13 **ABSTRACT**

14 To assess the feasibility of observing changes in the magnetic field produced by the  
15 piezomagnetic effect, an improved model of the piezomagnetic field corresponding to  
16 the Mw 9.0 Tohoku-oki earthquake is presented. In contrast to an earlier study, the  
17 proposed model explicitly considers the spatial distribution of slip on the seismic fault,  
18 and the results from this new model differ significantly from those of the previous  
19 model where slip distributions were ignored. Quantitative aspects of the piezomagnetic  
20 effect are discussed through comparisons of data and models. One feature clarified is  
21 that, because the fault rupture is so far offshore, the expected amplitudes are quite small  
22 at onshore existing observation sites; consequently, there would have been little chance  
23 of observing sizable piezomagnetic signals at inland sites during the Tohoku-oki  
24 earthquake. Nevertheless, piezomagnetic signals were reportedly detected at a few sites,  
25 possibly indicating that the stress sensitivity or the initial magnetization was larger (by  
26 several factors) than assumed. On the other hand, relatively large variations in the  
27 magnetic field of up to 10 nT may have occurred offshore. This means that if  
28 ocean-bottom sensors had been installed, larger piezomagnetic signals would have been  
29 detected. Moreover, the piezomagnetic field in offshore areas is sensitive to the detailed

30 slip distribution, suggesting that observations of the magnetic field at ocean-bottom

31 sites might provide important constraints on determination of slip models.

## 37 **1. Introduction**

38

39 The piezomagnetic effect, which describes changes in magnetization caused by  
40 mechanical stress, predicts changes in the Earth's magnetic field following a major  
41 earthquake. In earlier studies (e.g. Sasai, 1991, 1994, and references therein), a  
42 constitutive law of the relation between stress changes and magnetization changes has  
43 been proposed, as follows:

44

$$45 \quad \Delta M_i = \frac{3}{2} \beta \Delta T_{ij} M_j, \quad (i, j = x, y, z) \quad (1)$$

46

47 where  $\Delta M_i$  is the change in remanent and induced magnetization,  $\Delta T_{ij}$  is the deviatoric  
48 stress tensor,  $M_j$  is the initial total magnetization (i.e. the sum of induced and remanent  
49 magnetization without changes in stress), and  $\beta$  is a proportional coefficient that is  
50 usually referred to as the (piezomagnetic) stress sensitivity. Because of the  
51 piezomagnetic effect, it should be possible to monitor changes in stress in the Earth's  
52 crust with geomagnetic observations. Changes in the magnetic field that arise from the  
53 piezomagnetic effect are referred to as piezomagnetic fields. These fields are inverted to

54 changes in magnetization in terms of the magnetic Coulomb's law, and further inverted  
55 to changes in stress in terms of eq. (1).

56       However, the usefulness of the piezomagnetic effect as a tool for monitoring  
57 changes in stress is still not clear. Whether or not the piezomagnetic field can be  
58 observed depends on the spatial distribution of the piezomagnetic field which, in turn,  
59 depends on source type, depth and distance. If the piezomagnetic field has a detectable  
60 magnitude that is restricted to just a narrow area, then its detection will be difficult with  
61 poorly or sparsely spaced arrays of instruments. Numerical examinations of realistic  
62 source models need to be performed in order to assess the detectability of the  
63 piezomagnetic field.

64       The piezomagnetic stress sensitivity is another uncertain factor that determines  
65 whether or not the piezomagnetic field is detectable. While the proportional relation (i.e.  
66 eq. 1) is partially inferred from considerations based on thermodynamics (e.g.  
67 Nakamura and Nagahama, 1997), and the values of stress sensitivity can be determined  
68 by theoretical considerations (Stacey and Johnston, 1972), the actual magnetization  
69 fraction and type varies from rock to rock and representative values for a particular  
70 region must be determined from magnetic anomaly maps, geology and laboratory  
71 experiments. Laboratory experiments (e.g. Nagata and Kinoshita, 1967) suggest that

