20 **Abstract**

21 A reliable technique for distinguishing anatomically similar diploxyloids, *Pinus*  
22 *densiflora* and *P. thunbergii*, was designed by employing near-infrared (NIR) spectroscopy in  
23 combination with multivariate analysis. In total, 24 wood blocks, with half of them being of *P.*  
24 *densiflora* and the rest of *P. thunbergii*, were selected from the collections of the Kyoto  
25 University xylarium and scrutinized to build an acceptable model for discriminating between  
26 the two species. The prediction model was constructed only from heartwood, and the best  
27 performance was obtained for wavenumbers of 7300–4000  $\text{cm}^{-1}$  in the second derivative  
28 spectra. To apply this model to actual materials obtained from historical wooden buildings, 12  
29 aging wood samples were analyzed and compared by microscopic identification.  
30 Unexpectedly, the spectral differences between the species were smaller than those caused by  
31 aging, and the prediction error was approximately 50%. The spectra of the aging samples  
32 were quite distinct in the specific region characteristic of absorbed water ( $5220 \text{ cm}^{-1}$ ); this  
33 was demonstrated clearly by principal component analysis. Therefore, for the proposed  
34 model to be suitable for use in practical applications, further investigations of aging wood  
35 samples and the corresponding spectroscopic data are necessary in order to understand the  
36 effects of aging on the spectral data.

37

## 38 **Introduction**

39 *Pinus densiflora* and *P. thunbergii* are varieties of pine trees that are very popular in  
40 Japan. The former is known as akamatsu and mematsu, and the latter as kuromatsu and  
41 omatsu. Both are planted widely in Japan for timber production and as ornamental trees and  
42 are a characteristic feature of classical Japanese gardens. *P. densiflora* is commonly seen  
43 growing on the low mountains and hillsides, while *P. thunbergii* is native to the coastal areas.

44 Anatomically, the two species are nearly identical in terms of the resin canal, which  
45 is surrounded by thin-walled epithelial cells and window-type cross-field pitting and exhibits  
46 a distinct transition from earlywood to latewood. The key difference between the two species  
47 was reported to be the degree of dentate thickening of the ray tracheids (Fig. 1). However,  
48 this difference is rather subjective and can be misleading, particularly in old samples, whose  
49 cell walls have nearly deteriorated. Consequently, in many previous studies, these pine wood  
50 species have been identified simply as diploxylons and their particular species has been left  
51 undecided. Therefore, an alternative method that could allow for the identification of the  
52 particular species without requiring special experimentation would be highly desirable.

53 In this regard, near-infrared (NIR) spectroscopy, which is known as a rapid, accurate  
54 and reproducible analysis technique, is an attractive choice. NIR spectroscopy is also suitable  
55 for assessing wood materials because the bands attributable to the vibrations of the chemical  
56 bonds involved in the formation of the cell wall allow for the direct and indirect estimation of

57 the chemical and physical properties of the materials. When combined with multivariate  
58 analysis, NIR spectroscopy can be used to distinguish between different wood species.  
59 Schimleck et al. demonstrated that principal component analysis (PCA) could be used to  
60 distinguish between pine and eucalyptus and also to differentiate between samples of the  
61 same eucalyptus species grown at different sites [1]. Soft independent modeling of class  
62 analogy has also been used to classify wood samples, including red and white oak [2] and  
63 larch species [3]. Regression analysis, especially partial least square (PLS) regression, is a  
64 powerful method of accurately estimating the chemical compositions of wood samples [4]  
65 and of determining their enzymatic hydrolysis [5] and decay resistance [6], in addition to their  
66 physical properties, such as fiber length [7-9], cellulose microfibril angle [10], and stiffness  
67 [11]. The method of distinguishing species coupled with regression analysis, called partial  
68 least squares-discriminant analysis (PLS-DA), has been used as a tool for differentiating true  
69 mahogany from three other similar species [12, 13]. Sandberg and Sterley [14] could  
70 successfully distinguish between heartwood and sapwood samples of Norway spruce using  
71 the PLS algorithm. Watanabe et al. [15] could differentiate between aging and degraded  
72 samples of softwood, such as *Chamaecyparis obtusa*, *Torreya nucifera*, and *C. pisifera* using  
73 PLS.

