## ABSTRACT

We present results from MMT/Hectochelle spectroscopy of 390 red giant candidate stars along the line of sight to the recently-discovered Galactic satellite Crater 2. Modelling the joint distribution of stellar positions, velocities and metallicities as a mixture of Crater 2 and Galactic foreground populations, we identify $\sim 62$ members of Crater 2, for which we resolve line-of-sight velocity dispersion $\sigma_{v_{\rm los}} = 2.7^{+0.3}_{-0.3}$ km s$^{-1}$ about mean velocity of $\langle v_{\rm los} \rangle = 87.5^{+0.4}_{-0.4}$ km s$^{-1}$ (solar rest frame). We also resolve a metallicity dispersion $\sigma_{\rm [Fe/H]} = 0.22^{+0.04}_{-0.03}$ dex about a mean of $\langle {\rm [Fe/H]} \rangle = -1.98^{+0.1}_{-0.1}$ dex that is $0.28 \pm 0.14$ dex poorer than is estimated from photometry. Despite Crater 2's relatively large size (projected halflight radius $R_{\rm h} \sim 1$ kpc) and intermediate luminosity ($M_V \sim -8$), its velocity dispersion is the coldest that has been resolved for any dwarf galaxy. These properties make Crater 2 the most extreme low-density outlier in dynamical as well as structural scaling relations among the Milky Way's dwarf spheroidals. Even so, under assumptions of dynamical equilibrium and negligible contamination by unresolved binary stars, the observed velocity distribution implies a gravitationally dominant dark matter halo, with dynamical mass $4.4^{+1.2}_{-0.9} \times 10^6$ $M_\odot$ and mass-to-light ratio $53^{+15}_{-11}$ $M_\odot/L_{V,\odot}$ enclosed within a radius of $\sim 1$ kpc, where the equivalent circular velocity is $4.3^{+0.5}_{-0.5}$ km s$^{-1}$.

## 1. INTRODUCTION

The Milky Way's dwarf-galactic satellites represent an extremum of galaxy formation. They include the smallest, least luminous, least chemically enriched and most dark-matter dominated galaxies known. Their abundances as functions of size, luminosity, metallicity and dark matter density are sensitive to the nature of dark matter (e.g., the ability of dark matter particles to cluster on scales of $\sim$ tens of pc) as well as to how galaxy formation proceeds within low-mass dark matter halos (e.g., Pontzen & Governato 2014; Di Cintio et al. 2014; Read et al. 2016). Empirical information has increased dramatically during the last decade, as deep imaging surveys have grown the number of known Galactic satellites from $\sim 10$ to several tens (e.g., Belokurov et al. 2007; Koposov et al. 2015; Bechtol et al. 2015; The DES Collaboration et al. 2015) and spectroscopic campaigns have measured stellar kinematics and chemical abundances for tens to thousands of objects per system (e.g., Battaglia et al. 2006; Martin et al. 2007; Simon & Geha 2007; Walker, Mateo & Olszewski 2009; Kirby et al. 2010).

The combination of structural and chemodynamical

parameters from photometric and spectroscopic surveys, respectively, reveals empirical scaling relations that serve as targets for models of dwarf galaxy formation and evolution. For example, the size/luminosity relation traced by dwarf spheroidals extends the one observed for disk galaxies but is offset from relations traced by central bulges and larger elliptical galaxies (Kormendy & Bender 2012). Moreover, the least luminous dwarf galaxies also exhibit the lowest metallicities, extending the galactic luminosity/metallicity relation over $\sim 5$ orders of magnitude in luminosity (Kirby et al. 2013). Finally, correlations among internal line-of-sight velocity dispersion, size, and luminosity have been interpreted as evidence for similarity among the dark matter halos that dwarf galaxies inhabit (Mateo et al. 1993; Strigari et al. 2008; Walker et al. 2009b).

While it is clear that dwarf galaxies' structural and chemodynamical properties are interconnected, physical interpretations are complicated by our ignorance regarding the extent to which these empirical correlations are driven by selection effects. At a given distance and luminosity, smaller galaxies have higher surface densities and hence are detected more easily than are larger galaxies. Careful quantification of sensitivities for various imaging surveys (e.g., Koposov et al. 2008) leaves open the possibility that large numbers of large, low-luminosity galaxies exist undetected, perhaps modifying what are apparent size/luminosity correlations and/or other relations involving quantities that correlate with size and luminosity.

In fact dwarf galaxies continue to be discovered down to the faintest surface brightnesses to which current imaging surveys are sensitive. Most recently, (Torrealba

et al. 2016, T16 hereafter) used data from the ATLAS survey (Shanks et al. 2015) to discover Crater 2, a dwarf galaxy at distance $D \sim 117$ kpc from the Sun. With absolute magnitude $M_V \sim -8.2$ and projected halflight radius $R_{\rm h} \sim 1.1$ kpc, Crater 2 exhibits the faintest surface brightness of any known dwarf galaxy, with $\mu_V \sim 31$ mag arcsec$^{-2}$. Relative to other Galactic satellites of similar luminosity (or size), Crater 2 is exceptionally large (or underluminous).

In order to gauge how this outlier status translates into chemodynamical scaling relations, and in order to study the dark matter content of Crater 2 in general, here we present results from initial MMT/Hectochelle spectroscopic observations of 390 stars along the line of sight to the galaxy. From the spectroscopic data, we estimate line-of-sight velocity as well as effective temperature, surface gravity and metallicity for each individual star. We then use these measurements to characterise Crater 2's internal chemodynamics, to study its dark matter content, and to place Crater 2 in the context of the population of known Milky Way satellites.

## 2. OBSERVATIONS AND DATA REDUCTION

We observed Crater 2 using the Hectochelle multi-object fiber spectrograph (Szentgyorgyi et al. 2011) on the 6.5m MMT on Mt. Hopkins, Arizona. Hectochelle's field of view subtends $1°$ in diameter and thus is well-matched to Crater 2's projected halflight radius of $R_{\rm h} \sim 31'$ (T16). Hectochelle has been widely used for the study of MW dwarf galaxies (e.g., Mateo et al. 2008; Belokurov et al. 2009; Walker et al. 2009a), and achieves velocity precision better than 1 km s$^{-1}$ (Walker et al. 2015).

### 2.1. *Target Selection*

In order to identify stars for spectroscopic targeting, we selected red giant branch (RGB) candidates from the photometric catalog provided by the VLT/ATLAS survey (Shanks et al. 2015). The left panel of Figure 1 shows the color-magnitude diagram for point sources near the center of Crater 2. The overplotted isochrone (Dotter et al. 2008) corresponds to age=12 Gyr, [Fe/H]=−1.7 and distance modulus $m - M = 20.3$, closely following the ridge line identified by T16. In addition to bona fide red giants at the distance of Crater 2, this isochrone likely coincides with less-luminous but nearer dwarf stars in the Milky Way foreground. In order to avoid biasing our spectroscopic observations in metallicity, we selected RGB candidates spanning a range of $\sim 0.5$ magnitudes in color around the isochrone. The right panel of Figure 1 shows positions of these RGB candidates on the sky. In both panels, larger markers identify the RGB candidates for which we obtained spectra of sufficient quality to present here. Having obtained a catalog of RGB candidates, we allocated fibers to individual stars, giving lower priority to fainter targets.

