37 Marena et al. introduce a parameter-free algorithm to quantify super-structures and
38 connected clusters in SMLM datasets. The algorithm is tested on simulated and
39 experimental datasets demonstrating that it can be used as an unbiased tool to extract
40 information beyond simple clustering.

Understanding biological function requires the identification and characterisation of complex patterns of molecules. Single-Molecule Localisation Microscopy (SMLM) can quantitatively measure molecular components and interactions at resolutions far beyond the diffraction limit, but this information is only useful if these patterns can be quantified and interpreted. We provide a new approach for the analysis of SMLM data that develops the concept of structures and super-structures formed by interconnected elements, such as smaller protein clusters. Using a formal framework and a parameter-free algorithm, (super-)structures formed from smaller components are found to be abundant in classes of nuclear proteins, such as heterogeneous ribonucleoprotein particles (hnRNPs), but are absent from ceramides located in the plasma membrane. We suggest that mesoscopic structures formed **by** interconnected protein clusters are common within the nucleus and have an important role in the organisation and function of the genome. Our algorithm, “SuperStructure”, can be used to analyse and explore complex SMLM data and extract functionally relevant information.

100 Introduction

101

102 Single-molecule localisation microscopy (also known as SMLM) (van de Linde et al.,
103 2011; Schermelleh et al., 2010; Henriques et al., 2011; Sauer and Heilemann, 2017)
104 is now commonly employed for quantitative analysis of molecular structures and
105 interactions both in cell-based (Cisse et al., 2013; Kapanidis et al., 2018; Chong et al.,
106 2018) and *in vitro* experiments (Revyakin et al., 2006; Deniz et al., 2008). Unlike other
107 light microscopy techniques, SMLM achieves resolutions far beyond the diffraction
108 limit and its typical output is a list of 3D coordinates (or localisation events) that are
109 naturally analysed using efficient clustering algorithms borrowed from quantitative big-
110 data analysis and even astronomy (Owen et al., 2010; Sengupta et al., 2011; Garcia-
111 Parajo et al., 2014; Baumgart et al., 2016; Spahn et al., 2016; Griffié et al., 2016).
112 However, traditional clustering algorithms rely on user-defined parameters that are
113 intrinsically intertwined with the notion of similarity that is necessary to define a cluster.
114 These parameters can be either hypothesised by physical intuition or inferred via pre-
115 emptive analysis (Burgert et al., 2017; Williamson et al., 2020; Malkusch and
116 Heilemann, 2016), yet their choice has a significant impact on the results, in turn
117 hindering the portability of clustering algorithms and the comparison between different
118 datasets.

119 At the same time, recent evidence suggest that assemblies of proteins
120 (Brangwynne et al., 2015; Larson et al., 2017; Strom et al., 2017; Sabari et al., 2018;
121 Cho et al., 2018; Maharana et al., 2018; Chong et al., 2018) and chromatin (Bintu et
122 al., 2018; Boettiger et al., 2016; Frank and Rippe, 2020) form functional complex
123 structures that are not fully captured by standard clustering algorithms. For example,
124 the hnRNP protein SAF-A is suggested to form a dynamic and functional mesh-like
125 structure while interacting with RNA to maintain transcriptionally active genomic loci
126 in a decompacted configuration (Nozawa et al., 2017; Michieletto and Gilbert, 2019).
127 Other examples include SC35, a nuclear protein involved in RNA splicing and
128 chromatin elongation (Lin et al., 2008) and that displays localised nuclear speckles
129 (Xie et al., 2006; Jackson et al., 2000), or actin and microtubules which form elongated
130 and inter-connected networks involved in cell motility and division, as well as in the
131 synaptic plasticity of dendritic spines (Resch et al., 2002; Rogers et al., 2003; Izeddin
132 et al., 2011). Additionally, recent super-resolution studies indicate that chromatin is
133 also functionally organised in connected nano-scale compartments (Prakash et al.,
134 2015; Szabo et al., 2018; Nir et al., 2018; Maiser et al., 2020). Rapidly evolving
135 methods of chromatin tracing (Boettiger et al., 2016; Wang et al., 2016; Beliveau et
136 al., 2015; Nir et al., 2018; Bintu et al., 2018) and super-resolved imaging of the
137 accessible genome (Xie et al., 2020) require sophisticated algorithms to analyse the
138 topology of the generated paths (Goundaroulis et al., 2019). In order to understand
139 the relationship between these complex structures and the underlying biological
140 mechanism and functions of the genome (Bronstein et al., 2015; Khanna et al., 2019;
141 Leidescher et al., 2020 *Preprint*; Smeets et al., 2014) a more sophisticated and
142 standardised analysis of SMLM data is urgently required.

143 It is clear that quantification of complex structures is a ubiquitous problem in
144 molecular and cell biology and it is intimately connected to cellular function. Motivated
145 by this problem, here we introduce a new algorithm termed "SuperStructure", which
146 extends in a novel and original way the popular density-based clustering algorithm
147 DBSCAN. SuperStructure allows (i) a parameter-free detection and quantification of
148 complex structures made of connected clusters in SMLM data and (ii) a parameter-
149 free quantification of the density of molecules within clusters.

150 Here, we demonstrate the capabilities of SuperStructure on simulated datasets
151 and then use it to analyse two groups of experimental datasets: (i) nuclear proteins
152 involved in RNA processing, namely SAF-A, hnRNP-C and SC35 and (ii) ceramides
153 lipids involved in cellular trafficking at the membrane. We find that interconnections
154 between clusters are abundant in classes of proteins in the hnRNP family and that
155 they are surprisingly absent from ceramides, suggesting this feature is relevant for the
156 biological function of SAF-A and hnRNP-C. Therefore, SuperStructure enables us to
157 discover new facets of protein organisation in human cells and provides a better
158 understanding of the molecular mechanisms underlying the organisation of sub-
159 cellular (super-)structures.

160 Finally, since SuperStructure is parameter-free, it provides the community with a
161 standardised tool for the discovery and quantification of complex patterns in SMLM
162 data. Furthermore, beyond helping our understanding of complex biological structures,
163 it might be used to assess the fluorophore blinking quality and thus offers versatility in
164 assessing also technical imaging properties (van de Linde and Sauer, 2014; Hennig
165 et al., 2015; Sieberg and Herten, 2011).

166
167

168 Results

169
170

171 Super Structure Algorithm

172

173 SuperStructure is best explained in relation to the well-known DBSCAN algorithm.
174 DBSCAN detects clusters by grouping together high-density localisations and
175 classifies as outliers low-density ones (Ester et al., 1996). In practice, DBSCAN
176 determines that a localisation is part of a cluster if more than N_{min} other localisations
177 are found within a neighbourhood distance ε (or if it is part of the neighbourhood of
178 another localisation with this property). Conversely, SuperStructure extracts
179 connectivity information from the rate at which the number of detected clusters N_c
180 changes with the neighbourhood radius ε for a fixed N_{min} (see Fig.1). Indeed, the
181 curves $N_c(\varepsilon)$ contain important overlooked information about the structure of
182 connections. To simplify the analysis, and without loss of generality, we set $N_{min} = 0$,
183 which means that we do not require a minimum number of localisations within the
184 neighbourhood to define a cluster. As a consequence, $N_c(\varepsilon)$ is necessarily a
185 monotonically decreasing function as for $\varepsilon = 0$ every localisation is detected as a
186 single cluster and increasing ε yields fewer but larger clusters. Following on, the rate
187 at which N_c decays with ε is an indicator of how quickly localisations, and then clusters
188 of localisations, coalesce, thus indicating how much localisations and clusters are
189 connected.

190 The $N_c(\varepsilon)$ curves provided by SuperStructure identify different clustering regimes
191 (Fig.1): the first (small ε) regime describes the merging of localisations within clusters
192 (intra-cluster regime); the second (intermediate ε) regime captures the growth of
193 clusters into super-structures (first super-cluster regime) and finally the third (large ε)
194 regime describes the merging of super-clusters into higher-order super-structures
195 (second/third super-cluster regimes). The $N_c(\varepsilon)$ curve in the first regime typically
196 follows a Poissonian function (Eq.1) and its decay rate is related to the density of
197 emitters ρ_{em} within the clusters (see Methods and Figs.1 and S1). The width of the
198 Poisson function also sets the critical value of ε at which this first regime is expected
199 to end (Eq.2). On the other hand, the decay in the second and third regimes follows

200 an exponential decay with characteristic length-scale λ and are highly dependent on
201 the connectivity between (super-)clusters, as well as on the density of (super-)clusters
202 (Eq.4).

203 The number of super-cluster regimes depends on the homogeneity of both
204 cluster distribution and connections. In the two extreme cases of a completely
205 connected or unconnected homogeneous distribution of clusters, we expect a single
206 super-cluster regime. However, while in the former case this regime is exponential
207 (because the clusters are connected), in the latter it assumes a Poissonian functional
208 form (see respectively Eqs.4 and 3). This is not surprising, as free (unconnected)
209 clusters that are randomly distributed behave (on a larger scale) as single emitters
210 inside clusters (see Methods and Fig.S1). Also, in the case of clusters embedded in a
211 random distribution of other localisations (such as noise), we obtain a Poissonian
212 decay. Importantly, a random distribution of localisations (also at high density) is
213 different from “connected” clusters, where nearby localisations are mostly distributed
214 in between clusters. As a result, the curves generated by SuperStructure allow us to
215 identify the presence/absence of connectivity by investigating the functional form of
216 the curves, as well as to extract their decay rates.

217 In heterogeneous systems that display a mix of randomly dispersed
218 localisations/clusters and connected ones over similar length-scales, we strongly
219 recommend restricting the analysis with ROIs over sub-regions that display
220 qualitatively similar phenotypes. A good example of heterogeneous system is given
221 by the nuclear protein SC35, which we analyse below. Restricting the analysis to ROIs
222 is also recommended when quantifying nuclear or cellular sub-structures that display
223 boundaries. Masking localisations falling outside these boundaries allows
224 SuperStructure to generate cleaner curves that are easier to interpret.

225 In order to quantify the intra-cluster density and (super-)cluster connectivities,
226 one needs to define boundaries between regimes and to fit every regime with the
227 corresponding function (see Eqs.1, 3 and 4). Regime boundaries and fitting ranges
228 can be either selected manually (where curves change their decay properties) or by
229 rigorously running a pre-emptive goodness-of-fit test. For instance, once the rough
230 regime range has been identified and fitted, one can modify the fit window to identify
231 the boundaries of the regime outside which the fit is no longer acceptable. Arguably,
232 the optimum regime is found by identifying the best goodness-of-fit window (e.g. the
233 range with the minimum chi squared). It is also possible to define a single function
234 fitting the entire curve by (a) defining a piecewise function where every “piece” is the
235 fit of the corresponding regime or by (b) adding together the contribution of the different
236 regimes (appropriately weighted).