72 stress sensitivities are on the order of  $10^{-9} \text{ Pa}^{-1}$ . A stress sensitivity of this order is  
73 usually assumed when the piezomagnetic effect is considered in studies of volcanoes  
74 (e.g. Currenti et al., 2005) and earthquakes (e.g. Okubo et al., 2011). However, these  
75 values are sometimes too small to explain the observed offsets in the magnetic field  
76 associated with stress changes (e.g. Nishida et al., 2004; Oshiman et al., 1990; Zhan,  
77 1989). The effective values of the stress sensitivity on the geophysical scale (i.e. larger  
78 than the laboratory scale) should be evaluated by comparing observational and  
79 theoretical models.

80       The 2011 Mw 9.0 Tohoku-chihou Taiheiyou-oki earthquake (herein referred to as  
81 the Tohoku-oki earthquake), which occurred on the boundary between the Pacific and  
82 Eurasian plates, is one event for which the magnitudes of the piezomagnetic field can be  
83 examined. The Tohoku-oki earthquake is the largest seismic event to have been  
84 observed with a dense network of modern geophysical instruments. Along with  
85 seismological and geodetic data, geomagnetic data were obtained for this extreme event.  
86 Utada et al. (2011) presented a prompt and comprehensive report on observed variations  
87 in the geomagnetic field associated with the Tohoku-oki earthquake. Together with  
88 several types of geomagnetic variations that followed the earthquake, they also reported  
89 that magnetic field offsets, which probably arose from the piezomagnetic effect, are

90 actually observed, but they are only up to 1.0 nT at the observation sites. In their  
91 conclusions, Utada et al. (2011) presented a negative view on the detectability of the  
92 piezomagnetic field.

93 Although the observations reported in Utada et al. (2011) provide constraints on the  
94 phenomena that actually occurred at the time of the earthquake, their conclusions about  
95 the piezomagnetic effect need to be reconsidered because they are based on  
96 oversimplified source models that ignore the spatial distribution of slip on the fault. Any  
97 reconsideration should incorporate improved piezomagnetic field models in the hope of  
98 clarifying the quantitative nature of the piezomagnetic field and evaluating the  
99 usefulness of observing it.

100 The aims of this study are to: (1) provide constraints on the piezomagnetic stress  
101 sensitivity around the Tohoku region, near the seismic fault of the Mw 9.0 Tohoku-oki  
102 earthquake; and (2) assess the usefulness of the magnetic observations as a tool for  
103 detecting stress changes. To these ends, improved models of the piezomagnetic field are  
104 presented, and the various models are compared and assessed using the data presented  
105 by Utada et al. (2011).

106

## 107 **2. Procedures for modeling the piezomagnetic field**

108

109 This study presents a new model of the piezomagnetic field in which the spatial  
110 distribution of slip on the plate-boundary fault is explicitly considered. In many studies  
111 of the piezomagnetic field in relation to earthquakes (e.g. Nishida et al., 2007), uniform  
112 slip models are employed. However, the slip on a fault is generally heterogeneous, and  
113 it is therefore preferable to explicitly consider the spatial distribution of slip. In a  
114 uniform slip model, the fault parameters are averaged to obtain a single slip parameter.  
115 Such a simplification is valid if the spatial scale of the slip on the fault is smaller than  
116 the distance between the observation site and the fault. This criterion is not satisfied in  
117 the case of the Tohoku-oki earthquake, for which the spatial scale of the slip and the  
118 distance from the surface expression of fault rupture to observational sites are of the  
119 order of 100 km. Therefore, the assumption of uniform fault slip used previously by  
120 Utada et al. (2011) is likely inadequate in the calculations of the piezomagnetic fields  
121 produced by the earthquake.