### 2.2. *Observations and Data Reduction*

On the nights of 27 April, 30 April and 11 May 2016, we used Hectochelle's 'RV31' filter to observe the spectral range $5150 - 5300$ Å, containing the prominent Mg b triplet, for three fields in Crater 2. Two fields provided different sets of targets in the center of Crater 2, and the third field was offset from the center by $1.5°$ to the east (see right panel of Figure 1). Exposure times ranged between $2 - 3$ hours per field. Table 1 provides details of the exposures, which provided spectra for 610 unique science targets. In each field, $\sim 40$ fibers observe regions of blank sky in order to facilitate sky subtraction.

In addition to science exposures, we also acquired exposures of ThAr arc lamps, taken immediately before and after science exposures, for the purpose of wavelength calibration. At the beginning of each night, we also obtained twilight sky exposures in order to correct for fiber throughput variations and calibrate our measurements of stellar-atmospheric parameters. For all exposures, the Hectochelle CCDs were binned by 3 pixels in the spectral direction and by 2 in the spatial direction. The effective resolution is $R \approx 32,000$. All data frames were processed using the TDC/Hectochelle pipeline, which provides 1D, throughput-corrected, wavelength-calibrated spectra, as well as their corresponding variance spectra, as described in detail by Caldwell et al. (2009).

Given the processed spectra for a given exposure, we follow the procedure of Koposov et al. (2011) to estimate the mean sky spectrum and to subtract it from each science spectrum. All processed and sky-subtracted spectra for this program are publicly available and included in the online database associated with this article.

We analyze each sky-subtracted spectrum following the procedure of Walker et al. (2015). Briefly, we fit a smoothed library of synthetic template spectra, obtaining Bayesian inferences for the line-of-sight velocity ($v_{\rm los}$) as well as stellar-atmospheric parameters including effective temperature ($T_{\rm eff}$), surface gravity ($\log g$) and metallicity ([Fe/H]). As in previous work, we use the synthetic library originally generated for the SEGUE Stellar Parameter Pipeline (Lee et al. 2008a,b, 'SSPP' hereafter), which contains continuum-normalized spectra computed over a regular grid in $T_{\rm eff}$, log g and [Fe/H] and assumes a piecewise-linear relation between [$\alpha$/Fe] and [Fe/H].

We perform the fits using the nested-sampling algorithm MultiNest[6] (Feroz & Hobson 2008; Feroz et al. 2009), which returns random samples from the posterior probability distribution function. From these samples, we record the mean, variance, skewness and kurtosis that summarize the 1D posterior PDF for each free parameter. Following Walker et al. (2015), we enforce quality-control criteria by discarding observations for which the PDF for $v_{\rm los}$ is non-Gaussian, as quantified by skewness $S$ and kurtosis $K$. That is, we retain only those observations for which $|S| \leq 1$ and $|K - 3| \leq 1$.

Finally, we adjust all means and variances, which represent our estimate and errorbar, according to results from our $\sim 500$ twilight spectra, from which we gauge zero-point offsets (and corresponding uncertainties) with respect to solar values. The offsets that we obtain from the twilights observed during our Crater 2 observations are similar to those obtained during the Draco observations reported by Walker et al. 2015. Specifically, we subtract the following values from our raw estimates of velocity, temperature, gravity and metallicity: $\Delta v_{\rm los}$=0.98 km s$^{-1}$, $\Delta T_{\rm eff}$=−397 K, $\Delta \log g$=−0.90 dex, $\Delta$[Fe/H]=−0.58 dex. To the raw variances we add the (squares of) the following standard deviations obtained from the twilight spectra: $\sigma_{v_{\rm los}}$=0.25 km s$^{-1}$, $\sigma_{T_{\rm eff}}$=11 K, $\sigma_{\log g}$=0.02 dex,

## 3. ESTIMATES OF STELLAR PARAMETERS

For each of the 390 observations that satisfy our quality-control criteria, Table 2 lists stellar position, $g$ and $i$ magnitudes from the ATLAS catalog, time of observation, signal-to-noise ratio, and our spectroscopic estimates of velocity, effective temperature, surface gravity and metallicity. Our estimates of spectroscopic quantities have median (minimum, maximum) errors of $\sigma_{v_{\text{los}}}$=0.7 (0.3, 3.2) km s$^{-1}$, $\sigma_{T_{\text{eff}}}$=93 (29, 1085) K, $\sigma_{\log g}$=0.3 (0.1, 1.1) dex and $\sigma_{\text{[Fe/H]}}$=0.13 (0.04, 0.92) dex. Along with the information in Table 2, all processed and sky-subtracted spectra, as well as random samplings of posterior PDFs generated by MultiNest, are included in the online database associated with this article.

## 4. CHEMODYNAMICS OF CRATER 2

The available data for Crater 2 consist of photometry from the ATLAS survey and our new Hectochelle spectroscopy. From the photometric data we obtain a sample of projected positions, $\vec{R}$, for the $N_{\text{RGB}}$=10680 RGB candidates, selected using the same isochrone mask employed by T16, that have projected positions within $R_{\text{max}}$= 175 arcmin of Crater 2's center at $\alpha_{\text{J2000}} = 177.310°$, $\delta_{\text{J2000}} = −18.413°$. For $N_{\text{spec}}$=390 of these RGB candidates, the spectroscopic data set provides measurements of LOS velocity $V$, metallicity $Z$, surface gravity $G$. Given a model, $\Theta$, that specifies the projected

stellar density, $\Sigma(\vec{R}|\Theta)$, of RGB candidates as well as the joint probability, $P(V,Z,G|\vec{R},\Theta)$, of spectroscopic quantities as a function of position, the two data sets have joint likelihood

$$\mathcal{L} \propto \exp\left[-\int_{\mathcal{R}} \mathrm{d}\vec{R}\, \Sigma(\vec{R}|\Theta)\right] \prod_{i=1}^{N_{\text{RGB}}} \Sigma(\vec{R}_i|\Theta)$$
$$\times \prod_{i=1}^{N_{\text{spec}}} P(V_i, Z_i, G_i|\vec{R}_i, \Theta), \qquad (1)$$

where the constant of proportionality does not depend on the model. The argument of the exponential factor is the (negative) expected number of RGB candidates counted over the 2D field $\mathcal{R}$; thus we model the count of RGBs inside any (infinitesimally) small area element within $\mathcal{R}$ as a Poisson random variable.