74 In this study, we first describe a simple technique that uses NIR spectroscopy in  
75 combination with PLS-DA for distinguishing *P. densiflora* from *P. thunbergii*, which were

76 classified at the xylarium of Kyoto University. The discriminant model was initially  
77 examined using complete sets of the wood samples. Later, the sapwood and heartwood  
78 samples were analyzed separately. Next, we demonstrate the applicability of the proposed  
79 method in determining the species of aging samples of wood, and discuss the factors that  
80 influence the precision of discrimination.

## 81 **Materials and methods**

### 82 **Sampling**

83 Wood blocks of *P. densiflora* designated as KYOw00029, 00225, 08058, 08059,  
84 09268, 13942, 19360, and 19361, and those of *P. thunbergii* designated as KYOw00030,  
85 00520, 05509, 05639, 08071, 10321, 11386, 13913, and 19176 by the xylarium at the  
86 Research Institute for Sustainable Humanosphere, Kyoto University  
87 (<http://database.rish.kyoto-u.ac.jp/cgi-bin/bmi/en/namazuru.cgi>) were used for establishing the  
88 discriminant model. The wood samples in these blocks were collected from all the sapwood  
89 and heartwood zones. However, in the case of the wood blocks of KYOw00029, 05639,  
90 08071, 09268, and 13913, only sapwood was collected. On the other hand, only heartwood  
91 was taken from KYOw00520, 19176, 19360, and 19361. Three parts were collected  
92 randomly from each wood block after NIR spectral analysis. Finally, wood samples from  
93 Chion-In temple in Kyoto, Japan and designated as KYO\_ID\_5165, 5166, 5168, 5170, 5173,  
94 5175, 5185, 5187, 5189, 5192, 5197, and 5252 [16] were used to test applicability of the

95 proposed method. Blocks were collected from each of these aging samples.

## 96 **Optical microscopy**

97 In the case of the wood samples obtained from the xylarium for the construction of  
98 the calibration model, radial sections approximately 30  $\mu\text{m}$  in thickness were cut using a  
99 sliding microtome and were stained with safranin. In the case of the wood samples from  
100 Chion-in, the corresponding sections were obtained by hand sectioning and were not stained.  
101 The sections were observed using a light microscope (Olympus BX51) equipped with a  
102 digital camera (Olympus DP73).

## 103 **NIR spectroscopy**

104 Each wood block after air-drying was milled with a rough file to produce a powder  
105 sample. Then, a tablet was prepared by collecting approximately 0.04 g of the powder, which  
106 was hand pressed following a previously published protocol [17]. The NIR spectrum was  
107 obtained using a PerkinElmer Spectrum 100N system for wavenumbers of 10000–4000  $\text{cm}^{-1}$   
108 at a spectral resolution of 16  $\text{cm}^{-1}$ ; 32 scans were made for each sample. The prepared tablet  
109 was placed directly on the NIR integrating sphere diffuse reflectance accessory (PerkinElmer),  
110 which had a triglycine sulfate detector. Both faces of each tablet were scanned. The  
111 absorbance spectrum was recorded by normalizing the single-beam spectrum against the  
112 background spectrum using a Teflon-based material (Spectralon; LabSphere, North Sutton,  
113 NH). The original spectrum was treated using the Savitzky–Golay second derivative [18]

114 using 9 points and a fifth-order polynomial for the smoothing before the multivariate  
115 analysis.