122 This study considers the heterogeneous fault slip models of Hayes (2011) and Shao  
123 et al. (2011) (herein, referred to as the USGS and UCSB models, respectively), which  
124 are derived from seismic wave inversion. Averaged slips from these models were used

125 in the calculations of Utada et al. (2011). These models were published immediately  
126 following the Tohoku-oki earthquake and we can expect further refinements as more  
127 complete geophysical data sets are taken in account (e.g. Koketsu et al., 2011).  
128 Nevertheless, important characteristics of the Tohoku-oki fault slip are apparent in both  
129 the USGS and UCSB models. For example, both models indicate large slip near the  
130 trench axis. With these slip distributions, it is possible to evaluate the importance of  
131 heterogeneous slip distributions and to compare our results with those of Utada et al.  
132 (2011).

133 Piezomagnetic fields that correspond to a heterogeneous slip model are calculated  
134 according to the following procedure. The fault plane (i.e. plate boundary) is divided  
135 into sub-faults, and on each sub-fault the slip is assumed to be uniform. The total  
136 piezomagnetic signal at any point is the sum of the contributions from all sub-faults, and  
137 each contribution can be calculated by analytical formulae (Utsugi et al., 2000). Using  
138 this procedure, we can calculate the piezomagnetic signals that correspond to  
139 heterogeneous slip models for the Tohoku-oki earthquake.

140 Because the above procedure involves formulae derived by Utsugi et al. (2000), all  
141 the assumptions involved in the formulations of Utsugi et al. (2000) are also used in the  
142 present models. The initial total magnetization of the crust is assumed to be uniform

143 between the ground surface and a constant Curie point depth. The Earth's crust is  
144 approximated by elastic half-space, surface of which locates at sea level. These  
145 assumptions are not satisfied in reality, thus producing some uncertainty in the models  
146 obtained for the piezomagnetic field. Errors should also be included in the slip models,  
147 as mentioned above. To estimate the importance of uncertainty in the slip models and  
148 Curie point depths, we calculate the piezomagnetic fields that correspond to the two slip  
149 models (USGS and UCSB) with two values of  $H$  (15 and 30 km). The values for  $H$  used  
150 here are the same as those used by Utada et al. (2011), and they provide reasonable  
151 estimates for the island arc of the Tohoku district and for the subduction zone east of the  
152 Tohoku district of Japan (Tanaka et al., 1999). The effects of heterogeneities in the  
153 initial magnetization will be discussed separately, later.

154

### 155 **3. Features of the new piezomagnetic models**

156

157 Using the above procedures, and the parameters listed in Table 1, models of the  
158 piezomagnetic field have been constructed. The spatial distribution of the expected  
159 amplitude of the piezomagnetic effect is shown in Fig. 1. Observations are assumed to  
160 have been made at sea level, i.e. the surface of a uniform elastic half-space. Below, I

161 enumerate the features that are commonly observed in the results and which correspond  
162 to all sets of parameters. It should be noted that the absolute values given in the results  
163 are strongly dependent on the assumed sets of parameters. For this reason, this analysis  
164 focuses on relative rather than absolute values.

165       Relatively large signals of the piezomagnetic field are expected to occur in offshore  
166 areas in all cases. For the UCSB slip model, piezomagnetic fields larger than 3 nT are  
167 predicted in offshore areas. For the USGS slip models, the predicted piezomagnetic  
168 fields are smaller than those for the UCSB model, yet changes larger than 1 nT are  
169 predicted.

170       In contrast, the expected amplitudes of piezomagnetic signals over the more distant  
171 onshore, including the sites of observation, are rather small. Over a vast part of the land  
172 area, the predicted amplitudes of the piezomagnetic field are up to 0.4 nT. Precise  
173 values of the expected changes at the observation sites are listed in Table 2, together  
174 with the observed changes reported by Utada et al. (2011). In some models, the changes  
175 predicted at some locations are as large as 0.6 nT. For example, the predicted change at  
176 the ESA site is 0.6 nT for model b (i.e. UCSB slip model with  $H = 30$  km) whereas the  
177 predicted change at the same site is zero for other models. There is no location where all  
178 the models predict changes greater than 0.4 nT.

