e.g., all participants were children in the same grade). For these studies, the standard deviation is denoted as acceptable (“acc.”). The column “Female” shows the proportion of female participants.

As also reported above, some studies provided effect sizes for more than one age. The reason is that some of the longitudinal studies included more than two waves of data, allowing computation of effect sizes for more than one interval. Specifically, the number of intervals ranged from 1 to 7 across studies. Because the goal of the meta-analysis was to comprehensively summarize all available data on mean-level change in domain-specific self-evaluations, it was important not to ignore information that multi-wave studies provided at later waves (i.e., Waves 3 and later). With regard to these multi-wave studies, the following two procedures should be noted. First, as described earlier, if a study included more than two assessments, each interval coded was at least 6 months or longer (as also required for 2-wave studies) and intervals coded from the same study did not overlap. Second, we ensured that all meta-analytic computations were conducted with independent samples (i.e., no participant provided information for more than one effect size included in the same analysis). Therefore, for each of the analyses, we first averaged effect sizes within studies and then conducted the meta-analytic computations. For this reason, we had to use different datasets depending on the specific analysis. In the moderator analyses, we used information from all 143 samples that provided effect sizes, by first averaging effect sizes within studies. In contrast, in the effect size analyses, which were conducted within age groups, we averaged effect sizes from multi-wave studies only within the specific age range.

Preliminary Analyses

We searched for potential outliers using the “influence” command of the metafor package (Viechtbauer, 2010). According to Viechtbauer and Cheung (2010), studies with absolute studentized deleted residuals larger than 1.96 should be inspected more closely. We examined whether there was evidence that these studies were influential by assessing their DFFITS values (i.e., difference between the predicted average effect for the study with vs. without including it in

model fitting; Viechtbauer & Cheung, 2010). There were very few relevant cases. For three of the domains of self-evaluations, there was no relevant case (mathematics, morality, romantic), for four domains there was one relevant case (academic, appearance, athletic, verbal), and for one domain there were two relevant cases (social). Given the relatively large number of effect sizes for most of the domains (see Table 3), the findings suggest that the influence of potential outliers was probably small. Moreover, we inspected the effect size codings of these studies, which did not suggest that there were any errors or implausible values in the effect sizes. We therefore retained all effect sizes in the meta-analytic dataset, which is consistent with methodological literature advising against routine deletion of studies with particularly large or small effect sizes (Viechtbauer & Cheung, 2010).

Next, we assessed whether there was evidence of publication bias in the data. We expected that publication bias would not be a problem in this meta-analysis because many studies included did not focus on mean-level change in domain-specific self-evaluations (i.e., they examined other research questions), but simply reported the relevant statistics (i.e., means and standard deviations of domain-specific self-evaluations) together with statistics on a larger set of variables. We used three methods to examine publication bias. First, for each of the domains of self-evaluations we examined the funnel graph, which displays the relation between effect size and the standard error of the effect size (Sutton, 2009). The funnel graphs exhibited a symmetrical shape typical of nonbiased meta-analytic datasets (Figure 1). Second, for each of the domains we conducted Egger's regression test (Egger, Smith, Schneider, & Minder, 1997). Since we conducted eight tests but did not expect publication bias in the present data (thus, 1 out of 20 tests would be expected to be significant by chance on the .05 level), we adjusted the significance level to $p < .0063$, following the Bonferroni method (i.e., dividing .05 by 8). The

results showed that for all domains Egger's test was nonsignificant, suggesting that the funnel graph did not deviate significantly from a symmetrical shape (Table 3). Third, we compared effect sizes from dissertations (as a category of gray literature) with effect sizes from peer-reviewed journal articles, by using mixed-effects meta-regression models. If dissertations yield effect sizes that differ significantly from journal articles, this is evidence for publication bias. For two of the domains of self-evaluations (athletic and romantic), no effect sizes from dissertations were available, so the test could not be conducted for these domains. For the remaining domains, the differences between journal articles and dissertations were nonsignificant (Table 3). For three domains (mathematics, morality, and verbal), only one or two effect sizes from dissertations were available; thus, the conclusions that can be drawn with regard to these domains are probably limited. Nevertheless, we note that all three methods used converged in suggesting that there was no evidence of publication bias.

Table 3
Tests of Publication Bias in Mean-Level Change (d_{year}) in Domain-Specific Self-Evaluations

Domain	Egger's regression test			Peer-reviewed journal articles versus dissertations ^a			
	k	z	p	k_j	k_d	z	p
Academic	75	0.802	.422	65	10	-0.398	.690
Appearance	108	-0.494	.621	102	6	-0.981	.327
Athletic	45	0.801	.423	45	0	—	—
Morality	20	-1.210	.226	18	2	0.173	.863
Romantic	11	-0.864	.388	11	0	—	—
Social	72	-1.302	.193	63	9	-0.817	.414
Mathematics	60	1.477	.140	59	1	-0.202	.840
Verbal	27	2.168	.030	26	1	-1.137	.255

Note. Regression coefficients are unstandardized. Dash indicates that model cannot be estimated due to lack of effect sizes from dissertations. d_{year} = standardized mean change d per year; k = number of effect sizes; k_j = number of effect sizes from peer-reviewed journal articles; k_d = number of effect sizes from dissertations.

^a 1 = dissertation, 0 = peer-reviewed journal article.

