Synthesis and complexes of a constrained-cavity Schiff-base dipyririn macrocycle†

Karlotta van Rees and Jason B. Love *

A new constrained-cavity [1 + 1] Schiff-base dipyririn macrocycle comprising an N₄ donor-pocket has been synthesised by spontaneous oxidation and *in situ* crystallisation. Access to Fe(II) and Zn(II) complexes is achieved by salt elimination reactions of the lithium salt. All compounds have been characterised by NMR and UV-vis spectroscopy, X-ray crystallography, and DFT analysis.

Dipyririns, also known as dipyrromethenes, represent a fascinating class of organic chromophores and are readily synthesised *via* oxidation from their dipyrromethane analogues. The π -conjugation in these bis-pyrrole compounds facilitates effective absorption of visible light through π - π^* transitions, and their boron difluoride adducts (BODIPY) belong to a family of fluorescent dyes with useful bioapplications.^{1–5} Dipyririns incorporate both a mono-anionic and bidentate ligand environment creating rich and diverse coordination and supramolecular chemistry, forming stable, highly crystalline complexes with a variety of metal ions, as highlighted by Baudron and co-workers.^{6–13} In addition, Betley and co-workers have demonstrated that transition metal complexes of dipyririns act as catalysts for C–H amination reactions.^{14–18}

Due to their planar N₄ donor-pockets, Schiff-base dipyririns are similar to porphyrins and their expanded porphyrin cousins and display a rich coordination chemistry along with unique redox-activity and photo-physical properties. Previously, we reported the donor-expanded acyclic dipyririn **1** and its uranyl(VI) complex and showed that this ligand acts as an electron conduit for inner- and outer-sphere redox reactions (Fig. 1).^{19–21} Sircoglou, Aukauloo and co-workers investigated the photo-physical properties of an acyclic zinc(II) and nickel(II) dipyririn-pyridine complex.²² In contrast to acyclic ligands, non-porphyrinic, macrocyclic dipyririns are rare. Naruta and

co-workers reported the phenanthroline-dipyririn macrocycle **2** (Fig. 1) and described the photo-physical properties of its magnesium(II) complex.^{23,24} Sessler, Katayev, and co-workers studied competitive binding of palladium(II) with the expanded Schiff-base dipyririn-diamide macrocycle **3** (Fig. 1).²⁵ Accordion-like dimanganese(II) Schiff-base dipyririn macrocycles have been investigated by Bowman-James and co-workers as a functional model for catalases.^{26,27} Smaller cavity macrocycles such as the benziporphyrins have also been prepared by Latos-Grażyński and co-workers for which metal-assisted C–H bond activation chemistry has been revealed.^{28–31}

The chemical and photochemical properties of the dipyririn framework combined with the unique control of coordination and organometallic chemistry afforded by a macrocyclic environment led us to investigate the formation of macrocyclic analogues of **1**. We report here the straightforward formation and isolation of a unique constrained-cavity [1 + 1] Schiff-base dipyririn macrocycle HL that comprises an N₄ dipyririn-imine donor set and describe the formation and properties of its lithium, iron, and zinc complexes.

The condensation of equimolar quantities of the mono-*meso*-substituted dipyrromethane dialdehyde **4** and bis(*m*-aminoisopropyl)benzene³² in acetonitrile at room temperature causes the macrocyclic product HL to crystallise directly from the reaction mixture as greenish-red crystals in 80% yield (Scheme 1 and ESI†). The ¹H NMR spectrum of HL shows an

imine proton resonance at 8.47 ppm and additional resonances indicative of C_2 -symmetry in solution. In addition, the disappearance of the *meso*-proton resonance from **4** reveals that spontaneous oxidation of the dipyrromethane to the dipyrin has occurred.

The MALDI-TOF mass spectrum of HL shows the expected molecular ion at m/z 524.5 ($[M + H]^+$) with no higher-order cyclisation products observed. Attempts to form HL using the dipyrin analogue of **4** (4^{ox} , ESI $^+$) in a condensation with the diamine under similar conditions results in a mixture of the starting materials and a variety of imine-containing products. Significantly, the formation of 4^{ox} requires oxidation with DDQ with photolysis under an inert atmosphere, which suggests that the simple aerobic oxidation that occurs during the synthesis of HL is driven by the formation of the macrocycle.^{33–35}

The X-ray crystal structure of HL (Fig. 2) reveals a fully planar conformation of the N_4 donor set with the *meso*- C_6F_5 substituent approximately orthogonal (82°) and the *para*-proton (H1) of the bridging phenyl group pointing into the macrocyclic cavity. The size of the cavity is defined by the

Fig. 2 Solid-state structure of HL and Li(L) viewed from side and top. For clarity, all hydrogen atoms (except H1) and solvent of crystallisation are omitted (displacement ellipsoids are drawn at 50% probability). Li(L) top view is depicted including close-contact atoms of adjacent molecule. Crystals of Li(L) were grown by slow evaporation of a concentrated *n*-hexane solution.

pyrrole ($N2 \cdots N3$) and imine ($N1 \cdots N4$) separations of 2.672(2) Å and 4.391(2) Å, respectively, so resulting in a small and rigid trapezoid-shaped binding pocket. This is significantly different to porphyrins such as tetraphenylporphyrin (TPP) in which an approximately square cavity of 2.921 Å by 2.914 Å is seen.³⁶