237 The work-flow for the application of SuperStructure is shown in Fig.1 and is
238 described in detail in Methods. Additionally, the codes and scripts are open source
239 and available at git repository (see below).

240
241

242 **Characterising SuperStructure Feature Extraction from Simulated SMLM data**

243
244 To evaluate the performance of SuperStructure, we analysed artificial datasets
245 consisting of inter-connected clusters of localisations on a 2D plane (see Fig.2A).
246 Clusters are homogeneously and randomly positioned on the plane with a cluster
247 density $\rho_{cl} = 8.2 \mu m^{-2}$ that is comparable to that of some nuclear proteins (see
248 below). Every cluster has average radius $R_{cl} \sim 40 nm$ and an overall internal
249 localisation density $\rho_{em} = N_{em}/\pi R_{cl}^2 = 16000 \mu m^{-2}$, where N_{em} is the number of

250 localisations per cluster. Pairs of clusters are connected with probability p_r by a sparse
251 points distribution and only if the distance between the clusters is less than $b = 1 \mu m$.
252 These choices allow us to readily tune the degree of “connectivity” in the system by
253 varying a single parameter p_r . A second parameter $p_{r_{conn}}$ is introduced to control the
254 density of localisations within the connections ρ_{conn} (see Methods for details).

255 The length-scales associated to density of emitters inside clusters ρ_{em} and to the
256 connections ρ_{conn} define the boundaries between the three regimes of $N_c(\varepsilon)$ (Fig.2B):
257 (i) for $\varepsilon \lesssim 12 nm$ the intra-cluster regime follows a Poissonian decay (Eq.1) with
258 density parameter $\rho_{em} = 16000 \mu m^{-2}$ (as expected since it was set by construction);
259 (ii) for intermediate values of ε the exponential super-cluster regime dominates (Eq.4)
260 and the fusion of connected clusters takes place (see inset of Fig.2B); (iii) for $\varepsilon \gtrsim$
261 $60 nm$ we expect to observe the coalescence of super- and non-connected clusters in
262 a second super-cluster regime; this is captured by a second exponential for $p_r \neq 0$
263 (Eq.4). Conversely, for $p_r = 0$, we observe a single super-cluster regime that is well
264 fitted by a Poissonian function with lower density (Eq.3), as it corresponds to the
265 density of clusters rather than emitters within clusters (see dark-green curve in Fig.2B).

266 Examination of Fig.2B (inset) highlights the exponential behaviour of the super-
267 cluster regime (ii) for different values of connectivity p_r . Importantly, a larger p_r results
268 in an effectively shorter decay length -- or larger spatial rate of merging -- for the
269 regime in which clusters merge into super-clusters. This strongly suggests that the
270 effective decay length (or rate) mirrors the connectedness of the underlying super-
271 structures (Fig.2C). In fact, these simulations reveal that the decay length represents
272 the combined contribution of clusters density ρ_{cl} and connectivity p_r . A larger density
273 of clusters can impact the decay length as much as a larger connectivity, as shown by
274 simulations at fixed p_r and different ρ_{cl} (Figs.2D, S2A and S2B). In particular, we find
275 that the functional form of the decay length is $\lambda \sim \rho_{cl}^{-1/2} p_r^{-0.3}$ (Figs.2D and E). The
276 cluster density contribution is $\sim \rho_{cl}^{-1/2}$ as it depends on the typical distance between
277 clusters and is relevant when comparing datasets with different cluster density. By
278 combining SuperStructure with a cluster analysis, one can estimate ρ_{cl} and normalise
279 λ to obtain the pure connectivity contribution in the decay length: $\lambda^* = \lambda / \rho_{cl}^{-1/2}$.

280 Finally, in order to characterise the contribution to the $N_c(\varepsilon)$ curves coming from
281 the density of localisations within the connections, we further simulated SMLM
282 datasets with a fixed, large connectivity p_r and varied the density of points in the
283 connections by tuning $p_{r_{conn}}$ (see simulated datasets in Fig.2A and Fig.S2F). As
284 expected, we observe a single super-cluster regime and the denser the connections
285 the shorter the decay length. This indicates that our algorithm is not only able to
286 describe how well clusters are connected, i.e. the number of connections per cluster,
287 but also how strongly they are connected, i.e. how dense the connections are. These
288 features are likely to be highly relevant for nuclear proteins.

289 Before applying this methodology to experimental data, we also tested the effect
290 of random noise in the system, i.e. unconnected isolated localisations from biological
291 or technical sources. We observed that in presence of random noise the decay of
292 SuperStructure curves becomes Poissonian for large ε (see Fig.S2C) with an effective
293 density ρ larger than the cluster density (see Fig.S2D). Decay lengths in the first super-
294 cluster regime (yellow regime) are still distinguishable even in presence of noise at
295 reasonable density (albeit smaller than the connection density), but their absolute
296 values are altered with weakly connected systems more severely affected (see
297 Fig.S2E). These observations suggest that, as in most analysis algorithms, large noise
298 might obscure exponential decays of connected systems. In case a single Poissonian

299 behaviour, or a combination of exponential and Poissonian decay, are found in the
300 SMLM dataset, it is therefore important to combine SuperStructure with an
301 independent cluster analysis at different lengthscales (for instance at 3 or 4 selected
302 values of ε) and a direct observation of the dataset, in order to exclude the presence
303 of hidden connectivity.

304

305

306 **Quantification of Super-Structures in Nuclear Proteins**

307

308 We now examine biological data and apply SuperStructure to dSTORM data acquired
309 for three different nuclear proteins (Fig.3A and B): the serine/arginine-rich splicing
310 factor SC35, the heterogeneous nuclear RiboNuclear Protein hnRNP-C and hnRNP-
311 U (also known as Scaffold Attachment Factor A, SAF-A). These proteins are
312 abundantly expressed in the nucleus of human cells and are involved with RNA
313 processing at different stages. SC35 is necessary for RNA splicing while hnRNPs are
314 implicated in regulation and maturation of mRNA but also in chromatin structure
315 (Nozawa et al., 2017; Xiao et al., 2012; Caudron-Herger et al., 2011). In particular,
316 SAF-A is thought to form a dynamic homogeneous mesh that regulates large-scale
317 chromatin organisation by keeping gene-rich loci in a decompacted state (Nozawa et
318 al., 2017; Michieletto and Gilbert, 2019). Hence, capturing the organisation of this
319 protein beyond the traditional single-cluster analysis is an important step towards
320 understanding how it regulates chromatin structure in different cell stages and
321 conditions.

322 Curves obtained from SuperStructure analysis after masking signal in the nuclear
323 region are shown in Fig.3C, where we highlighted the super-cluster regimes discussed
324 above. Global nuclear analysis is represented by filled curves, while analysis on
325 localised ROIs by dashed ones (hnRNP-C nuclear mesh and SC35 speckles). Both
326 hnRNPs display a first super-cluster regime for which the curves decay as
327 exponentials, suggesting that within this range distinct clusters are in reality
328 connected. Interestingly, while SAF-A displays a unique long super-cluster regime,
329 hnRNP-C seems to also show a second exponential regime (filled curve). However,
330 this regime appears at very large values of ε and is due to sparse clusters of
331 localisations in the nucleolus. Running SuperStructure on ROIs masking out the
332 nucleolus (dashed line) indeed generates a single exponential function, confirming
333 that hnRNP-C clusters are fully connected. We can therefore conclude that both
334 hnRNPs exhibit a single exponential regime, typical of fully connected meshes. On the
335 other hand, SC35 displays exponentials with different characteristic decay rates in two
336 distinct and significant super-cluster regimes (filled curve): one for intermediate $\varepsilon \in$
337 $[10,20] nm$, when clusters inside speckles merge (first super-cluster regime), and
338 another one for large $\varepsilon \in [40,150] nm$ indicating that speckles merge together and
339 with isolated clusters (second super-cluster regime). The SC35 connectivity is further
340 confirmed by running SuperStructure on ROIs masking the speckles, as we observed
341 a clear single exponential decay (dashed line). These regimes are further confirmed
342 by directly looking at the arrangement of identified clusters for certain values of ε (see
343 Fig.3A inset and 3B).

344 From the SuperStructure curves, we first obtained the density of intra-cluster
345 emitters by fitting the intra-cluster regime with the Poisson function (Eq.1).
346 Interestingly, both SAF-A and SC-35 form clusters with similar densities, while hnRNP-
347 C clusters are less dense (see Fig.3D and E). Then, in order to have a quantitative
348 description of the clusters/speckles connectivities, we fitted the curves in the

349 exponential regimes (Eq.4) to extract the decay length λ . However, a direct
350 comparison is possible only by normalising decay lengths by the cluster/speckle
351 density (see Methods for details and Fig.S3A and B). Fig.3F highlights that while
352 hnRNP-C has a short normalised decay length λ^* due to the highly connected clusters,
353 SAF-A displays a weaker decay (larger λ^*) due to sparser connections. Finally, SC35
354 displays one (intra-speckle) very connected, even more than that of hnRNPs (small
355 λ^*) followed by a regime (inter-speckle) that is much slower and so more weakly
356 connected than that of hnRNPs.

357 In summary, our analysis revealed that while different nuclear proteins may have
358 similar cluster sizes or densities of emitters within clusters (e.g., SAF-A and SC35)
359 they have distinct super-cluster arrangements and connectivities. For instance, we find
360 that the super-structures inside nuclear speckles are more connected than those
361 formed by hnRNPs and also denser (see Figs.3E, 3F and Table SI). We stress that
362 these features, which we further verified not emerging from technical artefacts (see
363 Fig.S3C), cannot be quantified using standard clustering algorithms or pair-correlation
364 functions. Additionally, the analysis in Fig.3E and F shows that our method is sensitive
365 enough to distinguish connectivity features of two closely related wild-type hnRNPs in
366 cell-based experiments.

367 The results presented in Fig.3 not only give us confidence that SuperStructure
368 can be applied to a variety of nuclear wild type or mutated proteins in different cells,
369 cell stages and conditions but that it also has the capability to extract unique features
370 that may yield new mechanistic insights into the functioning of such proteins. For
371 instance, the analysis of SC35 reveal that speckles are themselves made of clusters
372 that are as heavily inter-connected as the clusters formed by hnRNP proteins. Given
373 the fact that all these proteins interact with RNA, our findings suggest that RNA-binding
374 may facilitate the formation of connections between clusters of proteins; in turn, this
375 also points to a suspected structural role of non-coding RNAs in structuring the
376 organisation of the nuclear interior (Hall and Lawrence, 2016). Studying the effect of
377 RNA depletion on the super-cluster connectivity is therefore a natural next step to
378 perform in the future.

379 In general, while certain mutations or conditions may not alter the size of protein
380 cluster itself, they may affect the connectivity between clusters. In these cases, the
381 analysis provided by SuperStructure would be invaluable and indeed essential to
382 reveal the underlying mechanisms that guide the formation of such protein
383 assemblies.