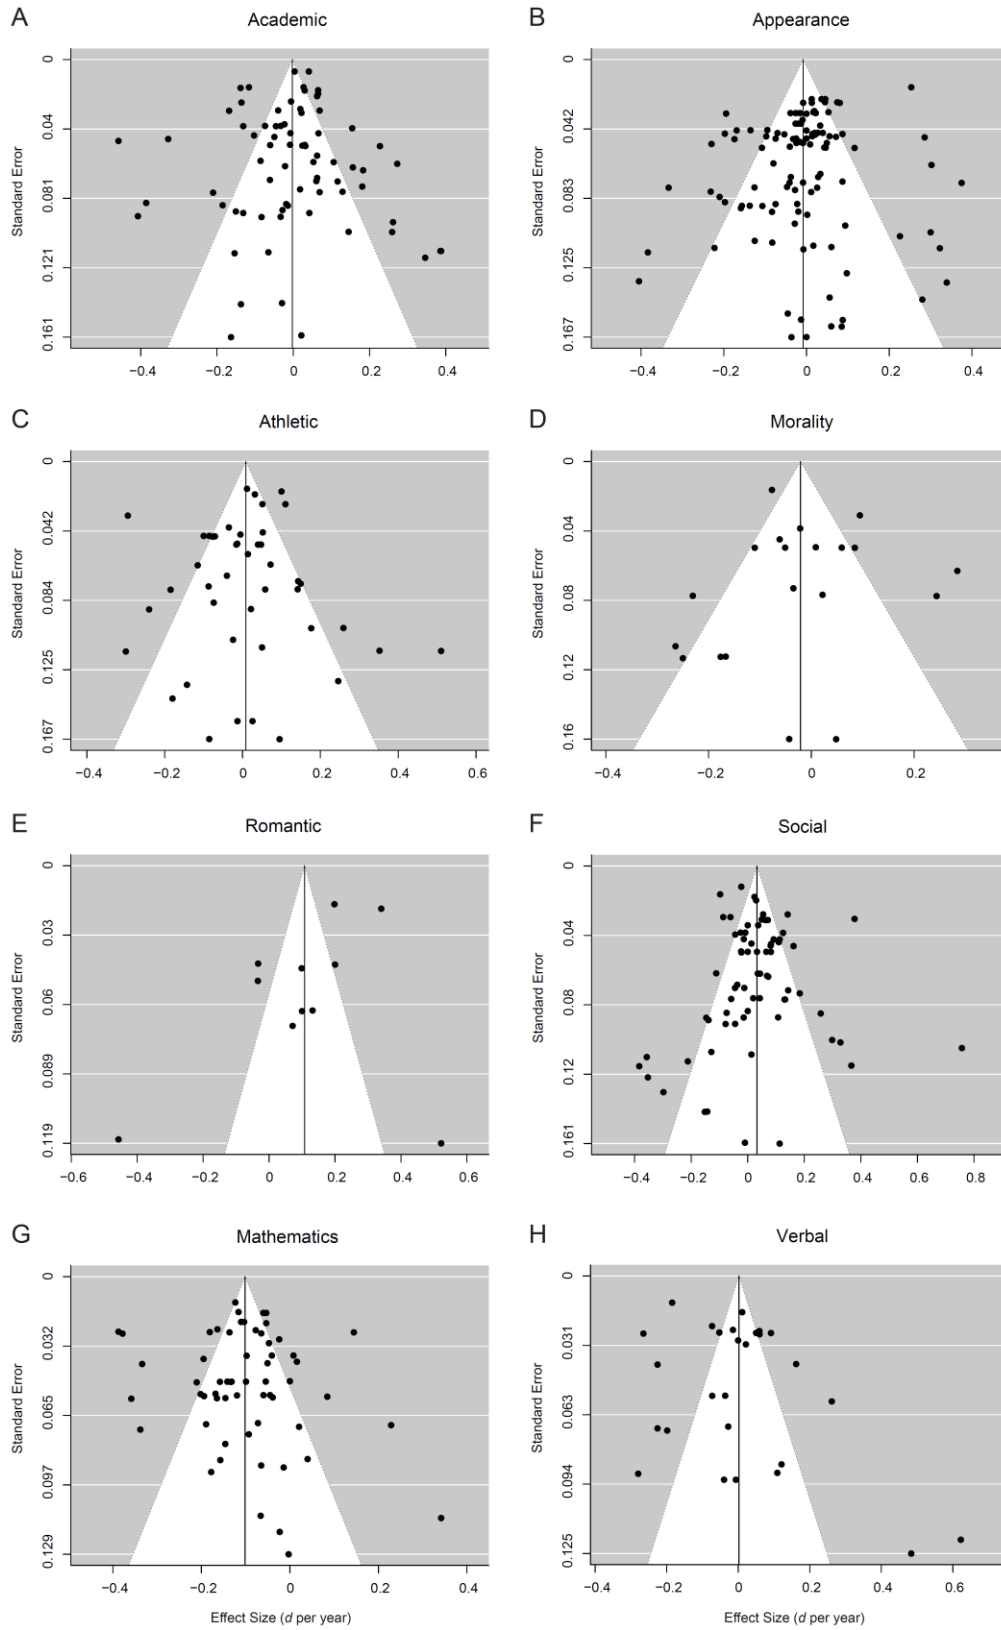

Figure 1. Funnel graphs displaying the relation between standard error and effect size.

Effect Size Analyses

As the goal of this meta-analysis was to map mean-level change in domain-specific self-evaluations on age, effect size analyses were conducted within age groups. For these analyses, we constructed multiple age groups across the observed age range (see Table 4). As in Orth et al. (2018), we did not use the mean age at Time 1 as age variable but, instead, the mean age at the center of the time interval on which the effect size was based. For example, if a sample was assessed at age 10 years at Time 1 and age 12 years at Time 2, the age at the center of the interval on which the effect size was based was 11 years. Although the difference between the two age variables (i.e., age at Time 1 and age at the center of the interval) may be irrelevant for short intervals (e.g., 1 year), the difference is more relevant for long intervals (e.g., 4 years). Because mean-level changes in domain-specific self-evaluations might change systematically across long intervals (e.g., the slope might become smaller or larger with age), the most meaningful age value related to the observed effect size is the center of the Time 1–Time 2 interval rather than age at the beginning (Time 1) or end (Time 2) of the interval.