Reaction between HL and one equivalent of $LiN(SiMe_3)_2$ in toluene cleanly generates the lithium complex Li(L) which was isolated as a dark purple solid in 91% yield. Its formation is apparent by the disappearance of the pyrrole proton in the 1H NMR spectrum and the appearance of a broad singlet at 1.57 ppm in the 7Li NMR spectrum. The X-ray crystal structure of Li(L) shows that the lithium coordinates to all four N-donor atoms within the macrocyclic cavity with an axial $Li \cdots F3'$ interaction from an adjacent molecule ($Li \cdots F3' 2.354(3)$ Å), forming an infinite chain structural motif (Fig. 2 and ESI †). The presence of the Li cation causes the bridging phenyl ring to tilt significantly, from 176.56° in HL to 112.79° in Li(L), resulting in a $C1 \cdots F3'$ distance of 3.570(2) Å. Attempts to doubly deprotonate HL (e.g., at C1–H1) using two equivalents of $LiN(SiMe_3)_2$ were unsuccessful. The twist of the bridging aryl group such that the unique H-atom H1 avoids interaction with the Li cation within the N_4 -donor set shows that, unlike the porphyrin analogues, the macrocyclic cavity is size-compromised.

The reactions between Li(L) and either $ZnBr_2$ or $FeBr_2$ cleanly generate the metal bromide complexes $ZnBr(L)$ and $FeBr(L)$, respectively (Scheme 2); the isolated yield for $FeBr(L)$ is low due to its poor solubility. HRMS of $ZnBr(L)$ and $FeBr(L)$ show molecular ion peaks at m/z 667.025720 ($[M + H]^+$) and 577.110887 ($[M - Br]^+$), respectively. The 1H NMR spectrum of $ZnBr(L)$ shows mirror symmetry with the geminal methyl groups appearing as two singlets at 1.80 ppm and 1.34 ppm, indicative of top/bottom asymmetry; this asymmetry is also seen in the ^{19}F NMR spectrum which displays five fluorine resonances.

The X-ray crystal structures of $ZnBr(L)$ and $FeBr(L)$ were determined (Fig. 3) and both exhibit square pyramidal geometries with axially coordinated bromide ligands. There is a noticeable difference in distance between the metal and the plane of the N_4 donor set; for zinc this is 0.593 Å above the plane while for iron it is 0.304 Å. Similarities can be found in previously reported structures of iron chloride octaethylporphyrin³⁷ and zinc chloride *m*-benzporphodimethene^{28,38} in which the Fe and Zn are *ca.* 0.47 Å and 0.51 Å, respectively, out

Crystals were grown by slow evaporation of dilute, saturated *n*-hexane solutions.

of plane. In contrast, for iron chloride and zinc chloride TPP complexes the metal ion is coordinated on the macrocyclic N_4 donor plane.^{39,40} This difference could be explained by the additional steric effect of the *para*-proton (H1) of the bridging phenyl group that points towards the cavity.

The UV-vis spectrum of HL shows two absorptions at 277 and 512 nm (Fig. 4) that are similar to those seen for other expanded dipyrroles and substituted BODIPY compounds.^{20,41,42} Upon deprotonation to form Li(L) and subsequent transmetalation to form ZnBr(L) and FeBr(L), significant red shifts occur in the UV-vis spectra, with the lower wavelength adsorption splitting into two. The experimental UV-Vis

spectra (with the exception of FeBr(L)) were reproduced by TD-DFT calculations using B3LYP functional and 6-311G(d,p) basis set (Fig. 4, 5 and ESI†). The energies of the transition states are over estimated, as seen with previously reported hetero-diarylmethene ligands and their complexes.⁴³ The electronic density of both the HOMO and the LUMO of HL and ZnBr(L) comprise π orbitals that are centred on the dipyrrole unit and the imines, highlighting the extended conjugation in these molecules. The dominant absorption band in HL at 277 nm is assigned as a mixture of HOMO to LUMO+3 (41%) and HOMO to LUMO+1 (13%) transitions, with the HOMO–LUMO transition appearing at 512 nm. This latter transition is comparable with (Fig. 1) the acyclic dipyrrole ligand **1**, which has the HOMO–LUMO transition at 540 nm.²⁰ The red-shifted dominant absorption bands at 595 and 557 nm for Li(L) and ZnBr(L), respectively, correspond to the HOMO–LUMO transition with the HOMO–LUMO+3 transition shifting to 303 and 300 nm, respectively. The UV-vis spectrum of the ZnBr(L) resembles that of the deprotonated ligand Li(L), suggesting the absence of any metal-centred transitions.

We have synthesised a new constrained-cavity [1 + 1] Schiff-base dipyrrole macrocycle that is spontaneously oxidised and crystallised during its preparation. The straightforward deprotonation of the macrocycle unveils a uninegative, N_4 -donor set that allows the formation of iron(II) and Zn(II) complexes; unlike porphyrinic analogues, these complexes retain the ancillary bromide ligands. The observation of ligand-centred electronic transitions suggests a potentially rich ligand-centred redox chemistry that, combined with the Lewis acidity of the

metal, could lead to new chemical transformations. Our current investigations focus on the catalytic redox behaviour of this ligand and its complexes as well as exploring the possibility of using the NC(H)N pocket in the formation of dinuclear complexes.