### 116 **Multivariate analysis**

117 PLS-DA and PCA were performed using a commercial software (Unscrambler v.9.8;  
118 CAMO Software, Inc., Woodbridge, NJ). Calibration and prediction samples from the 144  
119 spectra (72 each for the sapwood and heartwood samples) were randomly selected as the ratio  
120 at 2 to 1, that is, 96 were used for calibration, and 48 were used for the prediction set. Of the  
121 spectra used for calibration, 48 belonged to *P. densiflora* and 48 belonged to *P. thunbergii*. In  
122 the case of the spectra used for prediction, 24 belonged to *P. densiflora* and 24 belonged to *P.*  
123 *thunbergii*, as shown in Table 1. For the development of a discriminant model for use in the  
124 multivariate analysis, we assigned *P. densiflora* a class value of +1 and *P. thunbergii* a class  
125 value of -1 in the calibration set. The PLS factors were determined by cross validation; a  
126 single sample was kept out of the model, and its characteristics were predicted by  
127 constructing a model without the sample. Excessively high numbers may result in overfitting;  
128 therefore, the number of PLS factors was kept at fewer than 11. The coefficient of  
129 determination for calibration ( $R_c^2$ ) and the root mean square error of calibration (RMSEC)  
130 were used to assess the calibration performance. The models developed were evaluated by  
131 using the coefficient of determination of prediction ( $R_p^2$ ) and the root mean square error of  
132 prediction (RMSEP). The percentage of correct prediction was determined as the proportion

133 of the number of species discriminated correctly compared to the total number of samples  
134 from prediction set. PLS-DA to distinguish between sapwood and heartwood was also  
135 performed using the same procedure.

136 PCA was performed on the basis of the second derivative spectra of all the wood  
137 samples for wavenumbers of 7300–4000  $\text{cm}^{-1}$ . The PC loading was obtained from the model  
138 built for score plots.

## 139 **Results and Discussion**

### 140 **Discriminant model for determining the type of wood present**

141 Fig. 2a and b show original and second derivative spectra from heart and sapwood  
142 samples of *P. densiflora* and *P. thunbergii*. From the band at 5220  $\text{cm}^{-1}$  assigned to absorbed  
143 water in second derivative NIR spectra, sapwood samples seemed higher moisture contents  
144 than those of heartwood. However, it was difficult to identify whether *P. densiflora* or *P.*  
145 *thunbergii* from spectra because spectral pattern including the bands at 5980 and 5800  
146 specific to lignin and hemicellulose respectively, were almost same between these species.  
147 Therefore, we applied multivariate analysis and Table 2 shows the statistical summary of the  
148 discriminant models obtained on the basis of the original spectra and the second derivative  
149 spectra. To generate a better model, the regions of the NIR spectra corresponding to the  
150 wavenumbers of 10000–4000  $\text{cm}^{-1}$  were separated into four distinct ranges on the basis of the  
151 properties of the molecular vibrations. In the first range (10000–7300  $\text{cm}^{-1}$ ), the second or

152 third overtones were involved, although less information was obtained from the wood  
153 samples. The second range (7300–6050  $\text{cm}^{-1}$ ) mainly corresponded to OH overtone vibrations.  
154 The third range (6050–5500  $\text{cm}^{-1}$ ) corresponded to the CH vibrations and the vibrations from  
155 the aromatic framework, while in the fourth range (5500–4000  $\text{cm}^{-1}$ ), several combinatorial  
156 vibrations were present.

157         For the samples containing both sapwood and heartwood, the discriminant models  
158 shown in Table 2a were constructed on the basis of the NIR spectra without subjecting the  
159 spectra to any spectral pretreatment. All the models were unreliable because the  $R_p^2$  values  
160 were less than 0.60. Next, we obtained the second derivative spectra and created the  
161 discriminant models shown in Table 2b. Secondary differentiation can extract information  
162 hidden in the original spectra. Thus, researchers have often applied this algorithm to construct  
163 regression models. This spectral pretreatment decreased the number of factors relatively;  
164 however, the models obtained were not markedly better. Fig. 3a shows a histogram  
165 corresponding to the discriminant model based on the second derivative spectra for 7300–  
166 4000  $\text{cm}^{-1}$ . In this region, a few samples of both *P. densiflora* and *P. thunbergii* had class  
167 values of approximately 0, which indicated that this model could not be used for  
168 distinguishing between the two species.