For the age range from 6 to 18 years, we constructed 2-year age groups. Above age 18, few studies were available for most domains, so we constructed one age group from 18 to 22 years (i.e., the college years) and another age group from 22 to 28 years (i.e., all other years in emerging adulthood for which data were available). The youngest age group covered a 1-year period only (5 to 6 years); we did not combine effect sizes for age 5 to 6 years with the age group from 6 to 8 years, because in many countries and school systems, 6 years marks the transition from kindergarten (or no schooling) to school.

Note. Computations were made with random-effects models. Dash indicates that no data are available (if $k = 0$) or that estimate is not applicable (if $k = 1$). k = number of samples; N = total number of participants in the k samples; d_{year} = standardized mean change d per year; CI = confidence interval; Q = statistic used in heterogeneity test; τ^2 = estimated amount of total heterogeneity; I^2 = ratio of total heterogeneity to total variability (given in percent).

* $p < .05$.

Although the power of significance tests of mean-level change would be greater if we constructed broader age groups (which would then include a larger number of samples), it is important to emphasize that null-hypothesis significance testing of mean-level change was not a central goal in this meta-analysis (cf. Cumming, 2014; Fraley & Marks, 2007; Greenwald, 1975). In the present research, the goal was rather to obtain estimates of age-dependent mean-level change and, thus, narrower age groups provide more precision with regard to age. We used the weighted mean effect size (i.e., the point estimate) as best estimate of mean-level change in the age group, regardless of whether the estimate differed significantly from zero or not. In Table 4, we report the null-hypothesis significance tests of mean effect sizes for reasons of completeness.

Table 4 reports the meta-analytic findings for all domains of self-evaluations. Figure 2 illustrates the findings by aggregating the point estimates of mean-level change across the observed age range for each of the domains. The vertical axes show cumulative d values of domain-specific self-evaluations. Note that the cumulative d s are relative to age 5, so the point of origin (i.e., zero) is arbitrary. For age groups that covered more than one year (e.g., age 6–8; age 18–22), the estimate of yearly change (i.e., d_{year}) was used for each year included in the age group. Moreover, for age groups for which no effect sizes were observed (e.g., age 18 to 22 years in the athletic domain), the graphs are interrupted and continued with the next age group for which information is available.

Figure 2 illustrates that the trajectories of self-evaluations differed substantially across domains. We first focus on domains in which self-evaluations generally showed positive developmental trajectories. In the academic domain (Figure 2A), self-evaluations generally increased, despite slight decreases from age 5 to 6 years, and again from age 12 to 16 years. The figure shows that the strongest increases in academic self-evaluations occurred from age 6 to 10

years (i.e., during roughly the first four years of school) and from age 18 to 22 years (i.e., during the years when many individuals attend college). The net increase from age 5 to 28 years corresponded to almost one standard deviation (cumulative $d = 0.97$). In the social domain (Figure 2F), self-evaluations also increased at most ages. However, from age 5 to 8 years there was a relatively strong decrease ($d = -0.43$). Then, self-evaluations recovered and increased by $d = 0.57$ from age 8 to 18 years, with a slight dip at ages 14 to 16 years. Due to the initial decrease from age 5 to 8, the net increase from age 5 to 28 years was relatively small (cumulative $d = 0.22$). The third domain for which the overall trend was positive was the romantic domain (Figure 2E). For this domain, the youngest age group for which data were available was 12 to 14 years. From age 12 to 18 years, self-evaluations increased by $d = 0.80$, corresponding to a large effect size according to the guidelines by Cohen (1988). Later, from age 22 to 28 years, self-evaluations slightly declined in this domain ($d = -0.20$).

Next, there were two domains in which self-evaluations showed little mean-level change across the observed age range. In the appearance domain (Figure 2B), self-evaluations showed some small ups and downs, but the effect sizes of the increases and decreases were relatively small. For example, although self-evaluations of physical appearance declined from age 10 to 14 years (i.e., in prepubertal and pubertal years), the average decline was benign ($d = -0.17$). The net change from age 5 to 28 years was very small in this domain (cumulative $d = -0.12$). Similarly, in the athletic domain (Figure 2C) there were only small mean-level changes between ages 5 and 28 years. Although self-evaluations increased slightly from age 5 to 10 years ($d = 0.24$), later decreases and increases were even smaller in this domain, with cumulative $d = 0.10$ at age 28 years.