384

385

386 **Ceramides clusters at the plasma membrane are not connected**

387

388 To test our algorithm on a different class of molecules, we applied SuperStructure on
389 published dSTORM datasets (Burgert et al., 2017) taken on ceramides -- membrane
390 lipids involved in cellular trafficking (Fig.4A). The authors (Burgert et al., 2017) found
391 that bSMase treatment increases the size of ceramides clusters and the overall
392 localisation density. By applying SuperStructure analysis (Fig.4B), we confirmed these
393 results and further detected that the difference in localisation density persists inside
394 clusters (see Figs.4C, 4D, S4C and S4D). Furthermore, we detected the absence of
395 connectivity between clusters, as the large ε regime is well-captured by a Poisson
396 function (Eq.3), and not by an exponential (see Fig.4B and E). In other words, clusters
397 of ceramides behave as unconnected, uniformly and randomly distributed emitters.
398 The possibility of local connectivities at intermediate ε has been also ruled out as no

399 merging of clusters was observed (see Fig.S4A and B). The crossing of the curves
400 at $\varepsilon \approx 25 \text{ nm}$ is a consequence of the overall difference in localisation density (which
401 in turn causes a horizontal shift between the curves, see Fig.4B inset and 4C), rather
402 than a difference in local connectivities. The notable absence of connections between
403 clusters of ceramides further supports that the ones detected in hnRNP-U/C and SC35
404 are significant.

405
406

407 **Limitations and potential interpretation pitfalls**

408

409 While we have provided evidence that SuperStructure can detect connected clusters
410 and distinguish them from noise (at low density) or unconnected but dense clusters,
411 in this section we discuss potential pitfalls and interpretation issues.

412 First, as mentioned earlier, datasets should always be segmented in order to
413 identify the main region of interest (ROI). Spurious localisations outside the ROI (for
414 instance outside of the nucleus, if we are interested in nuclear proteins) may affect the
415 curves generated by SuperStructure and render their interpretation difficult. An
416 analogous issue may arise if the localisations are embedded within heterogeneous
417 structures, as in the case of SC35 proteins which form strongly connected structures
418 within nuclear speckles and weakly connected outside (see Fig.3). Due to this mixed
419 behavior over similar length-scales it is recommended to restrict the analysis to
420 regions that display similar structural phenotypes. Even better, and to be preferred
421 when possible, is to label the region or structure of interest with orthogonal markers.

422 The key difference between connected and unconnected (albeit possibly more
423 clustered) structures is the functional form of the SuperStructure curves. However, in
424 some cases Poisson curves may be difficult to distinguish from exponentials
425 (especially over short intervals). In this case the best way to identify connected clusters
426 (and distinguish them from noisier or more clustered sub-regions) is to restrict the
427 analysis over smaller ROIs to clear potential contaminations and to additionally
428 perform goodness-of-fit tests on the curves. Additionally, in these complex cases we
429 also suggest to perform an independent cluster analysis over different length-scales
430 and to directly observe datasets distributions.

431 As with all computational algorithms, the danger of incorrect interpretation can
432 be addressed with quality control. In the case of SuperStructure this means directly
433 monitoring the formation of connected clusters/structures while increasing ε .
434 Nonetheless, thanks to its parameter-free execution, SuperStructure may offer one of
435 the safest ways to currently analyse SMLM data.

436
437

438 **Discussion**

439

440 In this work we have introduced a novel algorithm that extends the traditional idea of
441 cluster analysis of SMLM data and that can quantify both the connections between
442 clusters and the density of emitters within clusters. SuperStructure introduces for the
443 first time the concept of “connectivity” between clusters, which is different from a
444 random distribution of points at high density. In this concept, connection points are
445 preferentially found in between clusters and this feature manifests itself in
446 SuperStructure curves behaving as single exponentials rather than Poissonian.
447 Because SuperStructure is parameter-free, it does not require any prior knowledge of

448 the sample and it thus takes a crucial step towards a more standardised, portable and
449 democratic quantification of complex patterns and super-structures in SMLM data.

450 Here, we have tested the capabilities of SuperStructure first on simulated
451 datasets, where we observed that it could capture not only the degree of connectivity
452 between clusters, but also the strength of the connections, and then on biological
453 dSTORM data from nuclear proteins and membrane lipids. SuperStructure allowed us
454 to discover that the speckles formed by the splicing factor SC35 are made of
455 connected clusters. Further, that the density of emitters in those clusters is high and
456 the connectivity between clusters even higher than that of hnRNP proteins. We argue
457 that this may reflect the RNA-binding feature that characterises both hnRNPs and
458 SC35 and that may be driving the formation of inter-connected nuclear super-
459 structures. We highlight that this discovery could not be made simply by looking at
460 clustering with traditional algorithms, as both proteins display clusters of similar size
461 at small/intermediate ϵ .

462 We further stress that SuperStructure is perfectly suited to compare different
463 datasets without a priori assumptions (albeit, as discussed before, segmentation to
464 ROIs is recommended for strongly heterogeneous structures). The datasets of nuclear
465 proteins we chose to analyse are an example of this. SAF-A, hnRNP-C and SC-35 are
466 three nuclear proteins involved in the metabolism of RNA at different stages and they
467 display three different connectivity phenotypes, which point to three different nuclear
468 functions. In particular, SAF-A, which also plays a major role in maintaining the
469 chromatin active loci in a decompacted state, is detected as a fully connected mesh.
470 This finding is in agreement with a previous study that hypothesised the formation of
471 a dynamic and RNA-interacting nuclear mesh made by SAF-A (Nozawa et al., 2017).
472 We thus argue that SuperStructure is a useful tool for studying the structural and
473 functional properties of this nuclear mesh. For instance, we expect that in absence of
474 RNA, the SAF-A mesh would be disrupted and its connectivity strongly weakened (not
475 necessarily affecting the protein clusters, which may be formed via an RNA-
476 independent mechanism, such as phase separation by weak unspecific interactions
477 of SAF-A's intrinsically disordered domain). In turn, the application of SuperStructure
478 would in this case be indispensable for understanding the link between the spatial
479 arrangement, mechanics and function of this nuclear protein. A similar example is
480 given by the V(D)J locus, whereby interacting segments appear to be trapped by a
481 protein or chromatin network whose (super-)structure is still poorly understood
482 (Khanna et al., 2019). We argue that SuperStructure can shed light also on this
483 problem.

484 In addition to all this, super-resolved chromatin tracing (Boettiger et al., 2016;
485 Bintu et al., 2018) and ATAC-PALM (Xie et al., 2020) generate complex datasets that
486 will benefit from “beyond-traditional-clustering” algorithms. Connections between
487 nano-domains and chromatin paths, do not resemble the structure of isolated clusters,
488 but rather that of a mesh of clusters, which would be perfectly suited for quantification
489 via the SuperStructure algorithm.

490 The use of SuperStructure is not limited to biological applications, and we
491 propose it can be used as a standardised and parameter-free tool for assessing
492 imaging technical aspects (van de Linde and Sauer, 2014; Hennig et al., 2015). One
493 of the main issues in SMLM data, especially in dSTORM, is the evaluation of
494 fluorophore blinking quality, as it strongly affects the localisation accuracy in the
495 analysis process. For example, an elevated blinking frequency would result in a high
496 emitters density (per frame) and therefore in a high localisation inaccuracy due to
497 overlapping emissions. A similar detrimental effect could also be due to a poor blinking

498 signal (few emitted photons per blinking event). As a consequence, lower localisation
499 precision of emitters may create pseudo-clusters, as well as pseudo-connections. We
500 envisage that SuperStructure would be well suited to evaluate the blinking quality of
501 fluorophores, for instance by measuring the emerging pseudo-connectivity in a
502 controlled setup, such as fluorophores attached to a grid.

503 As discussed above, SuperStructure has been developed with the aim of going
504 beyond “simple clustering” and in particular to measure connectivity between clusters.
505 However, our method might be used in combination with other pair-wise distance and
506 clustering methods. For instance, one can compute Ripley’s (pair-wise distance)
507 functions to preliminarily detect if localisations are uniform or clustered and, in case,
508 what is the average cluster radius. Yet, Ripley’s functions cannot identify single
509 clusters or complex structures. Thus, one could use SuperStructure to determine
510 whether the system under investigation displays connected or isolated clusters. At the
511 same time, by computing SuperStructure curves, one can have a firm ground to decide
512 the value of ε that can be used as input in DBSCAN for cluster analysis. This second
513 approach can be used, for example, to measure the size or shape of local super-
514 structures. Indeed, one can fix ε at the value that identifies super-structures, perform
515 a cluster analysis and calculate the gyration tensor of the identified clusters.

516 We tested the segmentation capabilities of the latter approach by estimating the
517 radius and circularity of SC35 speckles; we observed that it yields similar results as
518 the well-known SR-Tesseler software (Levet et al., 2015) (see Fig.S5). Albeit
519 SuperStructure lacks a Graphical User Interface, it has several advantages. Firstly,
520 the analysis is OS-independent and can be easily automatised to run on a large
521 number of cells. Secondly, since based on DBSCAN, the algorithm scales as $n_\varepsilon N^2$ in
522 its simplest implementation (where n_ε is the number of ε values used in the analysis
523 and N the total number of localisations). Yet, calculations on different ε are
524 independent and so SuperStructure scales extremely well with the number of CPUs
525 available. For instance, the analysis of $n_\varepsilon = 100$ values and 10^5 localisations can be
526 done on a 6-core CPUs machine in about 19 minutes. Thirdly, since our algorithm is
527 aimed at extracting “beyond-simple-clustering” information, it is flexible and intended
528 to be used in combination with other pair-correlation or segmentation methods that are
529 extensively employed for single-clustering analysis.

530 We conclude highlighting that SuperStructure provides an unbiased and
531 parameter-free estimation of (i) density of localisations within single clusters and (ii)
532 formation of super-structures made of connected clusters. Here we tested
533 SuperStructure both on in simulated and cell-based SMLM datasets. Importantly, we
534 revealed previously undocumented system-spanning structures made of connected
535 clusters of nuclear proteins that we argue may have a functional role in shaping
536 genome organisation. The use of SuperStructure on cells under different conditions or
537 with protein mutations is thus an exciting direction to uncover the biological
538 significance of these newly discovered nuclear structures.

544

545

546 Material and Methods

547

548 SuperStructure algorithm

549

550 SuperStructure is an algorithm that detects and quantifies super-structures formed by
551 inter-connected clusters on SMLM datasets. Additionally, it can also evaluate the
552 density of emitters inside clusters.

553 SuperStructure is mainly based on DBSCAN, a density-based algorithm to detect
554 clusters of points in arbitrary dimensional space. The key concept underlying DBSCAN
555 scheme is that it groups together points at high density, while it marks as outliers points
556 in low density regions. After defining a neighbourhood size ε , a point x can be part of
557 a cluster if the number of points $N(\varepsilon, x)$ within a circular region $\Omega(\varepsilon, x)$ of size ε centred
558 in x , exceeds some threshold N_{min} (or is within the region $\Omega(\varepsilon, y)$ of another point y
559 satisfying this condition).