179           It should be pointed out that these models are quite different from those that use  
180 uniform slip distribution. Figure 2 shows the calculated piezomagnetic field intensities  
181 that correspond to uniform slip models where the slip parameters are averaged over the  
182 fault plane. Numerous differences can be observed between Figs. 1 and 2. For example,  
183 the amplitudes of the signals predicted with the uniform slip model do not exceed 1.0 nT,  
184 except for some localized areas. If we focus on this result, the impression is that the  
185 detection of coseismic piezomagnetic signals is a hopeless task, even if the  
186 observational area is extended to the seafloor. However, the amplitudes of signals  
187 predicted by the heterogeneous slip model are larger than 1–2 nT across a wide area of  
188 ocean. In this case, the amplitudes of the coseismic piezomagnetic signals would have  
189 been detected, if suitable magnetometers had been installed in the region.

190           The large differences that exist between the uniform and heterogeneous slip models  
191 highlight the importance of considering the heterogeneous model for the Tohoku-oki  
192 earthquake. The large differences also indicate that many of the conclusions about  
193 piezomagnetic signals by Utada et al. (2011) need to be reconsidered and probably  
194 changed.

195

196 **4. Discussion**

197

198 The goals of this study were to provide constraints on stress sensitivity, and to  
199 assess the usefulness of magnetic observations as tools for monitoring stress. The  
200 former can be accomplished by comparing the data with the models. The latter can be  
201 achieved by analyzing the constructed model. These matters are further discussed  
202 below.

203

204 *4.1. Possible values of the piezomagnetic stress sensitivity*

205

206 To provide constraints on the stress sensitivity using the results of piezomagnetic  
207 modeling, I make reference to the data presented by Utada et al. (2011). The idea is as  
208 follows. In the proposed model, the stress sensitivity ( $\beta$ ) and the intensity of the initial  
209 total magnetization ( $M = (M_x^2 + M_y^2 + M_z^2)^{1/2}$ ) are assumed to be given as in Table 1.  
210 The assumed values are possibly different from the actual values. As the calculated  
211 value of  $F_p$  (denoted by  $F_p^{\text{calculated}}$ ) is proportional to the assumed value of  $\beta M$ ,  
212  $[(\beta M)^{\text{assumed}}]$ , the difference between  $(\beta M)^{\text{assumed}}$  and the actual value of  $\beta M$   $[(\beta M)^{\text{actual}}]$   
213 yields the disparity between the observed value of  $F_p$  ( $F_p^{\text{observed}}$ ) and the calculated  $F_p$

214  $(F_p^{\text{calculated}})$ . The value of  $(\beta M)^{\text{actual}}$  is given by

215

$$216 \quad (\beta M)^{\text{actual}} = \frac{F_p^{\text{observed}}}{F_p^{\text{calculated}}} \times (\beta M)^{\text{assumed}}. \quad (2)$$

217

218 If  $F_p^{\text{observed}}$  and  $F_p^{\text{calculated}}$  correlate well, it is possible to determine a plausible value of

219  $(\beta M)^{\text{actual}}$ .

220       Regrettably, the correlation between observed and calculated signals of the  
221 piezomagnetic field is not good (Fig. 3). This means that assumptions of a uniform  
222 Curie point depth, a uniform initial total magnetization, and/or an assumed slip model,  
223 are inadequate. In particular, ignoring the heterogeneity of the initial magnetization is  
224 possibly problematic because it is known to enhance the piezomagnetic field (e.g.  
225 Oshiman, 1990). Aeromagnetic surveys over the Tohoku region have shown that  
226 magnetic anomalies in this region are rather strong (i.e. 10–100 nT) (Fig. 4), raising the  
227 possibility of a strong heterogeneity in the initial total magnetization. Consideration of  
228 the heterogeneity of the initial magnetization is clearly important if we are to calculate  
229 the piezomagnetic field accurately. However, an accurate determination of the structure  
230 of the initial magnetization is generally laborious and full of possible errors; hence, an  
231 accurate determination of a generated piezomagnetic field is difficult in the presence of

232 a strong heterogeneity in the initial magnetization (e.g. Yamazaki, 2011).