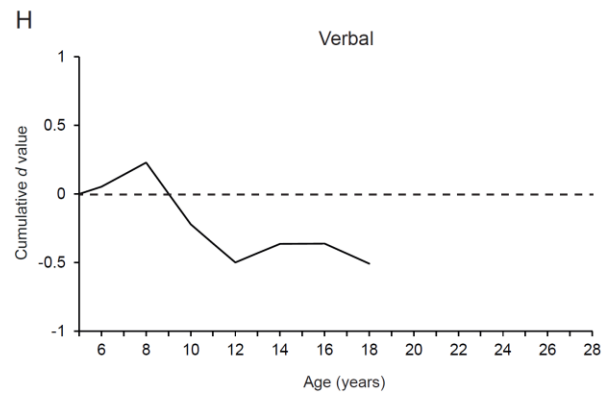

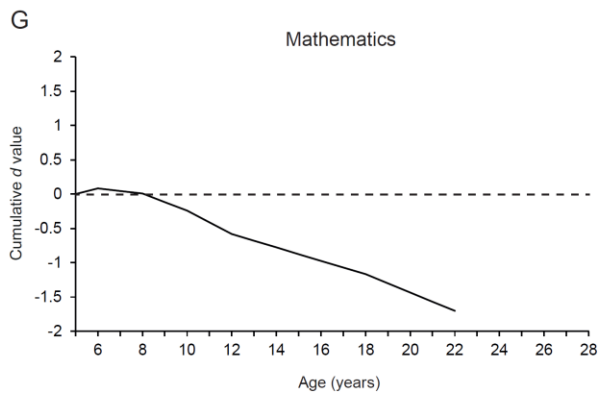

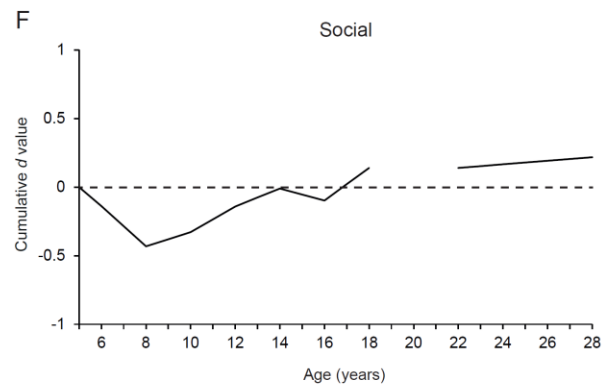

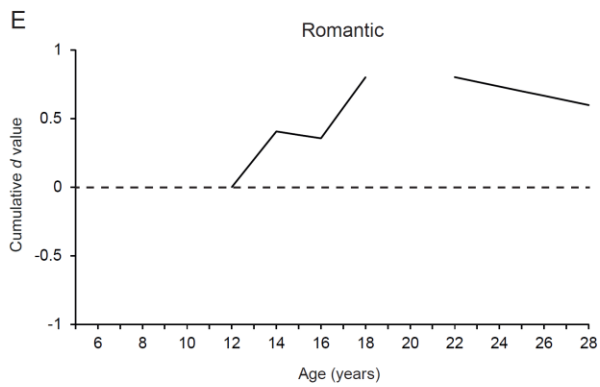

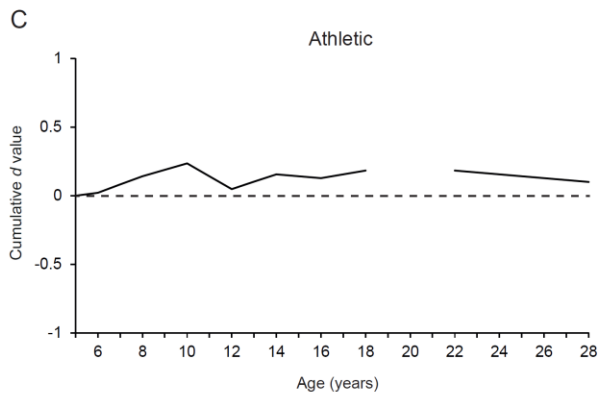

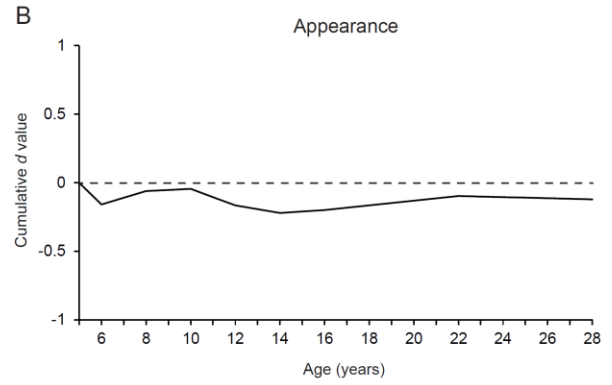

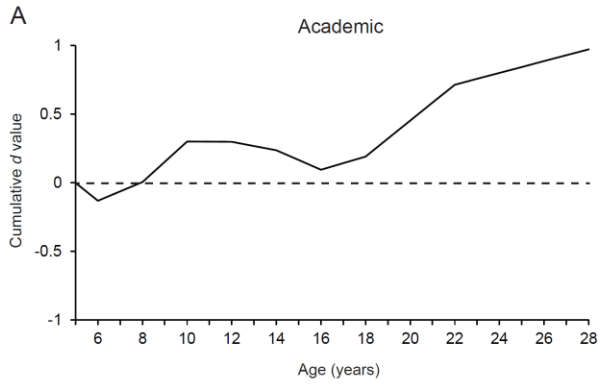

Figure 2. Mean-level change in domain-specific self-evaluations from age 5 to 28 years. The figure shows cumulative d values relative to age 5 years; thus, the point of origin (i.e., zero) is arbitrary. For age groups for which no effect sizes were observed (e.g., age 18 to 22 years in Panel C), the graphs are interrupted and continued with the next age group for which information is available.

Finally, in some domains self-evaluations generally showed negative developmental trajectories. In the morality domain (Figure 2D), there was a relatively strong decline from age 6 to 8 years, corresponding to one half of a standard deviation over two years ($d = -0.53$). In later years, there were only small mean-level changes, but, if anything, self-evaluations did not show any important increases in this domain. The strongest decrease emerged in the domain of mathematics (Figure 2G). Except for a slight increase from age 5 to 6 years ($d = 0.08$), self-evaluations decreased in this domain, at a relatively stable rate from age 6 to 22 years. The net decrease from age 5 to 6 years corresponded to a very large effect size (cumulative $d = -1.70$; note that the figure uses a different scale on the vertical axis for this domain). In the domain of verbal abilities (Figure 2H), average levels of self-evaluations also showed an overall negative trend. However, in this domain, self-evaluations first increased from age 5 to 8 years ($d = 0.23$) and only then showed a relatively large decline until age 12 years (the decrease corresponded to $d = -0.73$). Between ages 12 and 18 years, only small changes were observed in the verbal domain. Also, it should be noted that the net decrease in the verbal domain (cumulative $d = -0.51$ at age 18) was much smaller compared to the mathematics domain.

Moderator Analyses

The findings reported in Table 4 suggested that there was significant heterogeneity in effect sizes for most age groups in most domains. Moreover, most I^2 values (i.e., the ratio of total

heterogeneity to total variability) were relatively large. We therefore tested whether sample characteristics moderated the effect sizes.