For $\Theta$ we adopt a mixture model under which both data sets sample two stellar populations—Crater 2 members and Galactic foreground contamination—whose observables follow distinct chemodynamical distributions. We assume that the 2D spatial distribution of the member population (indicated hereafter by subscript '1') follows the circularly symmetric Plummer (1911) profile fit by Torrealba et al. (2016):

$$\Sigma_1(R|\Theta) = \Sigma_{0,1}\left[1 + \frac{R^2}{R_h^2}\right]^{-2}, \qquad (2)$$

where $\Sigma_{0,1}$ is the projected density at Crater 2's center and scale radius $R_h$ is the 2D halflight radius—i.e., the radius of the circle enclosing half the member stars. Also following Torrealba et al. (2016), we assume the foreground population (indicated by subscript '2' hereafter) follows a 2D spatial distribution that varies linearly across the field. We adopt the model

$$\Sigma_2(R, \theta|\Theta) = \Sigma_{0,2}\big[1 + k_2 R \cos(\theta - \theta_2)\big], \qquad (3)$$

where $(R, \theta)$ are polar coordinates with origin at the center of Crater 2, $\Sigma_{0,2}$ is the projected density of foreground stars at the origin, and gradient $k_2$ and its direction $\theta_2$ are additional free parameters. Given our mixture model, the conditional likelihood of spectroscopic quantities becomes a density-weighted sum of the probability distributions followed separately by each population:

$$P(V,Z,G|\vec{R},\Theta) = \qquad\qquad (4)$$
$$\frac{\Sigma_1(R|\Theta)P_1(V,Z,G|\vec{R},\Theta) + \Sigma_2(R,\theta|\Theta)P_2(V,Z,G|\vec{R},\Theta)}{\Sigma_1(R|\Theta) + \Sigma_2(R,\theta|\Theta)}.$$

We assume that, for both populations, distributions of velocities, metallicities and surface gravities are separable functions of position, such that $P_1(V,Z,G|\vec{R},\Theta) = P_1(V|\vec{R},\Theta)P_1(Z|\vec{R},\Theta)P_1(G|\vec{R},\Theta)$ (and similar for the foreground population). We further assume that member velocities and metallicities follow Gaussian distributions, each with constant dispersion about means that vary smoothly with position. In order to capture the effect of solid-body rotation and/or perspective-induced 'rotation' due to projection of Crater 2's systemic proper motion (Feast et al. 1961; Kaplinghat & Strigari 2008), we allow a velocity gradient with magnitude $k_V \equiv dV/dR$ to point in a direction specified by position angle $\theta_V$. We assume any metallicity gradient is azimuthally uniform and thus has only a magnitude, $k_Z \equiv dZ/dR$. Thus, for a

star at position $\vec{R}$, observations of velocity $V$ and metallicity $Z$, with respective measurement errors $\delta_V$ and $\delta_Z$, have probabilities

$$P_1(V|\vec{R},\Theta) = \mathcal{N}_V(\overline{V}_1 - k_V R \cos(\theta_V - \theta_i), \sigma_V^2 + \delta_V^2);$$
$$P_1(Z|\vec{R},\Theta) = \mathcal{N}_Z(\overline{Z}_1 - k_Z R, \sigma_Z^2 + \delta_Z^2), \qquad (5)$$

where $\mathcal{N}_X(\overline{X}, \sigma_X^2) \equiv (2\pi\sigma_X^2)^{-1/2}\exp[-\frac{1}{2}(X - \overline{X})^2\sigma_X^{-2}]$.

Finally, we assume that distributions of the following are independent of position: surface gravities for both populations, and velocities and metallicities for the foreground population. For the member population, this assumption is justified by Crater 2's extremely low surface brightness, which makes stellar encounters—and hence the mass segregation that would impart spatial dependence to the surface gravity distribution—negligible. For the foreground, it is justified by the smallness of the field compared to scales over which the Galactic distributions vary.[7] In order to prevent the number of free parameters from growing unwieldy, we estimate each of the position-independent distributions by smoothing the data with Gaussian kernels weighted by prior membership probabilities, $P_{mem}$ (or non-membership probabilities, $P_{non} = 1 - P_{mem}$ as appropriate) obtained using the expectation-maximization algorithm as described by Walker et al. (2009c). For example, we estimate the distribution of surface gravities for Crater 2 members as

[7] These assumptions of position independence refer to the distributions intrinsic to the populations that we observe, but because of selection effects they do not necessarily hold for the samples that we actually acquire. For example, our observations reach different limiting magnitudes (by up to $\sim 0.5$ mag) in each of the three observed fields, thereby imparting some spatial dependence to the observed distribution of log $g$. However, we confirm that we obtain nearly identical (except for slightly larger errorbars) results if we discard the spectroscopic data obtained for Fields 2 and 3, fitting only the data from the deepest (Field 1) observation.
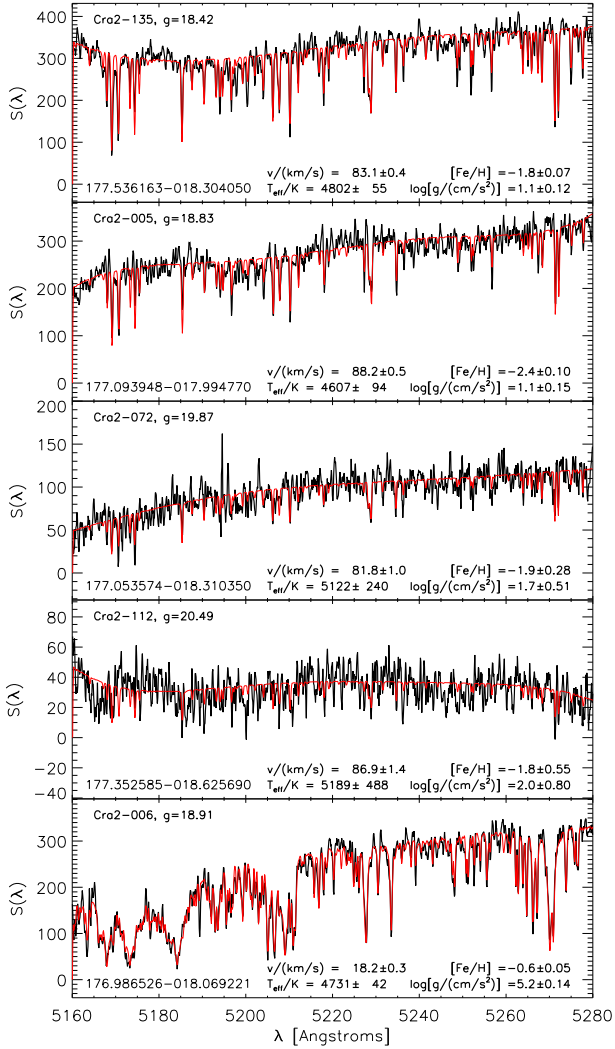

FIG. 2.— Examples of sky-subtracted MMT/Hectochelle spectra (black) for stars observed along the line of sight to Crater 2, with best-fitting models overplotted (red). Spectra in the top four panels correspond to likely red-giants within Crater 2; the spectrum in the bottom panel is a metal-rich dwarf star in the Milky Way foreground. Text in each panel indicates the star ID (see Table 2), $g$ magnitude from the ATLAS catalog, equatorial coordinates and our estimates of spectroscopic quantities.

$$\hat{P}_1(G) = \frac{\sum_{i=1}^{N_{\rm spec}} P_{{\rm mem}_i} \mathcal{N}_{G_i}(G, \delta_{G_i}^2)}{\sum_{i=1}^{N_{\rm spec}} P_{{\rm mem}_i}}, \qquad (6)$$

with measurement error $\delta_G$ serving as the smoothing bandwidth[8].