169         Sapwood could, therefore, be distinguished from heartwood, and discriminant  
170 models could be built, as summarized in Tables 2c and d. However, as was the case with the

171 dataset corresponding to the samples containing both sapwood and heartwood, all the models  
172 showed poor performances, as the  $R_p^2$  values were lower than 0.75. Fig. 3b shows a  
173 histogram based on the second derivative spectra for 7300–4000  $\text{cm}^{-1}$ ; for this region, the  
174 RMSEP value was 0.54 and the  $R_p^2$  value was 0.71, with some of the prediction samples from  
175 *P. thunbergii* having class values of 0 and similar to those of *P. densiflora*.

176 In the case of heartwood, even though a large number of factors were required, the  
177 calibration performance was comparatively better (Table 2e). However, the models obtained  
178 using the vibrations over 10000–7300  $\text{cm}^{-1}$  and 7300–6050  $\text{cm}^{-1}$  were less reliable; this was  
179 particularly true in the latter case, where the major bands were assigned to cellulose [19-21].  
180 This suggested that the cellulose contents were indistinct between *P. densiflora* and *P.*  
181 *thunbergii* as well as their crystalline properties.

182 The discriminant models obtained using the second derivative spectra are shown in  
183 Table 2f. The models exhibited better performances as the  $R_p^2$  values corresponding to a few  
184 of the NIR spectral regions were higher than 0.85. The best performance was obtained for  
185 7300–4000  $\text{cm}^{-1}$ ; this region showed an RMSEP value of 0.37,  $R_p^2$  value of 0.86 and 100 %  
186 accuracy of identification. As shown in Fig. 3c, the prediction model based on the  
187 corresponding region allowed us to classify all the samples from *P. densiflora* as having  
188 positive values, while the samples for classifying *P. thunbergii* were placed in another group  
189 and had negative values.

190 NIR spectroscopy is sensitive to the functional groups and is thus influenced by the  
191 chemical and structural features of the cell walls of the trees being investigated. Therefore,  
192 the difficulties encountered in classification using sapwood samples indicated that the  
193 chemical natures of *P. densiflora* and *P. thunbergii* were essentially indistinct. However, the  
194 fact that using heartwood samples yielded better results suggested that the heartwood  
195 components of the two species might be slightly different.

#### 196 **Applicability in investigating aging wood used in traditional buildings**

197 The applicability of the regression model developed was tested by reexamining  
198 actual wood materials used in traditional wooden buildings built in the medieval period.  
199 Chion-In temple in Kyoto is well known and is the main temple of Jōdo Shū ("The Pure Land  
200 School"). The wood materials used in the Shūedō (i.e., the Assembly Hall) had been studied  
201 during 2005–2010, and 25 wood samples had been classified as being of diploxylons [16].  
202 Twelve specimens were used in the present study. The enlarged radial sections of the ray  
203 tracheids of these samples are shown in Fig. 4. Of these 12 samples, only three were  
204 anatomically identified as *P. thunbergii* on the basis of the degree of dentate thickening in the  
205 ray tracheids. The PLS-DA models built up on the basis of heartwood were used in the  
206 identification of these materials. The percentage of coincidence with the anatomical  
207 identification results is listed in Table 3. In contrast to the prediction set samples shown in  
208 Tables 2e and f, the discriminant models failed to predict the species perfectly. One possible

209 reason behind this failure seems to be the fact that the wood used in Chion-in was sapwood,  
210 while the calibration models used for identification were created using heartwood. However,  
211 sapwood is usually not used as a building material, in order to minimize deterioration and  
212 maintain the structural strength. Given this background, we investigated these aging wood  
213 samples further using NIR spectroscopy in combination with multivariate analysis, as  
214 mentioned in the next segment.