560 The concept of clusters is subject to the choice of ε and N_{min} and therefore to
561 some sort of likeness or proximity. Furthermore, the *change* in number of clusters
562 detected by DBSCAN when varying ε contains some information of the underlying
563 distribution of points that has been overlooked.

564 SuperStructure progressively runs DBSCAN to detect the number of clusters N_c
565 within a broad range of the neighbourhood parameter ε , while N_{min} is kept fixed. The
566 resulting $N_c(\varepsilon)$ curves, and in particular the change $dN_c(\varepsilon, N_{min})$ due to a small change
567 in neighbourhood parameter $d\varepsilon$, contain fundamental information about the formation
568 and organisation of super-structures and connected clusters.

569 As we aim for a parameter free algorithm, without losing generality, we fix $N_{min} =$
570 0, which means no minimum number of other emitters necessary in the neighbourhood
571 to define a localisation as part of a cluster. For $\varepsilon = 0$, any point is found to be a cluster
572 by itself. Then, points merge upon increasing $\varepsilon \rightarrow \varepsilon + d\varepsilon$, resulting in $dN_c/d\varepsilon \leq$
573 $0 \forall \varepsilon$. Additionally, the larger $|dN_c/d\varepsilon|$, the more identified clusters are coalescing
574 together for a certain ε .

575 At ε smaller than the typical (true, rather than the one detected by DBSCAN)
576 cluster size, the decay of $dN_c/d\varepsilon$ is determined by the intra-cluster density of points
577 ρ_{em} (intra-cluster regime), as they are the points at the highest density. The decay of
578 this regime is gaussian and it is described by the Poisson Function:

579

580

$$N_c(\varepsilon) = \sum_{k=0}^m c_k \frac{(\pi\rho_{em}\varepsilon^2)^k}{k!} e^{-\pi\rho_{em}\varepsilon^2} \quad (1)$$

581

582 In order to understand the origin of this functional form, let's imagine to apply
583 SuperStructure algorithm by setting $N_{min} = 0$ and by increasing the radius ε . For
584 sufficiently small ε , every point is considered as a single cluster itself, as no other
585 points are detected in its neighbourhood. However, by increasing ε , the probability of
586 finding another point in the neighbourhood increases, implying that points start to
587 merge in bigger clusters for small ε . It is then legitimate to argue that the number of
588 detected clusters N_c decreases (with ε) as the probability of not finding any other
589 emitter in the neighbourhood. This is the so-called Poisson Avoidance Function
590 $N_c(\varepsilon) = P(n(\varepsilon) = 0) = e^{-\pi\rho_{em}\varepsilon^2}$ and it is a good approximation for very small ε , where
591 the contribution of clusters formed by 2 emitters dominates over clusters formed by 3

592 or more points. For larger ε , this function underestimates the number of detected
 593 clusters. The number of detected clusters can therefore be described by the probability
 594 of not finding more than m particles in the circle of radius ε . The function we are
 595 seeking is the linear combination of the probabilities of not finding any other point in
 596 the neighbourhood and finding one or more other points (up to $m - 1$). Being the
 597 probability of finding k particles $P(n(\varepsilon) = k) = \frac{(\pi \rho_{em} \varepsilon^2)^k}{k!} e^{-\pi \rho_{em} \varepsilon^2}$, it is then
 598 straightforward to get the functional form of Eq.1.

599 Note that $c_k = 1/(k + 1)$ in Eq.1 is to avoid overcounting clusters. In fact, if we
 600 consider two points within distance ε from each other (and hence in the same cluster),
 601 both points will count towards $P(n(\varepsilon) = 1)$ so this contribution must be divided by 2,
 602 etc. Importantly, Eq.1 displays a natural length-scale $\kappa_0 = (\pi \rho_{em})^{-1/2}$ that is
 603 intrinsically determined by the internal density of emitters ρ_{em} . Therefore, ρ_{em} is a
 604 parameter that can be quantified by fitting the $N_c(\varepsilon)$ curve and it can also be used to
 605 quantify the approximate upper limit of this regime (with 99% confidence level):
 606

$$\varepsilon^* \simeq 3\kappa_0 = 3/\sqrt{\pi \rho_{em}} = 3R_{cl}/\sqrt{N_{em}} \quad (2)$$

607 where R_{cl} is the average cluster radius and N_{em} is the average number of localisations
 608 within a single cluster. We successfully tested that SuperStructure curves are well-
 609 fitted by Eq.1 up to $m = 2$ using a system where we simulated localisation of points
 610 inside a single cluster (see Fig.S1).
 611

612 At ε of the order than the typical (true) cluster size, the decay is determined by
 613 the rate at which distinct clusters merge upon $\varepsilon \rightarrow \varepsilon + d\varepsilon$ (first super-cluster regime).
 614 This merging can be either due to (i) distinct clusters starting to overlap as their
 615 distance is smaller than ε or (ii) the presence of points -- which we call "connections"
 616 -- bridging two clusters. In case of total absence of connectivity and a homogeneous
 617 clusters distribution, the merging is only due to the random positioning of clusters and
 618 therefore it also follows a Poisson Function:
 619

$$N_c(\varepsilon) = f \sum_{k=0}^m c_k \frac{(\pi \rho_{cl} \varepsilon^2)^k}{k!} e^{-\pi \rho_{cl} \varepsilon^2} \quad (3)$$

620 where f is a normalisation factor and ρ_{cl} the density of clusters. We observed that
 621 SuperStructure curves of simulated systems are well-fitted by using $m = 1$. This
 622 equation holds also in presence of noise, but in that case $\rho_{cl} \rightarrow \rho_{cl} + \rho_{noise}$ (see
 623 Fig.S2). The decay is different in presence of connections between clusters:
 624 connected clusters will merge at smaller ε than unconnected ones (assuming same
 625 distance between the centres of clusters). In particular, the larger the number of
 626 connections or of the local density of connection points ρ_{conn} (i.e. thicker connections),
 627 the faster the merging of bridged clusters as a function of ε and thus the larger
 628 $|dN_c/d\varepsilon|$. The functional form of this second regime is exponential in presence of
 629 connections:
 630

$$N_c(\varepsilon) = g \cdot e^{-\varepsilon/\lambda} \quad (4)$$

632 where g is a normalisation factor and λ the decay length quantifying the rate of decay,
 633 and therefore the connectivity. This decay length can be used to discern systems that
 634 exhibit either different grades of connectivity or homogeneous meshes at different
 635

636 densities. Note λ purely quantifies the connectivity only when the cluster density ρ_{cl} is
637 small and homogeneous, as we could have underlying highly dense clusters
638 overlapping and therefore merging. We showed that $\lambda \sim \rho_{cl}^{-1/2}$ and therefore the pure
639 connectivity decay length can be further evaluated if the density of clusters is known:
640 $\lambda^* \sim \lambda/\rho_{cl}^{-1/2}$.

641 We need to stress that by choosing $N_{min} = 0$ connections will also be considered as
642 points to be merged. However, it is important that we identify “connection” points as
643 having a lower local density ρ_{conn} than the groups of points that are bridged by them
644 (clusters). In this way, they will merge in this second regime to form super-structures.
645 The limiting case in which the local density of connection points is the same as the
646 one in the clusters at the two ends of the connections is indistinguishable from the
647 case of one elongated cluster. A special case is that in which both clusters and
648 connections have the same density of points, but the connections are slightly detached
649 from the clusters, thus forming three independent clusters at intermediate ε which may
650 then merge (we assume this to be a rare event). The above reasoning can be
651 extended to multiply connected clusters via the analysis of pair-wise connections.

652 At larger ε , we could have additional super-clusters regimes if the system is
653 heterogeneous. Most common cases showing two (or more) super-cluster regimes are
654 the following: (1) inhomogeneous system displaying different connectivities at different
655 lengthscales, (2) connected clusters embedded in a noisy environment (in this case
656 we observe an exponential followed by a poissonian decay) and (3) unconnected
657 clusters within a random noise and/or unconnected clusters at different densities (in
658 this case we observe two or more poissonian decays).

659

660

661 **SuperStructure Pipeline**

662

663 In order to apply SuperStructure, we adopt the following steps:

664

665 *1. Generation of SuperStructure curves.* We run SuperStructure on a SMLM dataset
666 by first masking our data in the region of interest (ROI), such as the nucleus for nuclear
667 proteins as mentioned in the section below. Then, we choose a ε -range to analyse.
668 For example, in SMLM datasets of nuclear proteins a typical choice is $\varepsilon \in [0: 200] \text{ nm}$
669 with $d\varepsilon = 2 \text{ nm}$. One should notice that lower $d\varepsilon$ may be necessary for fitting the intra-
670 cluster regime. SuperStructure curves are generated by progressively running
671 DBSCAN clustering algorithm on the SMLM dataset in the chosen ε -range (and
672 $N_{min} = 0$). The DBSCAN software we use is from <https://github.com/qyaikhom/dbscan>
673 and the progressive run is performed with bash scripts available in the repository.
674 SuperStructure output curves are saved in a three-columns file ($\varepsilon, N_{cl}, N_{cl}/N_{loc}$), where
675 N_{cl} is the number of detected clusters for the corresponding ε and N_{loc} the number of
676 total localisations. Additionally, the classification of localisations in clusters is saved
677 on a separate file for every ε .

678

679 *2. Evaluation of SuperStructure regimes.* As a second step, we evaluate regimes by
680 plotting and investigating SuperStructure curves (we adopt a log-scale in the y-axis).
681 This step includes a preliminary check for the number of regimes and their decay
682 behaviour (exponential vs. poissonian). In the case we observe a single Poissonian
683 behaviour, we can state that the dataset does not show any, or very limited,
684 connectivity, and therefore we are in presence of homogeneous isolated clusters (and

685 eventually noise). Limited connectivity needs to be checked with a cluster analysis and
686 direct dataset observation in case noise has obscured an exponential decay. On the
687 other hand, if we observe a single exponential regime (a straight line in a log-linear
688 plot) we conclude that the system is made of fully connected clusters. If
689 SuperStructure curves show multiple super-cluster regimes, it is likely that the system
690 is heterogeneous. Indeed, multiple exponential regimes may reflect
691 heterogeneous/multi-scale connectivities combined with heterogeneous distributions
692 of clusters. Alternatively, we may find also a combination of exponential and
693 poissonian regimes and in this case the system may be made of connected clusters
694 embedded in a noisy region. Other more complex combinations may be possible;
695 however, one should notice that in heterogeneous systems it might be difficult to
696 recognise and fit super-cluster regimes. To clarify these contributions, it is useful to
697 combine the analysis of SuperStructure curves with a direct observation of the dataset
698 and identified structures and to run SuperStructure on smaller ROIs to analyse
699 different regions of the sample with similar structural phenotypes. Nonetheless,
700 SuperStructure will be able to unambiguously detect differences in connectivity and
701 behaviours in, e.g., samples that have been subjected to different conditions or
702 expressing mutated proteins.