Again we use MultiNest to estimate parameters for the 12-dimensional model described above. Table 3 lists these parameters as well as the adopted prior probability distributions, which are uniform over the indicated ranges and zero outside those ranges. The third

---

[8] In order to reduce noise in our estimate of the foreground velocity distribution, which is sparsely sampled, we smooth the data using a constant bandwidth of 5 km s$^{-1}$. We confirm that our results are insensitive to this choice among other plausible bandwidths.

FIG. 3.— Spectroscopically-measured surface gravity (top), metallicity (middle) and velocity (bottom) vs angular separation from Crater 2's center. Red (black) markers represent stars with posterior membership probability $\geq 50\%$ ($< 50\%$). Histograms display 1D distributions, with posterior PDFs for the two populations (Crater 2 members and Milky Way foreground) of our mixture model overplotted.

column of Table 3 summarizes the marginalized, 1D posterior distributions returned by MultiNest, giving median-likelihood values as well as intervals that enclose the central 68% and 95% of posterior probability. The bottom three rows of Table 3 give the corresponding constraints on posterior PDFs for quantities of interest (e.g., $\sigma_{v_{\rm los}}$, $\sigma_{\rm [Fe/H]}$, $R_{\rm h}$) that are functions of the free parameters ($\log_{10}[\sigma_V^2/({\rm km}^2{\rm s}^{-2})]$, $\log_{10}[\sigma_{\rm [Fe/H]}]$, $\log_{10}[R_{\rm h}/{\rm arcmin}]$, respectively)[9].

Plotted over the histograms of observed velocities, metallicities and surface gravities in Figure 3 are the marginalized posterior PDFs that we obtain for these quantities, for the two separate populations as well as their sum. Although the model is fit to the discrete multi-dimensional observations and not directly to the 1D histograms shown in Figure 3, the fit shows generally good agreement with the histograms. Moreover, our es-

---

[9] Our results are insensitive to whether our uniform prior was applied to the linear quantities or to their logarithms.
FIG. 4.— Samples drawn randomly from posterior PDFs for means and dispersions of velocity (left; solar rest frame) and metallicity (right) distributions for Crater 2. Histograms display marginalized, 1D PDFs for each parameter. In the right panel, the gray band represents the metallicity of $-1.7 \pm 0.1$ that is estimated by fitting isochrones to the photometric data (T16; see Section 4.3).

timate of Crater 2's halflight radius remains in excellent agreement with the value T16 estimate from photometry alone.

### 4.1. *Velocity and Metallicity distributions*

Figure 4 displays posterior PDFs we obtain for the means and dispersions of Crater 2's velocity and metallicity distributions. For the member population we estimate a velocity dispersion of $\sigma_{v_{los}} = 2.7^{+0.3}_{-0.3}$ km s$^{-1}$ about a mean velocity of $\langle v_{los} \rangle = 87.5^{+0.4}_{-0.4}$ km s$^{-1}$ in the solar rest frame. While Crater 2's velocity distribution is extremely cold, it is well-resolved by our Hectochelle sample. We find no evidence for a velocity gradient, placing only a (95%) upper limit of $k_V \le 0.06$ km s$^{-1}$arcmin$^{-1}$. We also resolve a metallicity dispersion of $\sigma_{[Fe/H]} = 0.22^{+0.04}_{-0.03}$ dex about a mean of $\langle [Fe/H] \rangle = -1.98^{+0.1}_{-0.1}$ dex, with no evidence for a metallicity gradient.

We also fit an alternative model in which any velocity gradient is attributed to the varying projection of Crater 2's systemic proper motion (Feast et al. 1961; Kaplinghat & Strigari 2008; Walker et al. 2008). This model is identical to the one described above, except that the parameters $k_V$ and $\theta_V$ are replaced by proper motion coordinates, which specify the mean velocity at position $\vec{R}$ (see Appendix of Walker et al. (2008) for details). We obtain estimates $\mu_\alpha = -19.0^{+17.0}_{-17.0}$ mas century$^{-1}$ and $\mu_\delta = -14.0^{+19.0}_{-19.0}$ mas century$^{-1}$ in the solar rest frame. Thus our non-detection of a velocity gradient in the original model translates into a non-detection of departures from zero proper motion.

### 4.2. *Membership*

Our mixture model lets us infer Crater 2's chemodynamical quantities without explicitly identifying member stars. Nevertheless, it may be useful—e.g., in selecting targets for further observation—to identify likely members. We use the posterior PDFs to compute, for each star with spectroscopic data, a posterior probability of membership[10]:

$$P(\text{member}|\vec{R}, V, Z, G, \Theta) = \frac{M}{M + N}, \qquad (7)$$

where

$$M \equiv \Sigma_1(R|\Theta) P_1(V|\vec{R}, \Theta) P_1(Z|R, \Theta) \hat{P}_1(G);$$
$$N \equiv \Sigma_2(R, \theta|\Theta) \hat{P}_2(V) \hat{P}_2(Z) \hat{P}_2(G).$$

An estimate of the number of Crater 2 members within our spectroscopic sample is given by $\Sigma_{i=1}^{N_{spec}} P(\text{member}_i|\vec{R}_i, V_i, Z_i, G_i, \Theta) = 62.2^{+0.9}_{-0.6}$. Red markers in Figures 1 and 3 identify the 62 stars for which $P(\text{member}|\vec{R}, V, Z, G, \Theta) > 0.5$.

Examining the top panel of Figure 3, one probable member star (Cra2-224, with $P_{\text{member}}|\vec{R}, V, Z, G, \Theta) \sim 0.96$) has conspicuously high surface gravity ($\log g = 5.29 \pm 0.42$), which is more typical of the foreground contamination. The reason for the large membership probability in this case is that the measured surface gravity has a relatively large error compared to the median error, and the measured velocity ($v_{los} = 82.9 \pm 1.60$) and metallicity ([Fe/H]$= -2.02 \pm 0.38$) are both close to the means we estimate for Crater 2. In any case, our results for Crater 2 do not change if we discard this star altogether from our analysis.

### 4.3. *Comparison with Photometric Metallicity*

Fitting isochrones to the ATLAS photometric data, T16 estimate that Crater 2's stellar population has age $10 \pm 1$ Gyr and metallicity [Fe/H]$= -1.7 \pm 0.1$. Our spectroscopic metallicities indicate a lower mean metallicity of $\langle [Fe/H] \rangle = -1.98^{+0.1}_{-0.1}$. Given this mild discrepancy, either the photometric estimate is systematically metal-rich or the spectroscopic metallicities that we obtain for individual stars are systematically metal-poor. For two reasons, we consider the latter scenario to be more likely. First, the colors and magnitudes of probable members in our spectroscopic data set show good agreement with the isochrone calculated for [Fe/H]$=-1.7$ (left panel of Figure 1). Second, our fits to the solar twilight spectra acquired during our Crater 2 observations (Section 2) return mean metallicity of $-0.58$ dex (Section 2). While we treat this value as a zero-point offset and subtract it from all raw metallicity estimates, there is no guarantee that the same level of systematic error applies at all metallicities. In any case, the disagreement between photometric and spectroscopic metallicities is significant only at the $\sim 2\sigma$ level.