The variables mean year of birth and proportion of female participants were continuous and were included as such in the moderator variables. For the categorical variables, we focused on specific contrasts due to low numbers of samples in some of the categories. For country, we contrasted samples from the United States (40% in the full meta-analytic dataset) with samples from other countries (60%).⁴ For ethnicity, we contrasted samples that were White/European (66%) with other samples (34%). In the moderator analyses, we also controlled for mean age of the sample, to ensure that any moderator effects of other sample characteristics were not due to a confounding with the age of the sample. Table 5 shows descriptive statistics and intercorrelations of the moderators.

Table 5
Descriptive Statistics and Intercorrelations of Moderators

Variable	<i>M</i>	<i>SD</i>	1	2	3	4	5
1. Mean age	13.45	3.83	—				
2. Mean year of birth	1986.29	9.55	-.42*	—			
3. Female (proportion)	0.54	0.33	-.03	.05	—		
4. Country ^a	0.40	0.49	.09	-.46*	.05	—	
5. Ethnicity ^b	0.66	0.47	-.06	.04	.02	-.30*	—

Note. The number of samples is $k = 143$.

^a 1 = United States, 0 = other.

^b 1 = White/European, 0 = other.

* $p < .05$.

Table 6 shows the results of the mixed-effects meta-regression models. We began by examining the full set of samples covering the observed age range from 5 to 28 years (see values in the left half of Table 6). Since we conducted a large number of tests (i.e., 40, as we tested five moderators in each of eight domains), we adjusted the significance level to $p < .0013$, following the Bonferroni method (i.e., dividing .05 by 40). The results showed that none of the moderators had a significant effect. Thus, the findings do not suggest that sample characteristics such as mean year of birth, gender, country (i.e., United States vs. other), and ethnicity (i.e., White/European vs. other) systematically influence mean-level change in domain-specific self-evaluations.

Given that the majority of samples, in most domains, had a mean age ranging from 10 to 16 years (Table 4), we repeated the moderator analyses for this subset of samples. These analyses may yield additional insights for two reasons. First, samples with an age 10 to 16 years are more homogeneous with regard to age, so the analyses provide information specific to this developmental period (i.e., preadolescence and adolescence). Second, by holding age relatively constant, the analyses may provide a more valid test of cohort effects on mean-level change (Baltes, Cornelius, & Nesselroade, 1979). Table 6 (values in the right half) shows the multiple regression coefficients of the moderators. Again, since we conducted a large number of tests (i.e., five moderators across seven domains; for the romantic domain, this model could not be tested), we adjusted the significance level to $p < .0014$, following the Bonferroni method (i.e., dividing .05 by 35). The results showed that none of the moderators had a significant effect in this subset of studies either.

Table 6

Mixed-Effects Meta-Regression Models for Sample Characteristics Predicting Mean-Level Change (d_{year}) in Domain-Specific Self-Evaluations

Discussion

In this meta-analysis, we synthesized the available longitudinal data on mean-level change in domain-specific self-evaluations. Analyses were based on data from 143 independent samples, including 112,204 participants. The age associated with effect sizes ranged from 5 to 28 years. The results suggest that self-evaluations change systematically in many domains over the course of development from early childhood to young adulthood. The developmental trajectories of self-evaluations were positive, or at least relatively positive, in the domains of academic abilities, social acceptance, and romantic relationships. In contrast, self-evaluations showed negative, or at least relatively negative, developmental trajectories in the domains of morality, mathematics, and verbal abilities. Little mean-level change was observed in the domains of physical appearance and athletic abilities. Moderator analyses were conducted for the full set of samples and for the subset of samples between ages 10 and 16 years. The moderator analyses suggested that the pattern of mean-level change did not significantly differ by birth cohort and

gender, for samples from the United States versus other countries, and for samples with White/European versus other ethnicity.

Implications of the Findings

As reviewed in the Introduction, previous research had yielded a relatively inconsistent picture of the normative development of domain-specific self-evaluations. Nevertheless, several important themes emerged from the review of the literature. In the following, we will focus on these themes.

The transition from early to middle childhood. Previous work in this area suggested that self-evaluations decline from about age 5 to 8 years (Harter, 2006c). The general hypothesis was that self-perceptions are unrealistically positive in very young children and that, ironically, social-cognitive advances such as improvements in the use of social comparison information and social perspective taking lead to more realistic and, consequently, less positive, self-evaluations as children transition from early to middle childhood (Harter, 2006b, 2006c; Ruble et al., 1980). For most domains, this hypothesis was not supported by the present meta-analytic findings, as illustrated in Figure 2. In many domains—such as academic abilities, physical appearance, athletic abilities, and mathematics—mean-level change was small in this age period, with cumulative decreases or increases not larger than $d = 0.15$. Self-evaluations of verbal abilities even showed a slightly larger increase. However, in the domains of morality and social acceptance, self-evaluations did show a substantial decline, with effect sizes of about $d = -0.50$. Thus, it is possible that social-cognitive advances, as well as stricter expectations by parents, account for declining self-evaluations in these domains. Moreover, we note that the decline of morality self-evaluations in middle childhood could be related to negative changes that have been observed for agreeableness and honesty-humility (Klimstra, Jeronimus, Sijtsema, &

Denissen, 2020; Soto et al., 2011). Taken together, the present findings suggest that in most domains self-evaluations are relatively stable from age 5 to 8. Thus, the notion that self-evaluations typically show a substantial, or even dramatic, decline in the transition from early to middle childhood should be revised.