703
704 *3. Fit of SuperStructure regimes.* Once regimes have been identified, one needs to
705 define the boundaries where regimes crossover from one to another. This can be
706 either done manually or by using a pre-emptive goodness-of-fit test (this procedure
707 would also define fitting ranges). The intra-cluster regime is typically fitted with a
708 Poisson Equation (Eq.1) to evaluate the density of emitters inside clusters as well as
709 to obtain an estimation of the upper limit of the intra-cluster regime (using Eq.2). For
710 super-cluster regimes, we use Eq.3 if they show a Poissonian decay (curved on a log-
711 linear plot) or Eq.4 if they otherwise appear straight on a log-linear plot; from the latter,
712 we quantify the connectivity parameter λ . We can then additionally calculate the
713 cluster density ρ_{cl} to extract the pure connectivity part $\lambda^* = \lambda/\rho_{cl}^{-1/2}$. The cluster
714 density ρ_{cl} can be computed by performing a cluster analysis with DBSCAN on local
715 circular regions representative of that decay regime and by fixing ε at the start of that
716 regime. For instance, by counting the number of clusters one obtains by fixing ε at the
717 beginning of the yellow area in Fig.3. In the section below and in Fig.S3, we describe
718 in detail the procedure for λ normalisation for the nuclear proteins' datasets. Finally,
719 and optionally, it is also possible to define a single function fitting the entire curve by
720 either (a) defining a piecewise function where every "piece" is the fit of the
721 corresponding regime or (b) adding together the contribution of the different regimes
722 (appropriately weighted). We performed fits with a combination of bash and gnuplot
723 scripts available in the repository.

724
725

726 **Simulated datasets generation and SuperStructure analysis**

727

728 The simulated dataset consists of spatially homogeneous and interconnected clusters
729 randomly distributed on a plane. We set to work with clusters made by taking random
730 clusters centres on the plane and by sampling $N_{em} = 80$ emitters within a Gaussian of
731 standard deviation $\sigma_{em} = 20\text{ nm}$, thereby setting the cluster radius to $R_{cl} = 2\sigma_{em} =$
732 40 nm with a 95% confidence and the intra-clusters emitters density at $\rho_{em} =$
733 $16000\ \mu\text{m}^{-2}$. The clusters are positioned in a $L = 3.5\ \mu\text{m}$ large area and their number
734 N_{cl} is varied in order to consider different clusters densities. In the example shown in

735 the main text, we fixed $N_{cl} = 100$ thus fixing a cluster density to about $\rho_{cl} = 8.2 \mu m^{-2}$
736 roughly similar to the values found in experiments for some nuclear proteins. Pairs of
737 clusters are connected with probability p_r if they are positioned closer than a distance
738 $b = 1 \mu m$. The value of p_r is calculated as the ratio between the actual drawn
739 connections and $N_{cl}(N_{cl} - 1)/2$, which is the maximum possible connections (i.e.
740 when every cluster is connected with every other cluster). In order to generate a single
741 connection, we considered the vector joining the centres of two clusters and sampled
742 one emitter with probability $p_{r_{conn}}$ every $10 nm$. Emitters are sampled from a 2D
743 gaussian centred on the vector connecting the two clusters centres and with a width
744 $\sigma_{conn} = 10 nm$. In the main text we fixed $p_{r_{conn}} = 0.5$. Note that p_r controls the number
745 of connections, while $p_{r_{conn}}$ their density ρ_{conn} . We generated at least 20 independent
746 replicas for each simulated dataset using a combination of bash and python scripts,
747 then we run SuperStructure analysis in the range $\varepsilon \in [0:400] nm$ with a change $d\varepsilon =$
748 $2 nm$. If not differently specified, the first super-cluster regime was fitted with Eq.4 for
749 $\varepsilon \in [15:60]$, while the second super-cluster regime either with Eq.3 (unconnected
750 systems) or Eq.4 (connected systems) for $\varepsilon \in [70:300]$.

751

752

753 **Experimental details for generating experimental dSTORM dataset for SAF-A,** 754 **hnRNP-C and SC-35**

755

756 *Cells Preparation for dSTORM imaging.* hTERT-RPE1 cells (ATCC, cat# ATCC-CRL-
757 4000) were grown overnight in an 8-well Lab-Tek II Chambered Coverglass -- 1.5
758 borosilicate glass (Thermofisher scientific) at 37 degrees at initial concentration of
759 $10^5 cells/ml$ in $400 \mu l$ ($\sim 40\%$ confluency). We fixed the cells with 4% PFA (Sigma-
760 Aldrich) for 10 minutes, followed by wash in PBS, permeabilisation with 0.2% Triton X-
761 100 (Sigma-Aldrich) for 10 minutes, washed in PBS again and blocked with 1% BSA
762 (Sigma-Aldrich) for 10 minutes.

763 Immuno-fluorescence labelling was done by exposing the cells for 2 hours to (i)
764 hnRNP-U polyclonal rabbit antibody (A300-690A, Bethyl Laboratories) at $10 \mu g/ml$ or
765 (ii) hnRNP-C1/C2 (4F4) mouse monoclonal antibody (sc-32308, Santa Cruz
766 Biotechnology) at $0.2 \mu g/ml$ or (iii) SC-35 mouse monoclonal antibody (ab11826,
767 abcam) at $2 \mu g/ml$ and then washed. Then, cells were exposed for 1 hour to
768 secondary antibody. The secondary antibody was made by AffiniPure $F(ab')_2$
769 Fragment Donkey Anti-Rabbit or Donkey Anti-Mouse IgG (H+L) (711-006-152 and
770 715-007-003, Jackson ImmunoResearch Europe Ltd) conjugated to the organic
771 fluorophore CF647 (92238A-IVL, Sigma-Aldrich) at a stechiometric ratio of about 1.

772 Oxygen scavenger imaging buffer for dSTORM was prepared fresh on the day and
773 the recipe employed was similar to that of (McSwiggen et al., 2019). We mixed (i)
774 $5.3 ml$ of $200 mM$ Tris and $50 mM$ NaCl solution with (ii) $2 ml$ of 40% glucose solution,
775 (iii) $200 \mu l$ of GLOX, (iv) $1.32 ml$ of $1M$ 2-mercaptoethanol (Sigma-Aldrich) and (v)
776 $100 \mu l$ of $50 \mu g/ml$ DAPI solution (Sigma-Aldrich). The GLOX solution was made by
777 mixing $160 \mu l$ of $200 mM$ Tris and $50 mM$ NaCl with $40 \mu l$ of catalase from bovine liver
778 (Sigma-Aldrich) and $18 mg$ of glucose oxidase (Sigma-Aldrich).

779 The $8.9 ml$ final solution was enough to fill the chambers of the 8-well dish; a
780 coverglass was sealed at the top of the dish to prevent inflow of oxygen.

781

782

783 *dSTORM Acquisition.* We performed 3D-STORM acquisitions using a Nikon N-
784 STORM system with Eclipse Ti-E inverted microscope with laser TIRFilluminator
785 (Nikon UK Ltd, Kingston Upon Thames, UK). We equipped the microscope with a CFI
786 SR HP Apo TIRF 100x objective lens (N.A. 1.49) and applied a 1.5X additional optical
787 zoom. We also used a cylindrical astigmatic lens to obtain elliptical shapes for emitters
788 that reflect their z-position (Huang et al., 2008). Laser light was provided via a Nikon
789 LU-NV laser bed with 405, 488, 561, 640 nm laser lines. In particular, CF647
790 fluorophores were stochastically excited using the 640 nm laser beam with an
791 additional 405 weak pulse. Images were acquired with an Andor iXon 897 EMCCD
792 camera (Andor technologies, Belfast UK). The Z position was stabilised during the
793 entire acquisition by the integrated perfect focus system (PFS). Acquisition were
794 performed at room temperature.

795 For every nucleus, we acquired a stack of 20000 frames at 19 ms exposure time by
796 using the Nikon NIS-Element software. Acquired images have a 256 x 256 pixel
797 resolution with pixel size equal to 106 nm. For every condition (SAF-A, hnRNP-C,
798 SC35) we acquired 6 nuclei, i.e. 6 independent datasets.

799

800

801 *Raw images and post-processing analysis.* The raw stack of frames was initially
802 segmented based on a DAPI marker to carefully mask out the extra-nuclear signal.
803 Then, frames were analysed using FIJI (Schindelin et al., 2012) and in particular the
804 Thunderstorm plugin (Ovesný et al., 2014). Firstly, we filtered them by using Wavelet
805 functions to separate signal from noise. The B-Spline order was set to 3 and the B-
806 Spline scale to 2.0 as suggested in (Ovesný et al., 2014) for localisations of around
807 5 pixels size. In order to localise the emitters centroids, we thresholded filtered images
808 (threshold value was set 1.2 times the standard deviation of the 1st Wavelet function)
809 and calculated the local maximum relative to the 8 nearest neighbours. Finally, we
810 fitted the emitters signal distribution with elliptical gaussians (ellipses are necessary
811 for z-position reconstruction) using the weighted least square method and by setting
812 3 pixels as initial fitting radius and 1.6 pixels as initial sigma.

813 Localised data was then post-processed using the same plugin. (i) We corrected the
814 XY drift using a pair correlation analysis, (ii) filtered data with a position uncertainty <
815 40 nm, (iii) restricted the z-position to the interval [-100: 100] nm and projected the
816 data in a 2-dimensional plane, as the z-axis precision is around 100 nm.

817 Reconstructed images shown in the main text were created by using the average
818 shifted histograms method of the same plugin with a 10X magnification (10.6 nm/
819 pixel).