Despite this likely systematic error, our spectroscopic metallicities remain useful for ranking stars by metallicity and for identifying metal-poor Crater 2 members amongst the Galactic foreground (Section 4.2). Furthermore, our spectroscopic detection of a significant metallicity spread ($\sigma_{[Fe/H]} = 0.22^{+0.04}_{-0.03}$ dex) is supported by visual inspection of the spectra for probable members.

For example, the top two panels of Figure 2 display spectra for two probable members that have similar atmospheric parameters, but for which the best fitting templates yield [Fe/H] differences of $\sim 0.6$ dex. The more

---

[10] To save space, these probabilities are not listed in Table 2; however, they are included in the material that is made available in the online database.

TABLE 3
SUMMARY OF PROBABILITY DISTRIBUTION FUNCTIONS FOR CHEMODYNAMICAL PARAMETERS—CONSTANT VELOCITY DISPERSION MODEL

| parameter | prior | posterior | description |
|---|---|---|---|
| $\langle v_{\mathrm{los}} \rangle$ [km s$^{-1}$] | uniform between -500 and +500 | $87.5^{+0.4(+0.8)}_{-0.4(-0.8)}$ | mean velocity at center (Cra2) |
| $\log_{10}[\sigma^2_{v_{\mathrm{los}}}/(\mathrm{km}^2\mathrm{s}^{-2})]$ | uniform between -5 and +5 | $0.9^{+0.1(+0.2)}_{-0.1(-0.2)}$ | velocity dispersion (Cra2) |
| $k_{v_{\mathrm{los}}}$ [km s$^{-1}$ arcmin$^{-1}$] | uniform between 0 and +10 | $0.03^{+0.03(+0.05)}_{-0.02(-0.03)}$ | magnitude of maximum velocity gradient (Cra2) |
| $\theta_{v_{\mathrm{los}}}$ [deg.] | uniform between -180 and +180 | $-103.0^{+246.0(+279.0)}_{-51.0(-72.0)}$ | direction of maximum velocity gradient (Cra2) |
| $\langle[\mathrm{Fe/H}]\rangle$ [dex] | uniform between -5 and +1 | $-1.98^{+0.1(+0.21)}_{-0.1(-0.2)}$ | mean metallicity at center (Cra2) |
| $\log_{10}[\sigma^2_{[\mathrm{Fe/H}]}]$ | uniform between -5 and +2 | $-1.3^{+0.15(+0.28)}_{-0.14(-0.27)}$ | metallicity dispersion (Cra2) |
| $k_Z$ [dex arcmin$^{-1}$] | uniform between -1 and +1 | $0.001^{+0.005(+0.01)}_{-0.005(-0.01)}$ | magnitude of metallicity gradient (Cra2) |
| $\log_{10}[\Sigma_{0,1}/(\mathrm{arcmin}^{-2})]$ | uniform between -10 and +10 | $-0.57^{+0.05(+0.09)}_{-0.05(-0.1)}$ | 2D stellar density scale (Cra2) |
| $\log_{10}[R_{\mathrm{h}}/(\mathrm{arcmin})]$ | uniform between -1 and +3.5 | $1.47^{+0.03(+0.07)}_{-0.03(-0.07)}$ | 2D halflight radius (Cra2) |
| $\log_{10}[\Sigma_{0,2}/(\mathrm{arcmin}^{-2})]$ | uniform between -10 and +10 | $-0.64^{+0.0(+0.01)}_{-0.0(-0.01)}$ | 2D stellar density (foreground) |
| $k_2$[arcmin$^{-1}$] | uniform between 0 and +0.1 | $0.0005^{+0.0001(+0.0002)}_{-0.0001(-0.0002)}$ | gradient in 2D stellar density (foreground) |
| $\theta_2$ [deg.] | uniform between -180 and +180 | $-87.4^{+8.76(+17.72)}_{-8.46(-17.63)}$ | direction of gradient in 2D stellar density (foreground) |
| $\sigma_{v_{\mathrm{los}}}$ [km s$^{-1}$] | | $2.7^{+0.3(+0.7)}_{-0.3(-0.5)}$ | velocity dispersion (Cra2) |
| $\sigma_{[\mathrm{Fe/H}]}$ [dex] | | $0.22^{+0.04(+0.09)}_{-0.03(-0.06)}$ | metallicity dispersion (Cra2) |
| $R_{\mathrm{h}}$ [arcmin] | | $29.24^{+2.4(+4.95)}_{-2.19(-4.19)}$ | 2D halflight radius (Cra2) |

metal-rich star (top panel) displays stronger absorption features in general, including pronounced differences near the Ti II/Fe I features at 5227 Å, a Ca I/Fe I feature at 5270 Å, the Fe I doublet at 5273 Å, and an Fe II/Cr I feature at 5276 Å.

### 4.4. Scaling Relations

Figure 5 places Crater 2 in the context of well-known scaling relations involving the Local Group's dwarf galaxies. Crater 2's mean metallicity (regardless of whether we use the photometric estimate of [Fe/H]= $-1.7 \pm 0.1$ or our spectroscopic estimate of $\langle[\mathrm{Fe/H}]\rangle=-1.98^{+0.1}_{-0.1}$) and (dimensional) dynamical mass-to-light ratio ($R_{\mathrm{h}}\sigma^2_V/L_V G=10^{+3}_{-2}\,M_\odot/L_\odot$) are typical for dwarf galaxies of Crater 2's luminosity ($L_V = [1.5\pm0.1]\times 10^5 L_{V,\odot}$). Nevertheless, Crater 2's metallicity dispersion is slightly smaller than those of other dwarfs of similar luminosity. And, as already pointed out by T16, Crater 2 is a low-density outlier in the size-luminosity plane, with halflight radius ($R_h \sim 1.1$ kpc) nearly an order of magnitude larger than is typical for its luminosity (top panel of Figure 5).

Our spectroscopic measurements reveal that Crater 2 is unusually large in another respect, regardless of its luminosity. Figure 6 shows scaling relations involving only the dynamical quantities of size and velocity dispersion. While other dwarf galaxies with $R_{\mathrm{h}} \sim 1$ kpc have velocity dispersions of $\sim 10$ km s$^{-1}$ (top panel of Figure 6), Crater 2 is much colder, with $\sigma_{v_{\mathrm{los}}}=2.7^{+0.3}_{-0.3}$ km s$^{-1}$. Conversely, while there are other dwarf galaxies for which measured velocity dispersions are similarly cold, these dwarfs tend to be the the smallest 'ultra-faints', with $R_{\mathrm{h}} \lesssim 100$ pc (e.g., Segue 1, Segue 2, Leo IV, Leo V, Reticulum 2).