A low point in early adolescence? The literature suggested that mean levels of self-evaluations reach a low point in early adolescence (i.e., at age 10 to 14 years), in particular in the domains of academic abilities, social acceptance, and physical appearance (Eccles et al., 1984; Marsh, 1989; Wigfield et al., 1991). The general hypothesis was that developmental changes related to puberty and to the many environmental changes in the transition from primary to secondary school account for “hitting rock bottom” in this age period (Cantin & Boivin, 2004; Harter, 2006c; Simmons et al., 1979; Wigfield et al., 1991). In fact, self-evaluations showed a declining trend in many domains in early adolescence in this meta-analysis, including academic abilities, physical appearance, morality, mathematics, and verbal abilities, and low points emerged for the domains of physical appearance, morality, and verbal abilities. However, as illustrated in Figure 2, the declines in self-evaluations were relatively benign, with effect sizes of at most $d = -0.20$ (except for mathematics, for which the decline corresponded to $d = -0.54$). Moreover, self-evaluations in the social domains (i.e., social acceptance, romantic relationships) increased in early adolescence. Taken together, the present findings suggest that in many domains average levels of self-evaluations decline in early adolescence, but that most declines are relatively small and do not correspond to the hypothesis that the development of self-evaluations is generally characterized by reaching a low point in this age period.

However, even if there are no pronounced low points in the mean levels of self-evaluations, early adolescence might be characterized by other self-evaluation issues.

Specifically, early adolescents might show relatively large within-person fluctuations in self-evaluations over short terms such as days or weeks, for example due to all-or-none thinking and overgeneralizations (Harter, 2006c; Molloy, Ram, & Gest, 2011). In fact, research suggests that within-person fluctuations in global self-esteem decrease as early adolescents grow older and transition to later developmental stages (Meier, Orth, Denissen, & Kühnel, 2011). Also, the within-person instability of self-descriptions (Charles & Pasupathi, 2003) and affect (Larson, Moneta, Richards, & Wilson, 2002; Röcke, Li, & Smith, 2009) decreases with age. At the same time, self-concept clarity (i.e., the degree to which self-beliefs are clearly and confidently defined; Campbell et al., 1996) increases from early to middle adolescence and also throughout adulthood (Lodi-Smith & Roberts, 2010; Van Dijk et al., 2014). If self-evaluations of early adolescents fluctuate rapidly from moment to moment, or day to day, this may have contributed to the perception that the age period is especially problematic with regard to self-evaluations.

Development in late adolescence and young adulthood. The literature suggested that mean levels of self-evaluations increase from late adolescence (i.e., at about age 16 years) to young adulthood (Harter, 2006b). In these developmental stages, many personality characteristics develop in the direction of greater maturity and contribute to better functioning in social, educational, and work contexts (Bleidorn & Hopwood, 2019; Roberts & Wood, 2006; Roberts et al., 2008); consequently, positive mean-level changes can be expected for self-evaluations in these domains. Also, attachment anxiety in romantic relationships tends to decline in early adulthood, suggesting that self-evaluations in the romantic domain could become more positive (Chopik & Edelstein, 2014; Hudson, Fraley, Chopik, & Heffernan, 2015). The present findings supported this hypothesis with regard to self-evaluations of academic abilities, romantic relationships, and social acceptance. The largest effect size emerged for academic abilities ($d =$

0.87 from age 16 to 28 years), whereas the effect sizes were smaller for romantic relationships and social acceptance (at about $d = 0.30$). In many other domains, such as physical appearance, athletic abilities, and morality, mean-level change in self-evaluations was very small in this age period (cumulative effect sizes were not larger than $d = 0.10$). Thus, the findings suggest that positive changes in self-evaluations are restricted to general academic abilities and to the social domain. However, as noted above, these might be domains that are more relevant to the development of mature personality traits compared to other domains such as physical appearance and athletic abilities.

Similarity to the trajectory of global self-esteem. Another important theme that emerged from previous research in this area was that self-evaluations might, in some domains, show developmental trajectories that are similar to global self-esteem. As reported in the Introduction, global self-esteem tends to increase in early and middle childhood, remain at about the same level in adolescence, and increase strongly in late adolescence and young adulthood (Orth et al., 2018). Given that self-evaluations of academic abilities, physical appearance, romantic relationships, and social acceptance are substantially correlated with global self-esteem (e.g., Harris et al., 2018; Marsh, 1989; von Soest et al., 2016), there was reason to expect that the normative trajectories in these domains would be more similar to global self-esteem than the trajectories in other domains. The present meta-analytic findings supported this hypothesis for academic abilities, romantic relationships, and social acceptance. In these domains, self-evaluations generally showed a positive developmental trajectory similar to that of global self-esteem, even if there were some smaller deviations from this trend. The hypothesis was not supported for self-evaluations of physical appearance, which showed only little mean-level change across the observed age range. Supporting the hypothesis, however, was that self-

evaluations in domains for which correlations with global self-esteem are weaker—such as athletic abilities, morality, and mathematics—showed developmental trajectories that differed strongly from the trajectory of global self-esteem.

Overall, these findings are consistent with the notion that the development of global self-esteem is closely linked to that of domain-specific self-evaluations regarding academic abilities and social relationships. There are at least three theoretical models that could explain such a link (Marsh & Yeung, 1998). First, the bottom-up model proposes that domain-specific self-evaluations form the basis of global self-esteem and, consequently, causally influence the person's global self-esteem. For example, as discussed in the Introduction, sociometer theory suggests that self-perceptions of social acceptance and romantic appeal could determine the individual's feelings of self-esteem, because of the strong relevance of inclusion in close relationships and small groups in humans' evolutionary history (Leary, 2012; Leary & Baumeister, 2000; see also Kirkpatrick & Ellis, 2001; Kirkpatrick, Waugh, Valencia, & Webster, 2002). Second, the top-down model proposes that causality flows in the opposite direction; that is, from global self-esteem to domain-specific self-evaluations. Although the model does not advance domain-specific hypotheses, it is possible that the causal influence is stronger for some domains (such as social relationships) than for others (such as athletic abilities). Third, the horizontal model does not assume that global and domain-specific self-evaluations are causally linked to each other, but that other characteristics (e.g., genetic influences) account for the association between different self-evaluations. The few studies that tested the relations between global and domain-specific self-evaluations did not find evidence for the bottom-up and top-down models, thus supporting the horizontal model (Harris et al., 2018; Marsh & Yeung, 1998). However, more research on the validity of these models is needed. Robust knowledge about the

models would help to better understand the development of both global self-esteem and domain-specific self-evaluations.

