Abstract: In this paper we present *GeoWin* a generic tool for the interactive visualization of geometric algorithms. *GeoWin* is implemented as a C++ class that uses templates and object-oriented programming to be independent from the underlying geometric kernel. In this way, it can handle arbitrary types of geometric objects, as long as they provide a small set of basic operations. Currently, *GeoWin* is used as visualization tool for both the CGAL and LEDA projects.

Keywords: computational geometry, visualization, animation.

1 Introduction

The visualization of algorithms and data structures is very important in the design and implementation of algorithms, especially in the area of computational geometry. It is useful for the presentation of results, teaching, debugging and testing, the design of worst-case or degenerate inputs, and it often helps to discover problems and find new solutions. There are many visualization tools and systems available, e.g., *GeomView*[1], *OpenGL*[11] or *GeoSheet*[6]. However these systems have two serious disadvantages: they are very complex and it requires a lot of special knowledge to use them in a non-trivial way and, secondly, it is very difficult or even impossible to use them interactively. On the other hand, there have also been developed many interactive programs and systems for the animation of geometric algorithms, see [4, 13, 12] for examples. However, these systems have been designed and implemented in a very special closed environment and cannot be reused by other software systems.

In this paper we introduce *GeoWin* a generic tool for the interactive visualization of geometric algorithms.

By the use of templates and object-oriented

programming, *GeoWin* is a *generic* visualization and animation tool that can be used for arbitrary types of geometric objects, as long as they provide as small set of basic operations. This makes *GeoWin* independent from any concrete geometric kernel. Currently, it is used as visualization tool for both the CGAL (see [5]) and LEDA (see [9]) projects.

The design and implementation of *GeoWin* was influenced by the popular LEDA graph editor *GraphWin* (see [9], chapter 12). Both editors follow the idea to support certain styles of programming that are often used in demo and animation programs. Examples of such programming styles are the *edit & run* approach and the use of *result scenes* which both will be discussed in section 5 of this paper.

2 The *GeoWin* Data Type

A *GeoWin gw* is an editor that maintains a collection of geometric *scenes*. Each geometric scene in this collection has an associated *container* of geometric *objects* whose members are displayed according to a set of visual attributes (color, line width, line style, etc.). A scene can be *visible* or *invisible* and one of the scenes in the collection

can be *active*. The active scene receives all editing input and thus can be manipulated through the interactive interface of GeoWin (see section 3).

Both the container type and the object type have to provide a certain functionality. The container type must implement the STL list interface ([10]), in particular, it has to provide STL-style iterators, and for any object type T the following functions and operators have to be defined before it can be used in GeoWin.

- I/O operators for streams, LEDA windows, and LEDA postscript files

```
ostream& operator<<(ostream&,const T&);
istream& operator>>(istream&,T&);
window& operator<<(window&,const T&);
window& operator>>(window&,T&);
ps_file& operator<<(ps_file&,const T&);
```

- translate and rotate operations

```
Translate(T& o, double dx, double dy);
Rotate(T& o, double x, double y,
       double phi);
```

- basic geometric queries

```
BoundingBox(const T& o,
            double& x0, double& y0,
            double& x1, double& y1);
IntersectsBox(const T& o,
              double x0, double y0,
              double x1, double y1);
```

Any combination of container and object type that fulfill these requirements for containers and objects, respectively, can be associated with GeoWin scene in a `gw.new_scene()` operation. Currently, GeoWin is used to visualize geometric objects and algorithm from both the CGAL ([5]) and LEDA ([9]) libraries. In this context typical examples for containers of a scene are

```
std::list<CGAL::POINT_2<cart> >
```

or

```
leda_list<rat_circle> C;
```

The first one uses an STL list from the standard C++ library and points from the cartesian geometry kernel of CGAL, the second example uses a LEDA list of circles from LEDA's rational geometry kernel.

3 The Interactive Interface

The interactive interface of a GeoWin `gw` is started by calling `gw.edit()` or `gw.edit(sc)`. The first variant opens a GeoWin with an empty set of scenes and allows the user to interactively create and activate scenes from a menu. The second variant makes the supplied scene `sc` the active scene, i.e., `sc` is the edited scene.

At the top of the main window there is a default menu bar containing menus for em File and *Edit* operations, *Scenes* and *Window* setup, and other *Options* (Figure 1 shows a screenshot). This default menu can be changed and extended by user-defined menus and buttons.

In the same way, the following default actions associated with mouse and keyboard events occurring in the drawing area of the window can be replaced or extended by user-defined actions. The left mouse button creates a new object or scrolls the scene when the button is held down while dragging the mouse. The middle button selects a single object or a group of objects, and the right mouse button opens a context menu that allows to delete objects or to change individual attributes of objects.

Now we are ready to write our first GeoWin program. It just creates a scenes of polygons, changes the default filling color to grey and enters the interactive mode. You can see a screenshot of the program (after generating a hilbert polygon) in Figure 1.

```
#include <LEDA/geowin.h>

int main() {
    GeoWin gw;
    list<polygon> L;
    geo_scene sc = gw.new_scene(L);
    gw.set_color(sc,black);
    gw.set_fill_color(sc,greyl);
    gw.edit(sc);
    return 0;
}
```

4 The Programming Interface

In this section we will discuss some of the most important operations of the data type *GeoWin*. For a complete list of operations see the CGAL manual[5].

Creating and opening a GeoWin

For the creation of a GeoWin you can use one of the following constructors

```
GeoWin gw(const char* label);
```

creates a GeoWin with frame label `label`.

```
GeoWin gw;
```

creates a GeoWin with default label.

```
gw.display(int x, int y);
```

opens a GeoWin with the left upper corner at position (x, y) .

```
gw.display();
```

opens a GeoWin at default position.