Moreover, among Local Group dwarf galaxies with resolved velocity dispersion measurements, Crater 2 is plausibly the coldest irrespective of other observables. While Koposov et al. (2011) find evidence for a slightly colder (albeit with larger errorbars) sub-population in

the Bootes I dwarf, with $\sigma_{v_{\mathrm{los}}} = 2.4^{+0.9}_{-0.5}$ km s$^{-1}$, they measure an overall velocity dispersion of $\sigma_{v_{\mathrm{los}}} = 4.6^{+0.8}_{-0.6}$ km s$^{-1}$ for Boo I.[11] Kirby et al. (2013) and Simon et al. (2016) place (95%) upper limits of $\sigma_{v_{\mathrm{los}}} < 2.6$ km s$^{-1}$ and $\sigma_{v_{\mathrm{los}}} < 1.5$ km s$^{-1}$ for Segue 2 and Tucana III, respectively, but given their median velocity errors of 3.7 km s$^{-1}$ and 2.1 km s$^{-1}$, they do not resolve these dispersions. Also for Segue 2, Belokurov et al. (2009) report a resolved dispersion of $\sigma_{v_{\mathrm{los}}} = 3.6^{+1.7}_{-1.0}$ km s$^{-1}$, based on a Hectochelle sample with median velocity error 0.6 km s$^{-1}$. Several dwarf satellites of M31 have velocity dispersions constrained to be $< 3$ km s$^{-1}$, but all are unresolved (Collins et al. 2013). Indeed, among known dwarfs, only Leo V has a (marginally) resolved velocity dispersion that is colder than Crater 2's. Based on Hectochelle spectroscopy of Leo V, Walker et al. (2009a) report a marginally-resolved dispersion of $\sigma_{v_{\mathrm{los}}} = 2.4^{+2.4}_{-1.4}$ km s$^{-1}$, most recently confirmed by Collins et al. (2016), who report a marginally-resolved $\sigma_{v_{\mathrm{los}}} = 2.3^{+3.2}_{-1.6}$ km s$^{-1}$. While both estimates suggest Leo V is the colder galaxy, the available samples for Leo V are considerably smaller and the errorbars are considerably larger than we have for Crater 2.

In any case, Crater 2 is the most securely cold outlier with respect to scaling relations involving size and velocity. The simplest such relation is given by $\sigma^2_V \propto R_{\mathrm{h}}$, (McGaugh et al. 2007, Walker et al. 2010; top panel of Figure 6). An equivalent relation is $\sigma^2_V/(R^2_{\mathrm{h}}G) \propto R^{-1}_{\mathrm{h}}$, which (dimensionally) takes the form of a 'universal' mass-density profile (Walker et al. 2009b; bottom panel of Figure 6). Other equivalent relations are $\sigma^2_V/(R_{\mathrm{h}}G) \propto 1$ (Kormendy 1985; Donato et al. 2009; Salucci et al. 2012), and $\sigma^2_V/R_{\mathrm{h}} =$constant (Walker & Loeb 2014), implying constant scales for surface mass density and acceleration, respectively. Previous deviations from these scaling relations, which have been shown to extend over all galactic

[11] We find no evidence for sub-populations within Crater 2.

FIG. 5.— *Top to bottom:* Size, mean metallicity, metallicity dispersion and dynamical mass-to-light ratio vs absolute magnitude, for Galactic globular clusters (black points) as well as dwarf spheroidal satellites of the Milky Way (blue points with errorbars) and M31 (red points with errorbars). Quantities plotted for Crater 2 are adopted from Torrealba et al. (2016) and this work. With the exception of metallicity dispersions, which are adopted from Kirby et al. (2008, 2010); Simon et al. (2011); Willman & Strader (2012) data for globular clusters and dSphs are adopted, respectively, from the catalog of Harris (1996, 2010 edition; we include only clusters with velocity dispersion measurements) and the review of McConnachie (2012).

scales, have plausibly been attributed to tidal stripping and/or to an offset between separate relations followed by the satellite populations of the Galaxy and M31 (Collins et al. 2014). However, these arguments do not readily explain Crater 2's status as the most statistically significant outlier. Not only is Crater 2 a satellite of the Galaxy and not M31, but its round morphology, lack of a velocity gradient, obeyance of the luminosity/metallicity relation, and large Galactocentric distance make it unlikely to have undergone significant tidal disruption. In

FIG. 6.— Velocity dispersion vs halflight radius, for the population of dwarf spheroidals plotted in Figure 5 (excluding those for which the vertical errorbar is > 100%). Overplotted is the scaling relation $\mathcal{V}/(\mathrm{km\,s^{-1}}) = \sqrt{R_{\mathrm{h}}/\mathrm{pc}}$, where $\mathcal{V} \equiv \sqrt{3}\sigma_{v_{\mathrm{los}}}$ (McGaugh et al. 2007; Walker et al. 2010; Walker & Loeb 2014).

summary, Crater 2 is a diffuse, cold outlier in chemodynamical as well as structural scaling relations.

### 4.5. *Dark Matter Halo*

The available estimates of Crater 2's structural parameters and LOS velocity dispersion provide a crude approximation of the dynamical mass and mass-to-light ratio enclosed within a sphere that is centered on Crater 2 and has radius $r \sim R_{\mathrm{h}}$. With the implicit assumptions of spherical symmetry, dynamic equilibrium and negligible contribution of stellar binary motions to the observed velocity dispersion, the formula of Walker et al. (2009b) gives $M(R_{\mathrm{h}}) \approx 5R_{\mathrm{h}}\sigma_V^2/(2G){=}4.4^{+1.2}_{-0.9} \times 10^6 \ M_{\odot}$, corresponding to a dynamical mass-to-light ratio of $\Upsilon(R_{\mathrm{h}}) \approx 2M(R_{\mathrm{h}})/L_V{=}53^{+15}_{-11} \ M_{\odot}/L_{V,\odot}$ and an equivalent circular velocity of $V_c(R_{\mathrm{h}}) \equiv \sqrt{GM(R_{\mathrm{h}})/R_{\mathrm{h}}}{=}4.3^{+0.5}_{-0.5} \ \mathrm{km\ s^{-1}}$ at the halflight radius. Under the same assumptions, the similar formula of Wolf et al. (2010) gives similar results, with $M(\frac{4}{3}R_{\mathrm{h}}) \approx 4R_{\mathrm{h}}\sigma_V^2/G{=}7.0^{+1.9}_{-1.5} \times 10^6 \ M_{\odot}$, $\Upsilon(\frac{4}{3}R_{\mathrm{h}}) \approx 2M(\frac{4}{3}R_{\mathrm{h}})/L_V{=}85^{+25}_{-18} \ M_{\odot}/L_{V,\odot}$ and $V_c(\frac{4}{3}R_{\mathrm{h}}) \equiv \sqrt{GM(\frac{4}{3}R_{\mathrm{h}})/(\frac{4}{3}R_{\mathrm{h}})}{=}4.8^{+0.6}_{-0.5}\mathrm{km\ s^{-1}}$. Thus despite its extreme coldness, Crater 2 is sufficiently large that—insofar as the stated assumptions are valid—its support against gravity requires a dominant dark matter halo.