233       Nevertheless, we can attempt to provide constraints on the possible values of the  
234 stress sensitivity using data just from sites KAK and KTR. Around these sites, the  
235 gradient of the magnetic anomaly is relatively small (Fig. 4), and we can therefore  
236 anticipate that the model with uniform initial magnetization will provide reasonable  
237 calculated results. The amplitude of the piezomagnetic signal observed at KTR was  $-0.8$   
238  $\pm 0.2$  nT, whereas those predicted in the theoretical models (Fig. 1a–d) are between  $-0.2$   
239 and  $-0.3$  nT. The piezomagnetic signal observed at KAK was  $-0.22$ , whereas those  
240 predicted by theoretical models are between  $-0.07$  and  $-0.22$ . To explain the  
241 observations at KAK and KTR, the actual value of  $\beta M$  needs to be larger than the value  
242 assumed in the present calculation (i.e.  $1.0 \text{ Pa}^{-1} \text{ Am}^{-1}$ ) by factors of 2–3. Provided that  
243 the assumption of  $M = 1.0 \text{ A/m}$  (Table 1) is correct, the above result means that the  
244 stress sensitivity is about  $2.0\text{--}3.0 \times 10^{-9} \text{ Pa}^{-1}$ . This value is on the same order as that  
245 assumed in many piezomagnetic models (e.g. Johnston et al., 1989).

246

#### 247 *4.2 Potential usefulness of seafloor magnetic observations*

248

249       In all the models of the piezomagnetic field shown in Fig. 2, the amplitudes of the

250 piezomagnetic signals are expected to be small on land and relatively large offshore.  
251 Because the actual value of  $\beta M$  is possibly larger than assumed, as discussed in the  
252 previous subsection, the actual changes in the magnetic field are possibly larger than  
253 those shown in Fig. 1. In particular, large offsets in the magnetic field are expected near  
254 the trench axis. Although this result is obtained for an assumption that observations are  
255 made at sea level, piezomagnetic signals are also expected to be large at seafloor  
256 because the seafloor is rather closer to the rupture. If offshore ocean-bottom  
257 magnetometers had been installed, they would have detected significant amplitudes of  
258 piezomagnetic signals corresponding to the Tohoku-oki earthquake.

259 Observing piezomagnetic signals would not be very useful if the piezomagnetic  
260 signals were insensitive to details of the fault parameters, but the results of the  
261 piezomagnetic models demonstrate that this is not the case. Indeed, the spatial  
262 distributions of the piezomagnetic field are strongly dependent on the slip model that is  
263 adopted. It is possible that we could have improved the determination of earthquake  
264 source parameters if data from ocean-bottom magnetometers had been available, instead  
265 of relying solely on the results of inversions of seismic and geodetic data.

266 In general, it is difficult to measure accurately the distributions of slip for  
267 earthquakes that occur on an offshore plate boundary, because geodetic measurements

268 are made mainly on land. In the case of the Tohoku-oki earthquake, extremely large  
269 slips near the trench axis have been suggested by inversions of the seismic data (e.g.  
270 Hayes, 2011; Shao et al., 2011), but better constraints on slip distributions could have  
271 been obtained from seafloor geodetic measurements (Sato et al., 2011). Given that  
272 seafloor geodetic equipment is costly and difficult to manage, geomagnetic observations  
273 might provide useful additional data for monitoring interplate earthquakes along  
274 subduction zones. This solution may still apply, even when we consider magnetic  
275 anomalies on the seafloor, because heterogeneities in the magnetization of the crust may  
276 possibly enhance the generated piezomagnetic field (e.g. Oshiman, 1990).

277       Regrettably, there are also drawbacks to making seafloor magnetic observations.  
278 First, seafloor observations are quite costly. Second, it may be difficult to keep the  
279 sensors stably located during quakes, and if a sensor is displaced during a quake, an  
280 apparent change in the magnetic field will be recorded. Even if it were possible to  
281 obtain accurate data of the geomagnetic field at a certain point, it would be necessary to  
282 consider heterogeneities of the initial magnetization and ocean-bottom topography when  
283 converting the observed changes in the magnetic field to fault source parameters. For  
284 these reasons, the usefulness of observing the piezomagnetic field remains uncertain.  
285 However, similar difficulties also exist with respect to making ocean-bottom geodetic

286 observations. Not only are they are extremely costly, but monument stability during  
287 earthquakes is also a problem. It is also difficult to process the observations correctly  
288 and obtain precise geodetic information. A decision on prioritizing geodetic and  
289 geomagnetic techniques should be based on which drawbacks are most easily overcome.  
290 If costs allow, an integrated use of both techniques is most desirable because they  
291 independently bring useful information to bear on these tectonic phenomena.