820

821

822 **SuperStructure analysis of nuclear protein data**

823

824 SuperStructure analysis was run on the entire nuclear region by setting $N_{min} = 0$ and
825 by increasing ε in the range [0: 200] nm and “all-nucleus” curves were generated for
826 6 independent nuclei. We set change rate $d\varepsilon = 0.25$ nm for $\varepsilon \in [0: 10]$ nm and $d\varepsilon =$
827 10 nm for $\varepsilon \in [10: 200]$ nm. This choice was due to the higher resolution necessary to
828 extract intra-cluster information at small ε . As shown in Fig.3, SuperStructure “all-
829 nucleus” curves show that SAF-A has a single exponential super-cluster regime, while
830 hnRNP-C and SC35 have two regimes. In the hnRNP-C case, the second regime is
831 due to weakly connected and sparse clusters in nucleoli, while in SC35 to the
832 cluster/connectivity heterogeneity in the system (i.e. speckles). Therefore, we

833 additionally run SuperStructure analysis on local regions of interest (ROIs) for hnRNP-
 834 C and SC35 to obtain the isolated contribution for the first super-cluster regime. In
 835 particular for hnRNP-C we considered 5 independent circular ROIs per nucleus with
 836 radius $r = 1.5 \mu m$ within the nuclear mesh; for SC35, we considered 5 independent
 837 circular ROIs per nucleus with radius $r = 0.5 \mu m$ within speckles. We run the analysis
 838 on these ROIs and generated SuperStructure “local” curves (5 for each nucleus).
 839 The values of the intra-cluster density ρ_{em} were extracted by fitting with Eq.1 the intra-
 840 cluster regime in the “all-nucleus” curves in the range $\varepsilon \in [0,3] nm$. Resulting average
 841 values are: $\rho_{em}^{hnRNP-C} = 7973 \pm 1732 \mu m^{-2}$, $\rho_{em}^{SAF-A} = 16998 \pm 2444 \mu m^{-2}$ and
 842 $\rho_{em}^{SC35} = 18680 \pm 1520 \mu m^{-2}$.
 843 Then, we identified the super-cluster regimes of interest: the first super-cluster
 844 regimes of SAF-A and hnRNP-C, and both super-cluster regimes of SC35 (SC35-1
 845 and SC35-2). For SAF-A and SC35-2, the decay length λ was obtained by fitting “all-
 846 nucleus” curves with Eq.4. For hnRNP-C and SC35-1 instead, we fitted the “local”
 847 curves (5 curves per nucleus) and then we averaged λ values obtained from different
 848 “local” curves in the same nucleus. Fit ranges are $\varepsilon \in [16,100] nm$ for SAF-A, $\varepsilon \in$
 849 $[14,70] nm$ for hnRNP-C, $\varepsilon \in [8,20] nm$ for SC35-1 and $\varepsilon \in [40,150] nm$ for SC35-2.
 850 Finally, the values of λ for SAF-A, hnRNP-C, SC35-1 and SC35-2 were normalised by
 851 the cluster density: $\lambda^* = \lambda / \rho_{cl}^{-1/2}$. In the case of SAF-A and SC35-2, the normalisation
 852 was performed for λ for every nucleus by using the average cluster density ρ_{cl} of that
 853 nucleus. In particular, ρ_{cl} was calculated as the average of the cluster density in 5
 854 independent circular regions of radius r in the same nucleus as shown in the example
 855 of Fig.S3A. In the case of hnRNP-C and SC35-1 where λ values were obtained from
 856 “local” curves, the normalisation of λ was performed using the cluster density of the
 857 same local region; then λ^* values obtained from different regions in the same nucleus
 858 were averaged (see Table SI). The number of clusters estimation (to calculate the
 859 cluster density) was made with DBSCAN by setting $N_{min} = 0$ and ε close to the
 860 beginning of the exponential regime of interest, as shown in Fig.S3B, and by keeping
 861 only clusters with at least 30 particles. In order to compute the cluster density, for SAF-
 862 A and hnRNP-C we set local circular regions of radius $r = 1.5 \mu m$ and fixed $\varepsilon = 20 nm$
 863 for cluster analysis (for hnRNP-C the same local regions as defined above). For SC35,
 864 we considered two sets of local regions: (i) inside speckles to normalise the shorter
 865 decay length where we used ROIs with radius $r = 500 nm$ and fixed $\varepsilon = 10 nm$ for
 866 cluster analysis (same regions as above); (ii) outside speckles to normalise the longer
 867 decay length, where we used ROIs with radius $r = 1.5 \mu m$ and $\varepsilon = 40 nm$ for cluster
 868 analysis. Average nuclear values of λ , ρ_{cl} and λ^* are shown in Table SI.

869

870

871 SuperStructure analysis of ceramides data

872

873 SuperStructure analysis was run on the two ceramides datasets provided by the
 874 authors of (Burgert et al., 2017), namely +bsMase and -bsMase, by setting $N_{min} = 0$
 875 and $\varepsilon \in [0:200]$. We set $d\varepsilon = 0.5 nm$ for $\varepsilon \in [0:10] nm$ and $d\varepsilon = 2 nm$ for $\varepsilon \in$
 876 $[10:200] nm$. This choice was due to the higher resolution necessary to extract intra-
 877 cluster information at small ε . From the curves in Fig.4B, it is clear that there is not any
 878 strong connectivity (we observe a Poissonian decay). Therefore, we identified free
 879 unclustered emitters as noise. We have additionally run SuperStructure in 16
 880 independent local circular regions of radius $r = 1.5 \mu m$ to extract the quantities of
 881 interest. In particular, we measured the average densities of total localisations: $\rho_{loc}^+ =$

882 $595 \pm 130 \mu m^{-2}$ and $\rho_{loc}^- = 475 \pm 87 \mu m^{-2}$, respectively for + and - bsMase treatment.
883 This is in accordance with results in the original paper. Then, we fitted “local”
884 SuperStructure curves in the intra-cluster regime with Eq.1 for $\varepsilon \in [0:3] nm$: $\rho_{em}^+ =$
885 $22391 \pm 3306 \mu m^{-2}$ and $\rho_{em}^- = 15505 \pm 3470 \mu m^{-2}$ respectively for + and -bsMase
886 treatments. Finally, we fitted “local” SuperStructure curves in the super-cluster regime
887 with Eq.3 in the range $\varepsilon \in [50:200] nm$ for +bsMase and $\varepsilon \in [60:200] nm$ for -bsMase
888 (the difference in fit starting value is explained by the two curves horizontal shift): $\rho_{sc}^+ =$
889 $62.01 \pm 20.76 \mu m^{-2}$ and $\rho_{sc}^- = 43.56 \pm 11.05 \mu m^{-2}$. These values are in accordance
890 with the sum of cluster density and noise at the ε -value where the fit starts. We have
891 additionally performed a cluster analysis with DBSCAN and results are in agreement
892 with the original paper results (see Fig.S4 for details). In order to verify that there is
893 not any limited connectivity hidden by noise, we performed a cluster analysis also at
894 two different values of ε and monitored the change in density of clusters and density
895 of free emitters (see Fig.S4 for details).

896

897

898 Online Supplemental Material

899

900 **Table.SI** recapitulates values for λ , ρ_{cl} and λ^* in nuclear proteins data. **Fig.S1** shows
901 a simulated distribution of points inside a single cluster and how it is well represented
902 by Eq.1 in Methods. **Fig.S2** shows SuperStructure curves (or decay lengths) for
903 simulated datasets in different conditions: **(A)** different p_r and doubling the typical
904 cluster density; **(B)** different values of cluster density; **(C)** different p_r without and with
905 noise addition; **(D)** unconnected clusters with noise at different densities; **(E)** decay
906 lengths of the first super-cluster regime for different connectivities p_r as function of
907 noise density; **(F)** homogeneous mesh (high p_r) and different values of connection
908 density (controlled by $p_{r_{conn}}$). **Fig.S3 (A)-(B)** shows how the normalisation of λ was
909 performed in nuclear protein data (exhaustively explained in Methods); **(C)** shows that
910 nuclear proteins connectivity is not a technical artefact. **Fig.S4** shows that there is no
911 local connectivity in ceramides data and confirms original paper results on ceramides
912 cluster size. **Fig.S5** shows SuperStructure + DBSCAN segmentation capabilities by
913 estimating the radius and circularity of SC35 speckles alongside SR-Tesseler
914 software.

Figure 2. Evaluating SuperStructure on simulated datasets. **A.** Sketch representing the artificial dataset consisting of inter-connected clusters of localisations on a 2D plane. Clusters are characterised by an internal density of localisations ρ_{em} and radius R_{cl} and are randomly distributed on the plane at an average cluster density ρ_{cl} . Clusters can be connected by a sparse point distribution with probability p_r and connections have a density of points ρ_{conn} (controlled by the $p_{r,conn}$ parameter). **B.** Average SuperStructure curves (zoomed in the inset) for simulated datasets with different connectivity p_r . Other parameters are kept fixed: average cluster radius $R_{cl} \approx 40 \text{ nm}$, emitters density within clusters $\rho_{em} =$

1020 $16000 \mu\text{m}^{-2}$, cluster density $\rho_{cl} = 8.2 \mu\text{m}^{-2}$ and $p_{r_{conn}} = 0.5$ (which fixes the density of emitters within
1021 connections ρ_{conn}). The curves show the number of detected clusters normalised by the total number
1022 of localisations. Curves are the average of 20 independent simulated datasets. Shaded regions
1023 represent the standard deviation from the average. Three regimes can be distinguished: (i) intra-cluster
1024 (red), (ii) first super-cluster (yellow) and (iii) second super-cluster regime (blue). The decay in the intra-
1025 cluster regime corresponds to a Poisson avoidance function with density parameter $\rho_{em} = 16000 \mu\text{m}^{-2}$
1026 (Eq.1, dotted line in the inset). The first super-clusters regime can be fitted by a single exponential
1027 (Eq.4, dashed line in the inset) which returns an effective decay length λ . The second super-cluster
1028 regime can be fitted with another exponential if $p_r \neq 0$ (Eq.4, dashed line in the main figure). In case of
1029 $p_r = 0$, there is only one super-cluster regime and it follows a Poisson function with density parameter
1030 $\rho_{cl} = 8.2 \mu\text{m}^{-2}$ (Eq.3, dotted line in the main figure). **C.** Snapshots of detected clusters for an artificial
1031 dataset with connectivity $p_r = 0.004$ and by progressively increasing the value of the radius $\varepsilon =$
1032 $4, 24, 44, 84 \text{ nm}$. **D.** Decay length λ versus cluster density ρ_{cl} scales as $\rho_{cl}^{-0.5}$ for any value of connectivity
1033 p_r . **E.** Decay length λ versus connectivity p_r scales as $p_r^{-0.3}$ for different values of ρ_{cl} . In **(D)** and **(E)** 20
1034 independent datasets were fitted with Eq.4 and the resulting λ values were averaged. Vertical bars
1035 represent the standard deviation from the average.