In this context, it may be useful to address the interesting—and perhaps surprising—finding that the normative trajectory of academic abilities differed fundamentally from the domains of mathematics and verbal abilities. Whereas self-evaluations of general academic abilities showed a trajectory that was relatively similar to the positive trajectory of global self-esteem, self-evaluations of specific academic subjects showed a mostly negative developmental trajectory. Put differently, although mathematical and verbal abilities are considered important academic subdomains, developmental trends in self-evaluations of these subdomains cannot account for the developmental trend of general academic abilities. In our view, this discrepancy likely has to do with the fact (as reviewed in the Introduction) that general measures of academic abilities correlate much more strongly with global self-esteem than do specific measures (Esnaola et al., 2020; Marsh, 1986). A possible explanation is that children's and adolescents' self-concept of their general academic competences is only loosely related to specific experiences and grades in school subjects such as mathematics, first language, and foreign languages. Rather, it is possible that general academic self-evaluations are more closely related to the general positivity of the individual's self-concept, as indicated by measures of global self-esteem.

Moderators. A fifth theme in the literature on the development of self-evaluations is the search for moderators. Cross-sectional meta-analyses provide strong support for gender differences, such that girls and women perceive themselves more positively regarding morality and verbal abilities, whereas boys and men have more positive self-views of their athletic competences and mathematics abilities (Gentile et al., 2009; Wilgenbusch & Merrell, 1999).

However, despite gender differences in the average *levels* of self-evaluations, the few available longitudinal studies suggested that gender differences in the average *slopes* of trajectories are nonsignificant (Cole et al., 2001; Marsh, 1989; von Soest et al., 2016). The present meta-analytic findings supported the hypothesis that gender does not moderate the slopes of female and male trajectories of self-evaluations. It is important to note that this meta-analysis examines mean-level change and, consequently, is mute with regard to gender differences in the average level of trajectories. Consequently, the nonsignificant gender effect does not conflict with the findings from the cross-sectional meta-analyses cited above. The available evidence thus suggests that women and men differ in the average level of self-evaluations in some domains, but that the normative shape of developmental trajectories of self-evaluations does not differ by gender. Interestingly, a similar situation emerged in the study of global self-esteem. Despite robust evidence on the cross-sectional gender difference (Kling, Hyde, Showers, & Buswell, 1999; Zuckerman, Li, & Hall, 2016), the meta-analytic estimate of the gender difference in change was nonsignificant and virtually zero (Orth et al., 2018).

Research on generational changes in narcissism and self-esteem suggested that birth cohort membership could be a moderator of mean-level change in self-evaluations (Gentile et al., 2010; Twenge & Campbell, 2008; Twenge et al., 2008). Given sociocultural changes over the past decades, such as an increased focus on self-esteem by parents and grade inflation at school, more recent generations might show greater positivity, and more positive trajectories, in self-evaluations across many domains (Twenge & Campbell, 2010). However, the present meta-analytic findings did not support this hypothesis. In this meta-analysis, mean year of birth ranged from 1950 to 2007, so the nonsignificant moderator effects of birth cohort suggest that the shape of developmental trajectories of self-evaluations has not changed over the generations born since

the mid-20th century. For all domains of self-evaluation examined in this research, the cohort effect was nonsignificant and close to zero. Importantly, mean age was statistically controlled for in the analyses. Consequently, the effects of mean year of birth captured the unique cohort effects while holding age constant, which otherwise could have confounded the findings. Moreover, when we repeated the moderator analyses for samples with mean ages of 10 to 16 years (i.e., a subset of samples that were relatively homogeneous with regard to age), the same pattern of nonsignificant cohort effects emerged. Again, it is important to emphasize that this meta-analysis provides information only about effects on the slope but not the level of trajectories of self-evaluations. However, with regard to the average level of self-evaluations, a number of cross-sectional studies did not support the hypothesis that more recent generations differ systematically from previous generations (Trzesniewski & Donnellan, 2009, 2010; Trzesniewski et al., 2008).

The fact that the moderators tested in this meta-analysis were all nonsignificant (including the moderating effects of country and ethnicity) does not mean that there is no variability in the trajectories of self-evaluations. Rather, the heterogeneity statistics indicated that effect sizes did differ significantly across samples. Moreover, within samples, participants most certainly differed in the individual trajectories they followed. Therefore, future research should continue to test for moderators of the development of self-evaluations. Nevertheless, the present findings suggest that the pattern of findings on mean-level change is relatively robust and cannot be explained by differences in terms of gender, birth cohort, country (United States vs. other), and ethnicity (White/European vs. other).

Limitations and Strengths

A limitation of the present meta-analysis is that the samples predominantly came from Western cultural contexts; more precisely, from North America, Europe, and Australia. Only 10% of the samples were from other countries. Because of the low number of non-Western samples, the present research did not allow testing whether the pattern of findings replicates in samples from Asian, African, South American, or Central American countries. Thus, the findings of this meta-analysis essentially apply to Western countries. In future research, it would be highly desirable to more often collect data on self-evaluations in non-Western samples, to evaluate the degree to which developmental patterns generalize across cultures (Henrich et al., 2010).

Similarly, another limitation is that most of the samples included were predominantly White/European (66%). Consequently, in the moderator analyses, we focused on the contrast between White versus other samples, due to the low number of samples with predominantly Asian, Black, or Hispanic participants. Therefore, even if the moderator analyses indicated that White and other samples did not differ significantly, conclusions about the normative development of self-evaluations in specific non-White ethnic groups are not possible on the basis of the present meta-analysis. Therefore, future research should more often use ethnically diverse samples and test whether developmental patterns hold across different ethnic groups.