292

## 293 **5. Conclusions**

294

295 To calculate the piezomagnetic field that corresponds to the 2011 Mw 9.0  
296 Tohoku-oki earthquake, it is necessary to consider the best representation of the spatial  
297 distribution of slip along the fault, and in this paper, I demonstrate the importance of  
298 such a consideration, and construct an appropriate slip model. Although this model still  
299 cannot entirely explain the observed distribution of piezomagnetic signals, constraints  
300 are obtained from data at two onshore sites, where the model seems to provide adequate  
301 results. Comparisons between the data and the model show the stress sensitivity to be  
302 about  $2\text{--}3 \times 10^{-9} \text{ Pa}^{-1}$ , which is on the same order as that assumed in many  
303 piezomagnetic models. Models of the piezomagnetic field predict that changes in the

304 geomagnetic total forces, due to the piezomagnetic effect, will be relatively large in  
305 offshore areas closer to the rupture, and relatively small onshore, far from the rupture.  
306 Because the expected magnitudes of the piezomagnetic signals are small at existing sites,  
307 stress sensitivity of the piezomagnetic effect is likely to be on the order of  $10^{-9}$ , though  
308 this is not tightly constrained. Nevertheless, the possibility of a large piezomagnetic  
309 field occurring at ocean-bottom stations is not excluded. Details of the spatial  
310 distribution of the piezomagnetic field in oceanic areas are highly dependent on the slip  
311 model used. The implication is that detection of the piezomagnetic field with  
312 ocean-bottom magnetometers might have provided constraints on the slip models of the  
313 Tohoku-oki earthquake, if such observations had been available.

314

### 315 **Acknowledgments**

316

317 Slip models proposed by Shao et al. (2011) and Hayes (2011), and a program coded  
318 by M. Utsugi, were used to calculate the piezomagnetic fields. Numerical data on the  
319 geomagnetic anomalies around Japan were provided by the Geospatial Information  
320 Authority of Japan through their Web site. Comments and advice from anonymous  
321 reviewers and the journal editor (P. Shearer) helped to improve an earlier version of the

322 manuscript. The software Generic Mapping Tools (Wessel and Smith, 1998) was used to

323 prepare some of the figures, including maps.

390 **Fig. 1.** Models of the piezomagnetic field corresponding to the UCSB and USGS slip

391 models. (a) UCSB slip model with  $H = 15$  km. (b) UCSB slip model with  $H = 30$

392 km. (c) USGS slip model with  $H = 15$  km. (d) USGS slip model with  $H = 30$  km.

393 The rectangle represents the fault plane on which heterogeneous slip is considered.

394

395 **Fig. 2.** Models of the piezomagnetic field corresponding to averaged versions of the

396 UCSB and USGS slip models. (a) UCSB slip model with  $H = 15$  km. (b) UCSB

397 slip model with  $H = 30$  km. (c) USGS slip model with  $H = 15$  km. (d) USGS slip

398 model with  $H = 30$  km. The rectangle represents the fault plane on which uniform

399 slip is considered.

400

401 **Fig. 3.** Comparisons between observed and calculated piezomagnetic signals.

402 Calculated values in this figure are the averages of four piezomagnetic models.

403 Error bars in calculated values represent maximum and minimum values for the

404 four models. Error bars in observed values are from Utada et al. (2011). Open

405 circles indicate the results at sites KAK and KTR, where the magnetic anomalies

406 are rather small, while solid circles indicate the results at other sites.