#### 4.5.1. *Jeans Model*

The chemodynamical model described in previous sections assumes that the LOS velocity dispersion of Crater 2 members is independent of position. In order to exam-

ine the dark matter content of Crater 2 in more detail, we shed this assumption by adopting a model in which the LOS velocity dispersion depends on position via the spherically-symmetric Jeans equation:

$$\sigma_V^2(R|\Theta) = \frac{2}{\Sigma(R|\Theta)} \int_R^\infty \left(1 - \beta(r)\frac{R^2}{r^2}\right) \frac{\nu(r)\overline{v_r^2}(r)r}{\sqrt{r^2 - R^2}} \mathrm{d}r, \tag{8}$$

where (Binney & Mamon 1982)

$$\nu(r)\overline{v_r^2}(r) = \frac{1}{b(r)} \int_r^\infty b(s)\nu(s)\frac{GM(s)}{s^2}\mathrm{d}s. \tag{9}$$

Here, the function $b(r) \equiv b(r_1)\exp\left[2\int_{r_1}^r \beta_v(t)t^{-1}\mathrm{d}t\right]$ is determined by the velocity dispersion anisotropy parameter $\beta_v(r) \equiv 1 - \overline{v_\theta^2}(r)/\overline{v_r^2}(r)$, $\nu(r)$ is the 3D stellar number density profile (i.e., the deprojection of $\Sigma_1(R|\Theta)$), and $M(r) = M_{\mathrm{DM}}(r) + L_V(r)\Upsilon_{V,*}$ is the mass enclosed within radius $r$, which includes dark matter and stellar components (the enclosed stellar mass is the product of the enclosed luminosity, $L_V(r)$, and the stellar mass-to-light ratio, $\Upsilon_{V,*}$).

Our adoption of a Plummer profile for $\Sigma(R|\Theta)$ implies the assumption $\nu(r) = \frac{3}{4}\Sigma_{0,1}R_\mathrm{h}^{-1}[1 + R^2/R_\mathrm{h}^2]^{-5/2}$. We assume the dark matter halo has density profile of the form (Zhao 1996)

$$\rho_{\mathrm{DM}}(r) = \rho_s \left(\frac{r}{r_s}\right)^{-\gamma}\left[1 + \left(\frac{r}{r_s}\right)^\alpha\right]^{(\gamma-\beta)/\alpha}, \tag{10}$$

which specifies the enclosed dark mass profile $M_{\mathrm{DM}}(r) = 4\pi\int_0^r s^2\rho_{\mathrm{DM}}(s)\mathrm{d}s$.

With these assumptions, we replace the free parameter $\sigma_{v_{\mathrm{los}}}$ with the five free parameters that specify $\rho_{\mathrm{DM}}(r)$, a free parameter for the stellar mass-to-light ratio, and an additional parameter that specifies $\beta_v$, which we assume to be constant. We adopt the same broad priors on halo parameters and anisotropy as described by Geringer-Sameth et al. (2015). For the stellar mass-to-light ratio, we adopt a prior that is uniform between $-1 \leq \log_{10}[\Upsilon_{*,V}/(M_\odot L_\odot^{-1})]$. Unlike in previous work, our Jeans model is now embedded within the mixture model, specifying the velocity dispersion of Crater 2 members as a function of position.

Figure 7 displays 68% credibility intervals that we obtain for stellar and dark matter profiles for enclosed-mass and density. Again despite Crater 2's extremely cold velocity dispersion, and again subject to the validity of the assumptions of dynamic equilibrium and negligible contamination from binary stars, we find that dark matter dominates Crater 2's gravitational potential at all radii, with the dark matter density exceeding that contributed by stars by two orders of magnitude even at $r = 0$. Moreover, at radii $r \sim R_\mathrm{h}$, the results of our Jeans model stand in excellent agreement with the mass estimators of Walker et al. (2009b) and Wolf et al. (2010, bottom panel of Figure 7).

#### 4.5.2. Astrophysical 'J'-factor for Dark Matter Searches

Although this analysis suggests that Crater 2's gravitational potential is dominated by dark matter even at its center, the overall amount of dark matter in Crater 2—as constrained, say, within the halflight radius of

$r = R_\mathrm{h} \sim 1$ kpc—is modest relative to what has been estimated for other Galactic dwarf spheroidals at similar radii (Strigari et al. 2008; Walker et al. 2009b; Wolf et al. 2010). Combined with a relatively large distance of $\sim 120$ kpc, these attributes make Crater 2 a poor target in the search for indirect evidence of dark matter particle interactions—e.g., annihilation to gamma-rays. Using the dark matter density profile estimated above, we use the method of Geringer-Sameth et al. (2015) to compute the profile $\mathrm{d}J/\mathrm{d}\Omega \equiv \int_0^\infty \rho^2(l)\mathrm{d}l$, where $l$ increases along the line of sight and the 'J-factor' $J(\theta) \equiv \int_0^\theta 2\pi\sin(\theta')\mathrm{d}\theta'\mathrm{d}J(\theta')/\mathrm{d}\Omega$ is proportional to the flux of annihilation photons for a given particle physics model. At $\theta = 1.4°$, the angle corresponding to the projected radius of the outermost spectroscopic member, we obtain $\log_{10}[J/(\mathrm{GeV}^2\mathrm{cm}^{-5})] = 15.7 \pm 0.25$. For comparison, the most attractive dwarf-galactic targets for dark matter searches have $\log_{10}[J/(\mathrm{GeV}^2\mathrm{cm}^{-5})] \gtrsim 19$, even when evaluated at smaller angles (Geringer-Sameth et al. 2015; Bonnivard et al. 2015).

Finally, Figure 8 shows the LOS velocity dispersion profile of Crater 2, which we calculate by weighting all spectroscopic data points by the posterior probability of membership, given the data and our mixture model based on the Jeans equation. Where it is constrained by data, the velocity dispersion profile is approximately flat, as is the case for nearly all well-studied dwarf galaxies (Walker et al. 2007). The purple band indicates 68% credibility intervals on the velocity dispersion as a function of radius, calculated directly from the Jeans model described above. The red band indicates the velocity dispersion profile calculated from the Jeans equation, but in the case that there is no dark matter halo—ie., the gravitational potential arises only from the self-gravity of Crater 2 stars, for which we continue to allow stellar mass-to-light ratios in the broad range $-1 \leq \log_{10}[\Upsilon_*/(M_\odot/L_\odot)] \leq 1$. Compared to the original Jeans model that allows for a dark matter halo, this version without dark matter is disfavored overwhelmingly, as quantified by a Bayesian evidence ratio of $e^{106}$.