Figure 3. Application of SuperStructure algorithm to SAF-A, hnRNP-C and SC35 super-resolution data. **A.** Reconstructed dSTORM images by using the shifted histograms method with a pixel size of 10.6 nm . Insets of $4 \mu\text{m}^2$ size of reconstructed dSTORM images and spatial positions of the data. Palettes represent the cluster id computed by running SuperStructure with $N_{min} = 0$ and ϵ at the start of the first super-cluster regime. **B.** Identified clusters for increasing values of ϵ in the regimes where clusters merge. **C.** Normalised average SuperStructure curves in the range $[0; 150] \text{ nm}$. The number of detected clusters has been normalised with the total number of localisations in the system. The average is calculated over 6 independent datasets (nuclei). Solid curves: SuperStructure analysis was run on the entire nucleus and the resulting curves for the 6 independent datasets were averaged (“all-nucleus” curves). Dashed curves: SuperStructure analysis was run in 5 local regions of interest (ROIs) for each of the 6 nuclei, then the curves of each region (for each nucleus) were averaged (“local” curves). In hnRNP-C these local regions were chosen within the nuclear mesh (to exclude nucleoli) and in SC35 within speckles. Vertical dashed lines highlight different SuperStructure regimes: intra-cluster, first super-cluster and second super-cluster regimes. For SAF-A and hnRNP-C the exponential regime of clusters merging (first super-cluster regime) is highlighted with a solid straight line. In case of SC35, two regimes are highlighted: the merging of clusters within speckles (first super-cluster regime) and the merging of speckles with isolated clusters (second super-cluster regime). **D.** Normalised “all-nucleus” average SuperStructure curves in the range $[0; 200] \text{ nm}$ for the three proteins. Average is computed

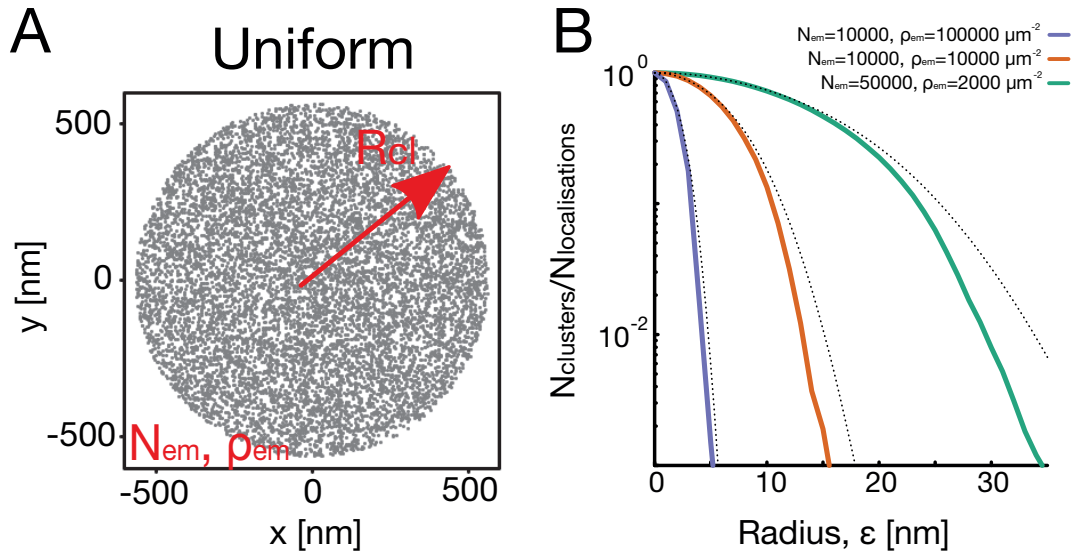

1101 over 6 nuclei. Shaded regions represent standard deviation from the average. Poisson fits (Eq.1) for
1102 the intra-cluster regime at small ε are shown in the inset. **E.** Intra-cluster density of emitters ρ_{em} as
1103 parameter of Poisson fit for 6 independent nuclei (Eq.1). **F.** Normalised decay length λ^* for the super-
1104 cluster regimes highlighted in **C** for 6 independent nuclei. SuperStructure curves were fit with Eq.4 to
1105 extract the decay length λ , then the normalisation $\lambda^* = \lambda/\rho_{cl}^{-1/2}$ was performed (where ρ_{cl} is the detected
1106 cluster density at the beginning of each regime of interest). P-values were calculated using a Student's
1107 T-test: *ns* $P > 0.05$; * $P < 0.05$; ** $P < 0.01$; *** $P < 0.001$.

Figure 4. Application of SuperStructure algorithm to ceramides data from (Burgert et al., 2017).
A. dSTORM reconstruction of ceramides dataset using the shifted histogram method. The left panel represents signal from cells treated with bSMase; the right panel is a control without treatment. **B.** SuperStructure curves of the two conditions for the entire dataset. Curves show the number of detected clusters normalised by the total number of localisations. The red region highlights the intra-cluster regime, while the blue region the Poissonian unconnected super-cluster regime. Shaded purple region highlights the horizontal shift between the two curves. Dashed lines represent Poisson fits at low and high ϵ . **C. – E.** Average density of total localisations (**C**), intra-cluster density extracted as parameter from Poisson fit (Eq.1) (**D**) and overall density in the super-cluster regime extracted as parameter from Poisson fit (Eq.3) (**E**) for + and -bSMase treatment datasets. Calculations and fits were performed on data and SuperStructure curves from 16 independent circular regions of radius $r = 1.5 \mu\text{m}$ within the original dataset. P-values were calculated using a Student's T-test: *ns* $P > 0.05$; * $P < 0.05$; ** $P < 0.01$, *** $P < 0.001$.

Figure S1. A. In order to test the Poissonian functional form (Eq.1) of the intra-cluster regime of SuperStructure curves, we simulated localisations inside clusters as a uniform distribution of N_{em} points distributed within a circle of radius R_{cl} . The resulting average density is ρ_{em} . The number of points included in any circular sub-region of radius ϵ is, on average, $n(\epsilon) = \pi\rho_{em}\epsilon^2$, and is in fact itself Poisson distributed. **B.** To check the theoretical prediction of Eq.1 we have created simulated datasets for various ρ_{em} and N_{em} . The theoretical predictions (dotted lines) with $m = 2$ are in good agreement with the SuperStructure curves, indicating that indeed Eq.1 correctly captures the behaviour of uniformly distributed points forming one idealised cluster. However, note that for $m = 2$ there is already an over-counting of clusters at large values of ϵ due to the fact that DBSCAN merges indirectly related emitters in a single big cluster. This suggests not to extend the summation to higher values of m . From Eq.1, the end of the intra-cluster regime can be approximated by the width of the Poisson function, i.e. $\epsilon^* \approx 3\kappa_0$ (at 99 % confidence level), where $\kappa_0 = 1/\sqrt{\pi\rho_{em}}$ is the decay length identified by Eq.1. This is confirmed by observing that predicted ϵ^* for the curves are $\epsilon^*(\rho_{em} = 2000 \mu m^{-2}) \approx 38 \text{ nm}$, $\epsilon^*(\rho_{em} = 10000 \mu m^{-2}) \approx 18 \text{ nm}$ and $\epsilon^*(\rho_{em} = 100000 \mu m^{-2}) \approx 5.3 \text{ nm}$, which correspond to $N_{cl}/N_{em} \approx 10^{-3}$ (when most of the points have been merged in a single cluster).

Figure S2. Average SuperStructure curves for different datasets. SuperStructure analysis was run on 20 independent datasets (in the same conditions) and the resulting curves were then averaged. Shaded regions represent the standard deviation from the average. Parameters are set to their standard values if not otherwise specified (see Methods). Palettes in the inset configurations represent cluster analysis at $\varepsilon = 80 \text{ nm}$. **A.** Locally connected clusters with different grades of connectivity and doubling the cluster density (from left to right): $\rho_{cl} = 8.2 \mu\text{m}^{-2}$ (left) and $\rho_{cl} = 16.3 \mu\text{m}^{-2}$ (right), connection density $p_{r\text{conn}} = 0.5$, no noise and different values of connectivity p_r . The higher cluster density makes SuperStructure curves more markedly distinct as a function of p_r , compared to the same curves for a lower density. **B.** Locally connected clusters with low connectivity and increasing cluster density: connectivity $p_r = 0.002$, connection density $p_{r\text{conn}} = 0.5$, no noise and different cluster densities ρ_{cl} . The first super-cluster regime maintains the single exponential decay, but the decay length λ decreases with the cluster density. In the main text, we showed that this dependence goes as $\lambda \propto \rho_{cl}^{-1/2}$. Also, the exponential decay λ_2 of the second super-cluster regime decreases with the density of clusters and this regime evolves from a Poisson-like (low ρ_{cl}) to an exponential decay (high ρ_{cl}). This behaviour seems to be a pure effect of the cluster density, as all other parameters remain unchanged. Black curve are Poisson decays attempts $\sim e^{-\pi\rho\varepsilon^2}$ to fit the second super-cluster regime. **C.** Locally connected clusters with different grades of connectivity and sparse noise addition: cluster density $\rho_{cl} = 8.2 \mu\text{m}^{-2}$, connection density $p_{r\text{conn}} = 0.5$, noise density $\rho_n = 0 \mu\text{m}^{-2}$ (left) / $\rho_n = 64 \mu\text{m}^{-2}$ (right) and different values of connectivity p_r . With high noise (8 times the cluster density), the 2nd super-cluster regime becomes Poissonian; the 1st super-cluster regime maintains its typical exponential decay, but the decay length is altered. Dotted lines represent fit with Eq.3 for $\varepsilon \in [70:300] \text{ nm}$. **D.** Unconnected clusters of points with