407

408 **Fig. 4.** The magnetic anomaly over the Tohoku region as observed by an aeromagnetic

409 survey at a height of 5000 m. Contour intervals are 10 nT. Observations were

410 conducted by the Geographical Survey Institute (predecessor of the Geospatial

411 Information Authority) of Japan in 1990, and the data are available on their Web

412 site, in Japanese

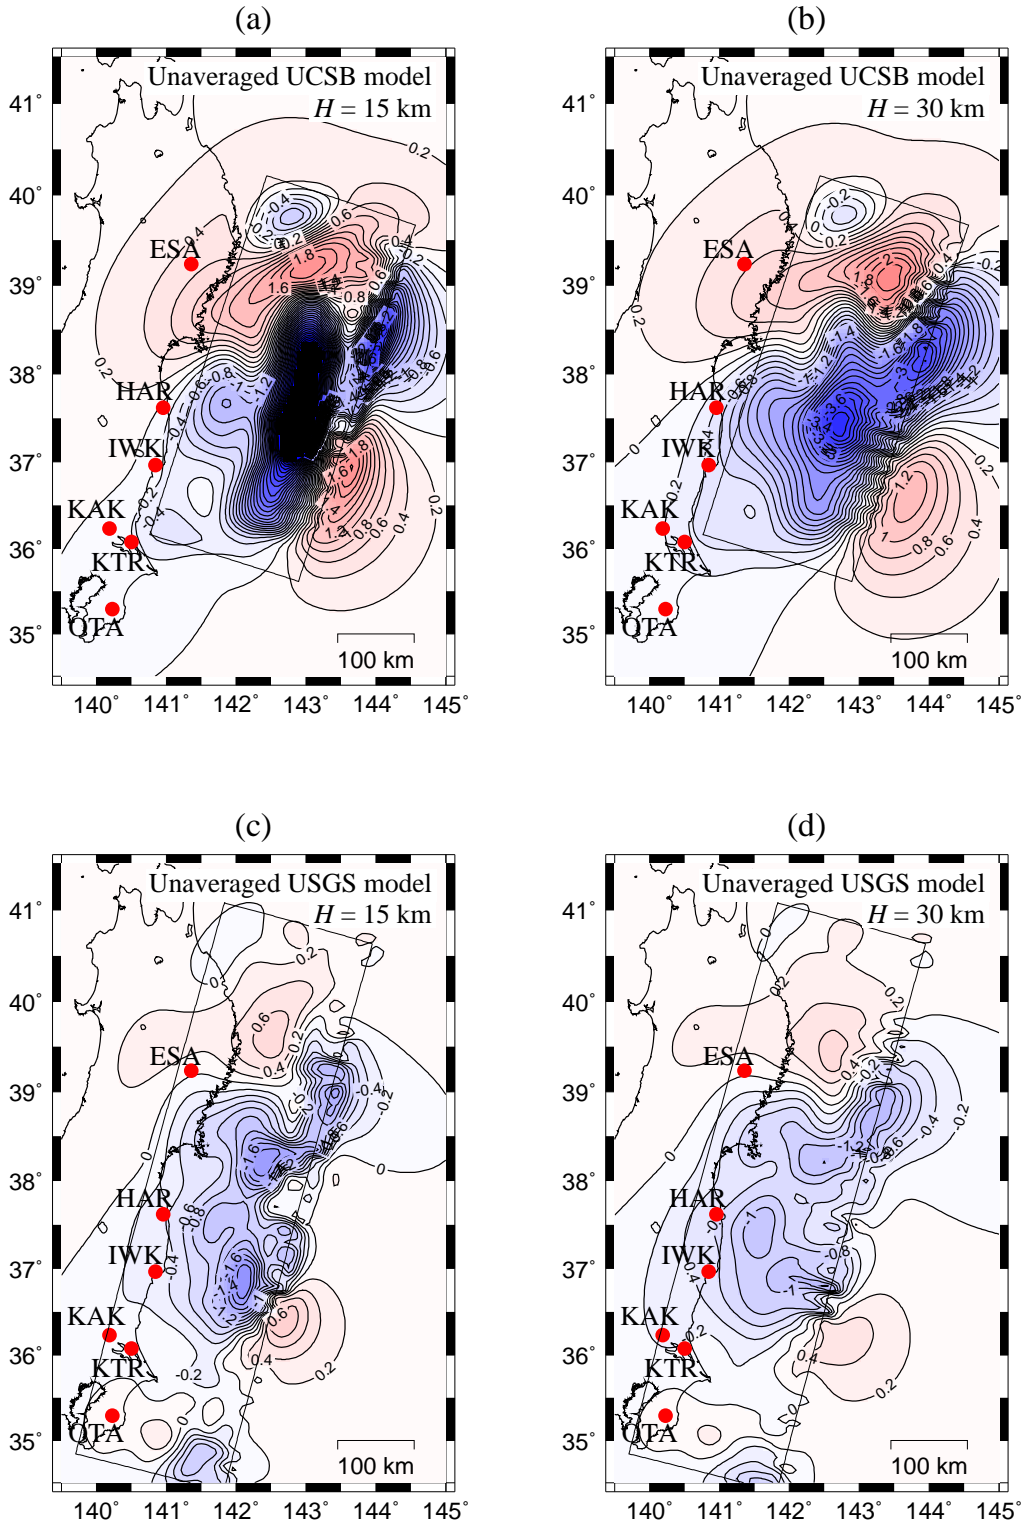

413 ([http://vldb.gsi.go.jp/sokuchi/geomag/menu\\_03/aeromag\\_data.html](http://vldb.gsi.go.jp/sokuchi/geomag/menu_03/aeromag_data.html); last access: 26

414 October 2012).

**Figure 3** Comparisons between observed and calculated piezomagnetic signals. Calculated values in this figure are the averages of four piezomagnetic models. Error bars in calculated values represent maximum and minimum values for the four models. Error bars in observed values are from Utada et al. (2011). Solid circles indicate the results at sites KAK and KTR, where the magnetic anomalies are rather small, while open circles indicate the results at other sites.

**Figure 4** The magnetic anomaly over the Tohoku region as observed by an aeromagnetic survey at a height of 5000 m. Contour intervals are 10 nT. Observations were conducted by the Geographical Survey Institute (predecessor of the Geospatial Information Authority) of