### 5. SUMMARY & DISCUSSION

Table 4 summarizes the observed properties of Crater 2, listing the structural parameters measured by T16 along with chemodynamical parameters measured from our Hectochelle spectroscopy. While Crater 2's metallicity and dynamical mass-to-light ratio are similar to those of other dwarf galaxies of similar luminosity, its large size and cold velocity dispersion make Crater 2 an extremely low outlier in terms of both stellar surface density and dynamical mass-density.

For an object of Crater 2's luminosity and size, the self-gravity of the stars alone generates a line-of-sight velocity dispersion of just $< 1$ km s$^{-1}$. Taken at face value, even velocity dispersions as cold as $\sim 2-3$ km s$^{-1}$ imply a dominant dark matter component, as we have found. However, given the ability of unresolved binary-star orbital motions alone to generate velocity dispersions of the observed magnitude (Olszewski et al. 1996; Hargreaves et al. 1996; McConnachie & Côté 2010, Spencer et al., in preparation), the current dynamical evidence for dark matter in Crater 2 is somewhat precarious. Robust es-

[1] Torrealba et al. (2016)
[2] calculated using the solar motion measured by Schönrich et al. (2010)
[3] $M(R_{\mathrm{h}}) \approx 5R_{\mathrm{h}}\sigma^2_{v_{\mathrm{los}}}/(2G)$; assumes equilibrium, negligible binary stars
[4] $V_c(R_{\mathrm{h}}) \equiv \sqrt{GM(R_{\mathrm{h}})/R_{\mathrm{h}}}$
[5] $\Upsilon \approx 2M(R_{\mathrm{h}})/L_V$

FIG. 7.— Density and enclosed-mass profiles for Crater 2's stellar and dark matter components, from our mixture model based on the Jeans equation (Section 4.5). Colored bands represent 68% credibility intervals at each radius. Crosses represent estimates of masses enclosed within spheres of radius $R_{\mathrm{h}}$ (Walker et al. 2009b) and $\frac{4}{3}R_{\mathrm{h}}$ (Wolf et al. 2010).

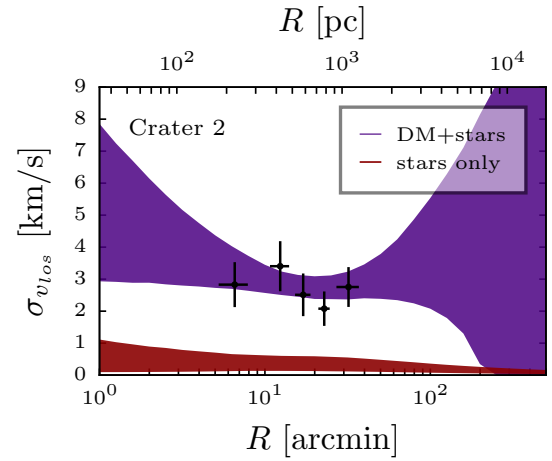

FIG. 8.— Projected velocity dispersion profile of Crater 2. The purple colored band indicates the 68% credibility interval at each projected radius, from our mixture model based on the Jeans equation (Section 4.5). Black crosses indicate the binned velocity dispersion profile estimated using the resulting membership probabilities as weights (note: the model represented by the purple shaded region was fit to unbinned photometric and spectroscopic data). The red colored band indicates the velocity dispersion profile expected in the case that Crater 2 lacks a dark matter halo and is bound only by the self-gravity of its stars, allowing for stellar mass-to-light ratios in the range $-1 \leq \log_{10}[\Upsilon_*/(M_{\odot}/L_{\odot,V})] \leq 1$.

timates of Crater 2's dark matter content will require repeat spectroscopic observations to detect and quantify the properties of its binary stars. To the extent that bi-

nary stars contribute to the velocity dispersion that we have measured, Crater 2 is intrinsically even colder and less dense than indicated above.

It will be up to a combination of numerical simulations

and various dark matter models to interpret these results in the context of a galaxy formation theory. For example, star formation and subsequent supernova winds can give up gravitational energy to standard 'cold' dark matter (CDM), lowering halo concentration as dark matter expands non-adiabatically (Pontzen & Governato 2014, and references therein). For example, examining the simulated dark matter halos of Milky-Way-dwarf-satellite analogs down to Crater 2's luminosity, Wetzel et al. (2016) show how this sort of process drops circular velocities by as much as $\sim 25$ km s$^{-1}$ to $\sim 10$ km s$^{-1}$ at radii of 1 kpc. However, the value that we estimate for Crater 2 would be off the lower end of the relation between $V_c$ vs $r$ plotted in Figure 2 of Wetzel et al. (2016). It remains to be seen whether the standard CDM model can be expected to produce objects like Crater 2 around galaxies like the Milky Way.

Alternatively, it may turn out that Crater 2 is more naturally produced in models that ascribe more exotic properties to the dark matter itself. For example, non-gravitational self-scattering of dark matter particles can flatten the central density 'cusps' that characterize halos formed in CDM cosmological simulations (e.g., Spergel & Steinhardt 2000; Loeb & Weiner 2011), perhaps lowering central dark matter densities to the level we infer for Crater 2. Another possibility is that the thermal free-streaming of sufficiently 'warm' dark matter—e.g., sterile neutrinos (Dodelson & Widrow 1994)—might prevent the formation of dense cusps in the first place (Bode et al. 2001). The same effect might also result from quantum pressure associated with the de Broglie wavelength of particles—e.g., axions—giving rise to light scalar fields (Marsh & Pop 2015).

Finally, we note that McGaugh (2016) has recently calculated the velocity dispersion expected for Crater 2 under the hypothesis of Modified Newtonian Dynamics (MOND; Milgrom 1983), which fits galactic rotation curves not by invoking dark matter, but rather by modifying gravity in the regime of low accelerations, $a \equiv GM_{\rm b}(r)/r^2 \ll a_0$, where $M_{\rm b}(r)$ is the baryonic mass interior to radius $r$ and $a_0 \sim 1.2 \times 10^{-10}$ m s$^{-2}$. Assuming spherical symmetry, isotropic velocity dispersions and adopting stellar mass-to-light ratio $\Upsilon_* = 2^{+2}_{-1} M_\odot/L_\odot$, McGaugh (2016) uses the formula of McGaugh & Milgrom (2013) to predict for Crater 2 a velocity dispersion of $\sigma_{v_{\rm los}} \approx 4$ km s$^{-1}$ in the 'deep-MOND' limit that ignores the external acceleration field of the Milky Way. Accounting for the external field lowers the prediction to $\sigma_{v_{\rm los}} = 2.1^{+0.9}_{-0.6}$ km s$^{-1}$, where the errorbars propagate uncertainty in the adopted $\Upsilon_*$. This prediction is consistent with the otherwise-unexpectedly cold velocity dispersion that we measure.

Of course, no model can be tested definitively based on what it predicts (or does not predict) for Crater 2 alone. But by extending the range of properties exhibited by the Milky Way's satellites, Crater 2 gives that population more leverage to distinguish amongst various models. Moreover, the discovery of Crater 2 at current surface brightness detection limits gives reason to be optimistic that the next generation of sky surveys will uncover even more extreme objects.