Unfortunately, the present meta-analysis did not allow examining age groups older than 28 years, given the lack of studies on young adulthood beyond 28 years, middle adulthood, and old age. In future research, it would be interesting to study the development of self-evaluations in adulthood. Given that global self-esteem shows substantial mean-level change across adulthood (Orth et al., 2018; for a review, see Orth & Robins, 2019), there is reason to expect that average levels of domain-specific self-evaluations also change in this period, at least in some domains.

We also note that—even if the observed age range was 5 to 28 years in the meta-analytic dataset—the number of adult samples was low for many of the domains, limiting the robustness of conclusions with regard to the normative development of self-evaluations above age 18 years.

A number of potential limitations are related to measurement of self-evaluations. For example, the primary studies included in this meta-analysis used different measures to assess self-evaluations, and some of the studies used measures that had been translated from English to other languages. Thus, the present analyses are based on the assumption that different measures, and foreign-language versions of the same measures, show convergent validity. Also, since we examined mean-level change, the analyses are based on the assumption that the measures show measurement invariance over time (Widaman, Ferrer, & Conger, 2010). Moreover, in the present meta-analysis we did not code information on the quality of measures, such as reliability, and it is possible that some of the heterogeneity in effect sizes could be explained by between-study differences in measurement quality. Nevertheless, it is important to note that many studies used established measures of the constructs, such as Harter's Self-Perception Profiles (e.g., Harter, 2012c) and Marsh's Self-Description Questionnaires (e.g., Marsh, 1990b; for a review of Harter's and Marsh's measures, see Donnellan, Trzesniewski, & Robins, 2015).

Nevertheless, an important strength of this meta-analysis is the large total number of samples that could be included in the analyses ($k = 143$), as well as the availability of effect sizes across a broad range of domains of self-evaluations. Moreover, we believe that the effect size measure used (i.e., the standardized mean change per year, d_{year}) significantly contributes to the validity of the meta-analytic findings. Based on age-specific estimates of d_{year} , the present analyses allowed drawing a relatively precise picture of normative development in domain-specific self-evaluations, by showing cumulative d values across the observed age range.

Furthermore, the analyses suggested that there is no publication bias in the meta-analytic dataset. We used three methods to assess publication bias, including funnel graphs (Sutton, 2009), Egger's regression test (Egger et al., 1997), and testing for differences between effect sizes from peer-reviewed journal articles versus dissertations as a category of gray literature (Ferguson & Brannick, 2012). The results of all three methods converged in suggesting that there is no evidence of publication bias in the present findings.

Conclusions

Based on longitudinal data from 143 samples with more than 110,000 individuals, this meta-analysis shows that average levels of domain-specific self-evaluations change in a systematic, normative way as individuals go through childhood, adolescence, and young adulthood. The developmental trajectories differed substantially across domains. The most positive trajectories of self-evaluations were observed with regard to general academic abilities and in the social domain. In contrast, the findings suggest that little mean-level change occurs in self-evaluations of physical appearance and athletic abilities. The most negative trajectories emerged with regard to specific academic abilities such as mathematics. The pattern of results did not differ significantly by birth cohort and gender, for samples from the United States versus other countries, and for samples with White/European versus other ethnicity, suggesting that the findings are robust and generalizable within Western cultural contexts.

Regarding the transition from early to middle childhood, the meta-analytic findings deviate from prior depictions in the literature. Thus, the notion that self-evaluations show a substantial normative decline in this age period should be revised. Similarly, the notion that self-evaluations reach a critical low point in early adolescence was not supported. Although the present findings suggest that self-evaluations typically do decline in many domains in early

adolescence, the declines were characterized by relatively small effect sizes. Nevertheless, it is important to reiterate that the present findings provide information about average developmental trajectories. Given that there are substantial individual differences in developmental trajectories of self-evaluations (Kuzucu et al., 2014; Young & Mroczek, 2003), it is likely that some children and adolescents do experience more dramatic declines and low points compared to others of their age group. Fortunately, research suggests that interventions aimed at improving domain-specific self-evaluations are effective (O'Mara, Marsh, Craven, & Debus, 2006).

Footnotes

¹ At the time of coding, the qualifications of the coders were as follows: The second, fourth, and fifth author had a Master's degree in psychology and the third author had a Ph.D. degree in psychology.

² When coding the first set of studies included in this meta-analysis (1806 to September 2015), interrater agreement was lower ($\kappa = .73$) for the variable sample type. As reported in Orth et al. (2018), the disagreement resulted from overlap between two categories, specifically “community samples (convenience)” and “community samples (regionally representative);” regionally representative was defined as representative for a region such as a county or city. Given the overlap, we merged these two categories into one category (denoted as community sample), resulting in high agreement for the revised variable of sample type ($\kappa = 1.00$). When coding the second set of studies included in this meta-analysis (September 2015 to October 2018), we used the revised variable, distinguishing the following categories: nationally representative, community, and college students.

³ In the analyses, we did not consider data from one sample from middle adulthood. More precisely, in this sample the mean age was 49.85 years at Time 1, and the study included a measure of physical appearance (Guérin, Goldfield, & Prud'homme, 2017). We ignored the data from this sample because its age differed fundamentally from the age of all other eligible samples, which ranged from 4.9 to 26.0 years as reported above. Inclusion of a single study from middle adulthood would not have allowed for any reliable conclusions about mean-level change in this developmental period. We did not examine the data from this sample and did not include its characteristics in the description of studies.

⁴ We used this contrast because the number of samples was large for the United States, whereas the number of samples was relatively small for all other countries, corresponding to the procedure used in the meta-analysis on the development of global self-esteem reported in Orth et al. (2018). We did not test other contrasts for country to avoid an increased risk of false-positive findings.