Japan in 1990, and the data are available on their Web site, in Japanese ([http://vldb.gsi.go.jp/sokuchi/geomag/menu\\_03/aeromag\\_data.html](http://vldb.gsi.go.jp/sokuchi/geomag/menu_03/aeromag_data.html); last access: 26 October 2012).

**Table 1**

Parameters assumed in the modeling of the piezomagnetic field.

Parameter	Value
Rigidity	$57(53) \times 10^9 \text{ Pa}$
Poisson's ratio	0.25
Magnetization	$1.0 \text{ A m}^{-1}$
Piezomagnetic stress sensitivity	$1 \times 10^{-9} \text{ Pa}^{-1}$
Curie point depth	15 and 30 km
Inclination of the ambient geomagnetic field	51.0 degree
Declination of the ambient geomagnetic field	-7.5 degree
Observation altitude	0 m

**Table 2**

Comparisons of coseismic changes in the geomagnetic total intensity, as predicted by the piezomagnetic models versus those calculated from data reported in Utada et al. (2011). Piezomagnetic field models are determined for Curie point depths of 30 and 15 km together with two slip models (USGS and UCSB).

Station code	USGS slip model		UCSB slip model		Observed (error)	
	30 km	15 km	30 km	15 km		
ESA	+0.05	+0.05	+0.55	+0.49	-0.09	(0.46)
HAR	-0.56	-0.37	-0.40	-0.06	-0.43	(0.36)
IWK	-0.48	-0.28	-0.44	-0.14	+0.21	(0.42)
KTR	-0.18	-0.10	-0.29	-0.18	-0.83	(0.20)
OTA	+0.14	+0.16	-0.08	-0.03	-0.01	(0.28)
KAK	-0.22	-0.14	-0.19	-0.07	-0.22	(0.10)