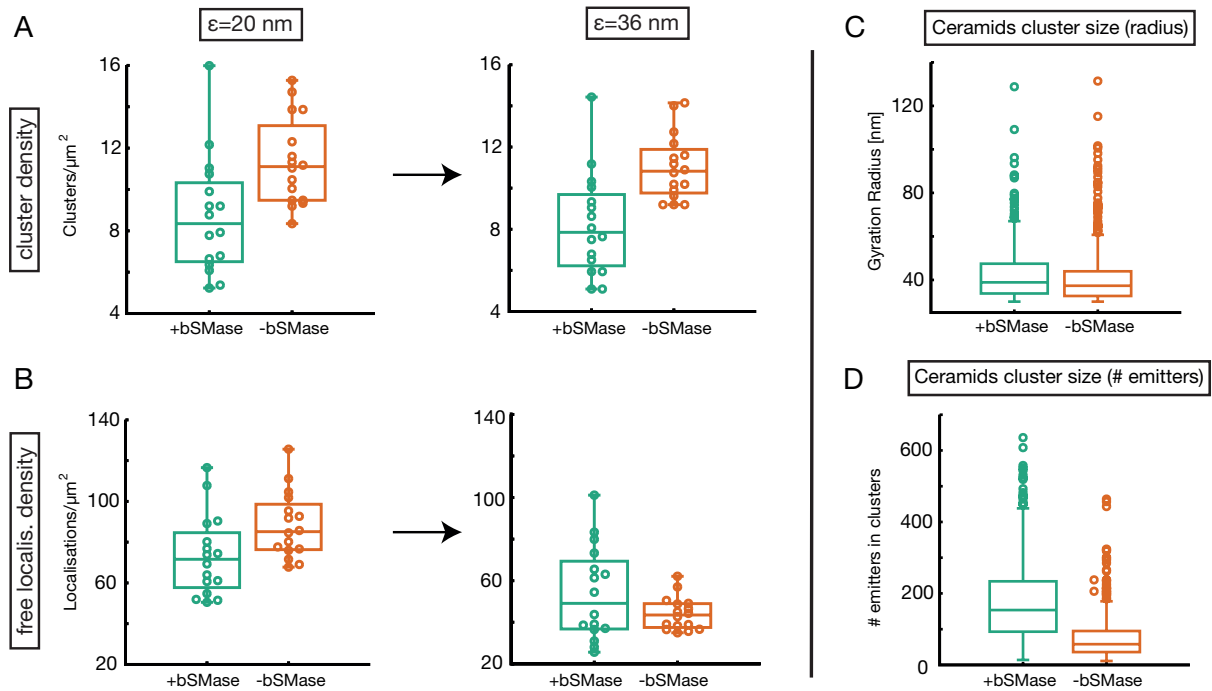

1261 increasing density of noise (other parameters are the same as **C.**). Eq.3 well describes the decay of the
1262 curves in the inter-cluster regime, with the density parameter ρ_{cl} and $\rho_{cl} + \rho_n$ respectively in absence
1263 and presence of noise. **E.** Average decay length of the first super-cluster regime for the connected
1264 systems represented in **C.** as function of noise density ρ_n . The fit to calculate the decay length λ has
1265 been made for $\varepsilon \in [20,60] nm$ for 20 independent datasets. Values of λ are then averaged. Bars
1266 represent the standard deviation from the average. Decay lengths for systems with different
1267 connectivities p_r are distinguishable as long as the noise density is below the connections density (\sim
1268 $500 \mu m^{-2}$). However, low noise density also alters the estimation of the decay length. The alteration is
1269 less severe for highly connected clusters. **F.** Fully connected meshes of clusters with increasing density
1270 of the mesh: cluster density $\rho_{cl} = 8.2 \mu m^{-2}$, connectivity $p = 0.025$, no noise and different values of
1271 connection density $p_{r_{conn}}$. The super-clusters regime is unique, the decay is exponential and the decay
1272 length λ decreases with the density of the mesh. Fit of λ was performed for $\varepsilon \in [20:60] nm$. The inset
1273 shows the dependence of λ on $p_{r_{conn}}$ in a fully connected mesh, which is $\lambda \sim p_{r_{conn}}^{-0.74}$.

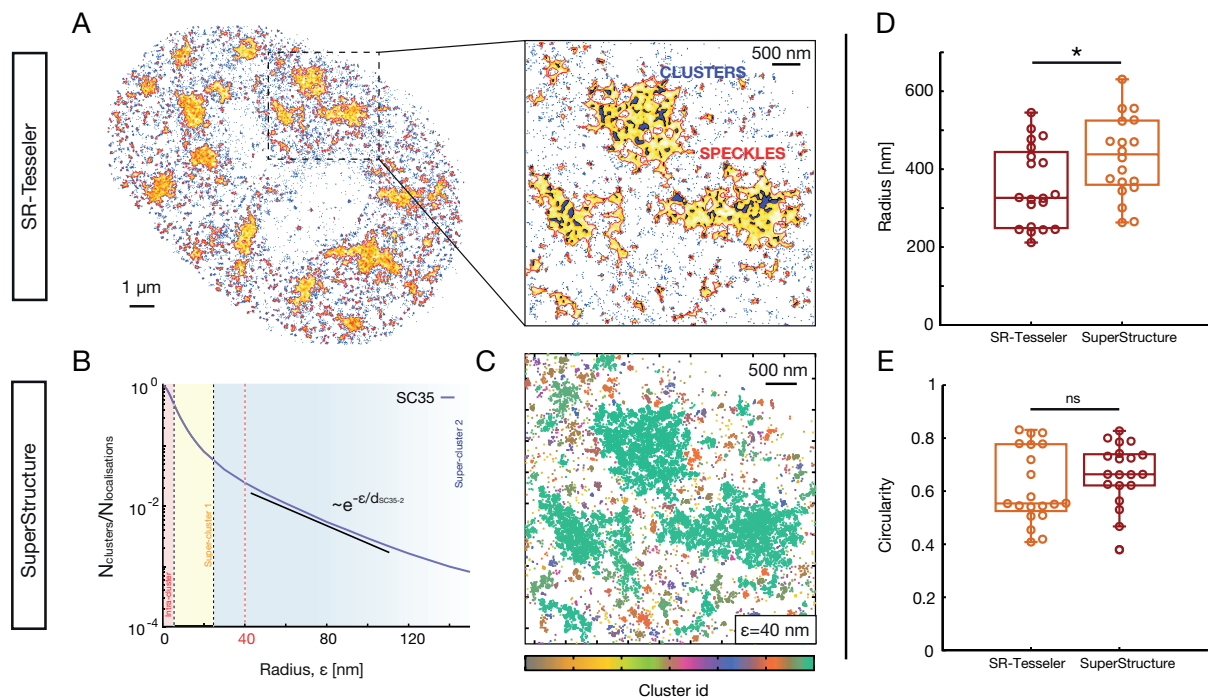

Figure S3. A. dSTORM reconstructed images of SAF-A, hnRNP-C and SC35 in a single cell where local circular regions for cluster density estimation purpose are highlighted. In case of SC35 two different region types are used, one inside speckles for the first exponential regime and one outside speckles for the second exponential regime. In the case of hnRNP-C and SC35 local circular regions were also used to compute SuperStructure “local curves” and the decay length λ in the first super-cluster regime as explained in Methods. **B.** Average SuperStructure curves for SAF-A, hnRNP-C and SC35 as shown and explained in the main text. Solid lines are the result of “all-nucleus’ analysis, while dashed lines are the result of a “local” analysis (in local circular regions). Exponential regimes of interest are highlighted, as well as the values of ϵ at which the cluster analysis is made for clusters density estimation purpose (purple dashed vertical line). **C.** Check that connections are not the result of technical artefacts due to bad blinking quality both in SAF-A and hnRNP-C data by monitoring λ (left) and λ^* (right) for different cluster densities ρ_{cl} . The bad blinking quality of fluorophores would lead to localisation inaccuracy of emitters at the borders of protein clusters and in turn this could lead to pseudo-connections between clusters. However, these pseudo-connections would be proportional to the clusters density: higher cluster density would result in stronger pseudo-connections, which would reflect to a decrease of λ^* with the clusters density. λ , ρ_{cl} and λ^* were calculated for the 6 independent nuclei as explained in Methods and are shown in Table SI. Every nucleus can be considered as a system where the blinking conditions are the same, but clusters densities may vary due to statistical fluctuations. While, λ (left) decreases with ρ_{cl} , as expected, λ^* (right) is constant for different densities, ruling out the hypothesis that connections are artefacts due to bad blinking quality.

Figure S4. A. - B. The absence of local connectivity was confirmed by analysing cluster density (**A**) and sparse localisations density (**B**) in the cross-over range. We monitored the density of ceramides clusters and that of free emitters at $\epsilon_1 = 20$ nm and $\epsilon_2 = 36$ nm. In order to calculate clusters density, DBSCAN was run at $N_{min} = 0$ and at the given value of ϵ and we kept only clusters with at least 10 particles. The remaining the particles were considered as free localisations. Clusters and free localisations were detected at $N_{min} = 0$ for 16 independent circular regions. The number of clusters remains constant in the considered ϵ regime, while the free localisations density significantly decreases, more severely for -bSMase cells. As a consequence, we can state that there is not significant merging of ceramides clusters, but only embedding of nearby free localisations in already formed clusters.

C. - D. Confirmation of the original paper results by calculating the ceramides cluster size both as gyration radius (**C**) and number of emitters (**D**). Protein clusters were detected at $N_{min} = 0$ at $\epsilon^+ = 20$ nm and $\epsilon^- = 24$ nm. In accordance with the analysis in the paper, we looked at the size of clusters with a radius bigger than 30 nm. Note that +bSMase ceramides clusters consist (on average) in 180 emitters in a circle of radius 42 nm. The resulting density is $32500 \mu\text{m}^{-2}$. This result is approximately in line with our prediction obtained with the Poisson intra-cluster fit, by considering that the standard deviation of both cluster radius and emitters is high. Similarly, -bSMase clusters have on average 78 emitters in an average cluster radius of 40 nm. The resulting density is $15500 \mu\text{m}^{-2}$.

Figure S5. Size and shape estimation of local super-structures emerging in SC35 dSTORM data (i.e. nuclear speckles) by using both SuperStructure and SR-Tesseler. Analysis was performed on a single cell as proof of concept. **A.** Super-structures detection by using SR-Tesseler software, a segmentation framework based on Voronoï tessellation (constructed from the localisations coordinates). Adjustments of the density factor allows to detect structures at different density levels, such as clusters (violet) or speckles (yellow). Blue dots represent no-segmented localisations. The software was downloaded from <https://github.com/flevet/SR-Tesseler/releases/tag/v1.0> and run on a Windows OS. **B.** SuperStructure curve of the same data. Analysis of decay regimes allows to identify $\epsilon = 40 \text{ nm}$ as a suitable value for super-structures identifications. **C.** Identified clusters at $\epsilon = 40 \text{ nm}$ with SuperStructure. Speckles detections are visually compatible with those of SR-Tesseler. **D. - E.** Radius and circularity of super-structures by using both SR-Tesseler and SuperStructure. Both radius and circularity are very similar, showing the power of SuperStructure in computing shape and size properties. In the analysis we considered the 20 largest identified structures (i.e. speckles). SuperStructure: the 2d symmetric gyration tensor $\overline{R^2}$ was computed and diagonalised for identified super-structures. The gyration tensor components R_{xy}^2 are defined as $R_{xy}^2 = \frac{1}{2N^2} \sum_{i=1}^N \sum_{j=1}^N (x_i - x_j)(y_i - y_j)$, where N is the total number of localisations in a super-structure, while x_i and y_i the x and y positions of the localisation i . The diagonalisation is necessary to obtain the major and minor axis of the speckles, namely γ_1 and γ_2 . We then calculated the speckles radius $R_g = \sqrt{\gamma_1 + \gamma_2}$ and their circularity $c = \sqrt{\frac{|\gamma_1 - \gamma_2|}{\gamma_1 + \gamma_2}}$. SR-Tesseler: radius and circularity parameters were obtained as output after Voronoï tessellation. P-values were calculated using a Student's T-test: *ns* $P > 0.05$; * $P < 0.05$; ** $P < 0.01$, *** $P < 0.001$.

Table SI. Decay length λ , detected clusters density ρ_{cl} and normalised decay length $\lambda^* = \lambda/\rho_{cl}^{-1/2}$ for SAF-A, hnRNP-C and SC-35 (in both super-cluster regimes SC35-1 and SC35-2). Both single-nucleus values and average over nuclei (\pm standard deviation) are shown. For SAF-A and SC35-2, λ was obtained by fitting “all-nucleus” SuperStructure curves, i.e. curves where the entire nucleus was analysed. On the other hand, for hnRNP-C and SC35-1, λ was obtained by fitting “local” SuperStructure curves, i.e. curves where local circular regions were analysed as explained in Methods. In the latter case, nuclear values showed in the table are the result of an average over 5 independent “local” values within the same cell.
