1 **George C. Williams' problematic model of selection and senescence: time to move on.**

2
3 Moorad et al [1] reinforces and elaborates on warnings made previously [2, 3] that Williams'
4 "hypothesis" should be treated with scepticism. A proper hypothesis should be based upon
5 the best information available at the time, and for the case of the evolutionary theory of
6 senescence, Hamilton's model of selection is superior to Williams'. Hamilton's insights
7 improved over Williams' by his appreciation for how fertility and juvenile survival schedules
8 play a critical role in defining selection. While Williams' model is not articulated
9 mathematically, it is clear that his hypothesis is motivated by his belief that the strength of
10 selection against mortality specific to some age follows from the frequency of individuals that
11 survived to that age [4]. However, Hamilton [5] was quite clear: the strength of selection is
12 equal to the proportion of newborns that came from *parents* that survived to that age (see
13 [1] or Equation 1 in the Appendix). Furthermore, Williams' explicitly states that juvenile
14 mortality cannot affect the evolution of senescence while Hamilton's formulae show us that
15 it can. It should be emphasized that Williams himself came to appreciate that Hamilton's
16 model describes the best way to think about how selection works [e.g., 6].

17
18 Under limited conditions, predictions made by these models converge. In all other situations,
19 Hamilton's predictions are more appropriate. We cannot think of any reason to motivate any
20 test of modern evolutionary theory by appealing to Williams' hypothesis because Hamilton's
21 superior motivating model is *always* available. Furthermore, tests that are motivated by
22 Williams' hypothesis risk propagating Williams' flawed verbal *model*, which has a tenacious
23 hold on the literature. The waters get muddied when modellers, such as Day & Abrams (DA)
24 [7], cast their results as consistent with Williams' hypothesis when, in fact, the highly specific
25 ecological conditions that they model do not resemble anything proposed by Williams'
26 general model. While such claims are true *technically*, this way of thinking is problematic as
27 it can lead to statements, such as this from DA [7], that appear to justify Williams' verbal
28 *model*,

29
30 "Williams' hypothesis continues to occupy the attention of evolutionary biologists ... It is true
31 that for organisms with high evolutionarily unavoidable mortality, investment in repair and
32 maintenance for ages that are seldom reached does not make sense."

33
34 A *hypothesis* can be based upon a poor general model and make good predictions valid under
35 special conditions. However, do these sorts of models warrant our attention when
36 alternatives exist that are more logically sound and make predictions that are more general?
37 For these reasons, we believe that while Williams' model of selection may hold historical
38 interest, it has no place in modern discussions of aging (NB – this objection has nothing to do
39 with Williams' other insights on senescence [see 8]).

40
41 DA objected to our statements pertaining to situations that correspond to where predictions
42 from Williams and Hamilton converge. Specifically, they focus on a form of population
43 regulation in which density suppresses fertility equally at all ages. When age-independent
44 mortality is added to such populations, fertility is enhanced due to the relaxation of ecological
45 constraints baked into the model, and selection is changed as a result. They make several
46 mischaracterizations of our views that warrant a response. We believe that these derive from
47 confusion over terminology, specifically in the dual-meanings of "extrinsic mortality" that we

48 employ in our attempt to synthesize a diverse field. This is discussed in our review where we
49 consider a situation in which the distinction between definitions become important (p. 525).
50 We take this opportunity to clarify our perspectives.

51

52 “Extrinsic mortality” can mean two different things when environmental changes can induce
53 changes in vital rates through ecological feedbacks (see Fig 1).

54 (1) For some [e.g., 7], ‘extrinsic mortality’ is understood in the context of *direct* effects only.

55 These are the proximate effects of a manipulation or treatment that raise mortality rates
56 equally at all ages (e.g., Fig 1, **A-D**). Here, the term does *not* consider knock-on effects
57 caused by feedbacks that can alter mortality or fertility rates which might be called the
58 *indirect* effects of extrinsic mortality.

59 (2) Others (including us) take the meaning of ‘extrinsic mortality’ to pertain to a possible
60 form of the *total* effects, or the summation of the direct and indirect effects. We believe
61 a focus on total effects is relevant because these are the proximate determinants of
62 Hamilton’s predictions. ‘Extrinsic mortality’ by this perspective means that the *total*
63 effect of a manipulation is comprehensively described by an increase in age-independent
64 mortality (only row **A** of **A – D** qualify).

65 The choice of definition has profound implications for how we might answer the deceptively
66 simple question, “How can the addition of extrinsic mortality alter selection?” We answered
67 that extrinsic mortality cannot have an effect (**A** and **D** in Fig 1): mortality must be age-
68 dependent to matter. This is correct from our perspective. When DA [7] ask this question,
69 they interpret extrinsic mortality to apply to effects in the *direct* sense only. They invoke a
70 particular model of density-dependent population regulation that causes fertility to increase
71 when mortality is added (the *indirect* effects). They note that this will cause selection against
72 late-life mortality to relax (**B**). This is correct, too, but their definition of “extrinsic mortality”
73 used in the *direct* sense is equivalent to the simultaneous addition of age-independent
74 mortality *and* fertility. We agree with Day & Abrams that the meaning of “extrinsic mortality”
75 can be vague; future studies can clarify their use of the term by specifying its causal
76 relationship with vital rates, as we do here.

77

78 Kozlowski *et al.* [9] share this confusion. This clarification should resolve the focus of both
79 parties’ objections and lay to rest any concern that we reject the role that density-
80 dependence might play in the evolution of senescence. On the contrary, we believe that this
81 ecological feature could be very important, but these studies shouldn’t be couched in terms
82 of Williams’s hypothesis both for the reasons given above but also because different sorts of
83 density-dependence can lead to radically different model predictions, some of which are not
84 consistent with Williams’ hypothesis [10]. We agree wholeheartedly with Kozlowski *et al.* [9]
85 that empirical investigation into the causes of selection as it relates to aging should establish
86 the nature of density-dependence, and we believe that the survey that they describe is a
87 valuable move in the right direction.

88

89 DA [7] make technical criticisms in their Appendix to which we respond in our own.

90

91 **Figure 1. Consequences of added age-independent mortality: direct effects, indirect effects,**
92 **and changes in selection.** Four scenarios that correspond to cases discussed in [9]; we have
93 illustrated how added age-independent mortality can affect vital rates *directly vs indirectly*.
94 Rows correspond to different scenarios (**A** - density independence; **B** - density dependence

95 through age-independent fertility; **C** - density dependence (fertility is more affected in the
96 old); and **D**) density dependence through age-independent mortality (no *total* effects). Black
97 lines indicate conditions before the added mortality and red lines indicate the conditions
98 afterwards. For more details see the Appendix.