Starting the interactive mode

```
void gw.edit();
```

starts the interactive mode without specifying an active scene.

```
bool gw.edit(geo_scene sc);
```

starts the interactive mode for scene `sc`.

Creating Scenes

Scenes are created by the `gw.new_scene()` Operation

```
geo_scene gw.new_scene(container<obj>& C);
```

creates a new scene with the associated container `C`

```
geo_scene gw.new_scene(function_t func,
                        geo_scene& sc_inp);
```

creates a so-called *result scene* whose contents is computed by applying function `func` to the objects of the input scene `sc_inp`. Result scenes will be discussed in more detail in section 5.

5 Animation with GeoWin

In this section we will describe three main approaches to interactive visualization.

5.1 Edit and Run

The *edit & run* style is very simple. It uses GeoWin only for constructing a certain input for the algorithm by entering the interactive mode (`gw.edit()`). Then the algorithm is applied to this input, the result is displayed, e.g., by changing the attributes of certain objects, or by simply producing a text output, and finally the program returns to the interactive mode. This loop can be interrupted by leaving `gw.edit` through the *Quit* button. The basic structure of an *edit and run* program is given below.

```
#include <LEDA/geowin.h>

int main() {

    list<object> L;
    geo_scene sc = gw.new_scene(L);

    while (gw.edit(sc))
    { ALGORITHM(L);
      "display or ouput result";
    }
    return 0;
}
```

Figure 2 gives a more concrete example that displays the result of a closest pair algorithms by changing the color of the closest pair to red. Note that this program assumes that there is a `CLOSEST_PAIR` function defined that takes a list of points (of some general type `point_t`) and writes a pair of points whose euclidean distance is minimal to the reference parameters `a` and `b`.

5.2 Result Scenes

A *result scene* is a scene whose contents (container of objects) depends on one or more *input scenes* (in this extended abstract we only deal with the case of one input scene).

The dependance is defined by a function that is applied to the objects of the input scenes. The contents of the result scene is simply defined to be the output of this function. Whenever the input scene is modified, e.g., interactively (if the input scene is active), the contents of the output scene is recomputed. In this way, it is very easy to write animation programs that show the result of an algorithm on-line while the user edits

the input to this algorithm, for example by moving points around, or by inserting or removing objects. The general structure of a program following the result scene approach is given below.

```
void algo(const list<object1>& in,
         list<object2>& out);

geo_scene sc_in = gw.new_scene(L);
geo_scene sc_out = gw.new_scene(algo,
                                sc_in);
gw.edit(sc_in);
```

Figure 3 shows a more concrete example program for the result scene approach. It assumes that there is function `INTERSECT` that implements an algorithm for computing the point of intersection (of type `point_t`) for a given set of straight line segments (of type `segment_t`). Then we can create a the result scene that depends on an input scene `sc_input` of points by calling `gw.new_scene(INTERSECT,sc_input)`. Most of the demo programs in LEDA and CGAL are written in this way. In particular, all algorithms working on an input set of points (e.g. all kinds of Voronoi and Delaunay diagrams) can be demonstrated very elegant in a single program. Then a particular algorithm or a combination of algorithms can be selected by simply changing the visibility of the scenes in the interactive interface

5.3 User-Defined Event Handling

This section presents a third way of writing visualization programs supported by GeoWin. Every edit operation of the interactive interface has an associated *event*. For instance, inserting a new object (by clicking the left mouse button) triggers a *new_object* event, deleting an object creates a *del_object* event, and moving an object around creates a *move_object* event. Application programs can handle these events by specifying corresponding call-back functions which are to be called whenever a certain event occurs.

We give an example of a sweep line animation that uses this technique. The program creates a special scene `sc_sweep` that contains a single vertical line, the sweep line, and it associates a call-back function `sweep_handler` with `move_object` events of this scene (by calling `gw.set_move_handler(sc_sweep,sweep_handler)`).

Now, during the interactive mode, the user can grab and move the sweep line with the mouse, and for each triggered motion event the sweep handler function is called, with the relative distance vector of the motion. Note that the call-back function associated with move object events has a boolean return type. The result of this function is evaluated by GeoWin and controls whether the actual motion is really executed. In the sweep example we use this fact to prevent any backward motion of the sweep line.

```
bool sweep_handler(GeoWin& gw, const line& sl,
                  double dx,
                  double dy)
{ if (dx < 0) {
    // do not move backward
    return false;
  }
  "perform sweep by vector(dx,dy)"
  return true;
}

int main()
{
  GeoWin gw("Sweep Demo");

  list<line> sweep_line;
  sweep_line.append(line(point(0,-100),
                        point(0,100)));

  geo_scene sc_sweep = gw.new_scene(sl);
  gw.set_color(sc_sweep,black);
  gw.set_visible(sc_sweep,true);

  gw.set_move_handler(sc_sweep, sweep_handler);
  gw.edit(sc_sweep);

  return 0;
}
```

The screenshot of Figure 4 shows a sweep line animation that uses the above described technique for the animation of Fortune's sweep algorithm for computing the Voronoi Diagram of a set of points in the plane. This animation allows to drag the sweep line across the plane while watching several different structures: the constructed Delaunay triangulation, the shore line bisector of parabolic arcs, and the circle events contained in the event queue.

6 Current and Future Work

- Support of three-dimensional geometry
We are currently working on the support of three-dimensional objects and algorithms. Figure 5 shows the output of prototype 3d-viewer while animating a 3d convex hull algorithm. We will incorporate this viewer into GeoWin.
- Improved support for incremental algorithms
Currently, incremental algorithms are not very well supported. We plan to associate incremental data structures directly with result scenes to make their visualization much more easy and elegant.
- Algorithm Animation
We plan to build a small library of animation software supporting the teaching and the presentation of geometric algorithms.