### 215 **Effects of aging**

216 To understand the reason for the failure in prediction of Chion-in materials, PCA was  
217 carried out in the wavenumber range  $7300\text{--}4000\text{ cm}^{-1}$  of the second derivative spectra (Fig.  
218 5a). The score plots showed that some of the wood samples from Chion-In temple localized  
219 on the left side and far from those belonging to *P. densiflora* and *P. thunbergii*. It is known  
220 that noncrystalline polysaccharides such as hemicellulose decrease in quantity in aging  
221 samples of *C. obtusa*, whereas the crystalline cellulose region is not affected [22].  
222 Furthermore, Yokoyama et al. reported that the equilibrium moisture content in *C. obtusa*  
223 decreases after aging [23]. Therefore, it seems that aging under dry conditions degraded the  
224 hemicelluloses, which are the adsorption sites for water in wood materials, resulting in a  
225 decrease in the equilibrium moisture content. In this regard, the wood samples from Chion-in  
226 temple were different in that there was no statistical difference between modern and aging  
227 woods in hemicellulose contents, given the presence of the band at approximately  $5800\text{ cm}^{-1}$ ;

228 this band is specific to furanose/pyranose, which form from hemicellulose [24] and exhibited  
229 a value of almost 0 in the PC1 loading (Fig. 5b). In addition, the amount of absorbed water in  
230 the Chion-in samples was higher, as a positive band was noticed at approximately  $5220\text{ cm}^{-1}$   
231 and was assignable to the combinational vibration of water; this was clearly visible in the  
232 PC1 loading. Moreover, the lignin content of the Chion-in samples was lower, as a band was  
233 noticed at  $5970\text{ cm}^{-1}$ ; this band is characteristic of aromatic skeletal vibrations [24] and  
234 exhibited negative values during PC1 loading. These interpretation was supported by the  
235 comparison with the second derivative spectra between modern and aging wood (Fig. 5c).  
236 Therefore, the lignin in the Chion-in samples seemed to be modified to a greater degree than  
237 was the hemicellulose, which resulted in a decrease in the hydrophobicity, as this increased  
238 the amount of absorbed water. These features were not observed in the spectra of the unaging  
239 wood samples. Hence, the samples from Chion-in could not be classified accurately. In order  
240 to be able to employ the proposed classification method for identifying historical and  
241 archeological wood samples, we have to consider the effects of aging on the characteristics of  
242 the samples, including on the quantity of absorbed water and the chemical components such  
243 as lignin and polysaccharides, whose chemical structure can be changed by oxidative and/or  
244 enzymatic reactions. Therefore, further investigations need to be performed to determine the  
245 optimal conditions for measurements as well as suitable data treatments to account for the  
246 spectral variations caused by aging, in order to be able to distinguish between *P. densiflora*

247 and *P. thunbergii* on the basis of the differences in their spectra.

## 248 **Conclusions**

249 When using unaging heartwood samples, we were able to identify *P. densiflora* and *P.*  
250 *thunbergii* by employing NIR spectroscopy in combination with multivariate analysis.  
251 However, when aging wood samples were used, the proposed method was ineffective in  
252 distinguishing between the two species. Thus, the method is not suitable for classifying wood  
253 samples from historical and archeological buildings. However, further research is underway  
254 to find the spectral features between these microscopically similar species more significant  
255 than those caused by aging.

256

## 257 **Acknowledgments**

258 The study was supported in parts by Grants-in-Aid for Scientific Research (Grant Numbers  
259 25252033, 22300309, and 24780169) from the Japan Society for the Promotion of Science  
260 (JSPS). The authors thank Ms. Izumi Kanai and Mr. Akio Adachi for their technical support.

352 **Figure legends**

353 Fig. 1. Optical micrographs of the standard radial section. (a) *P. densiflora* shows dentate  
354 thickening within the ray tracheid, while (b) these features are smooth in *P. thunbergii*. The  
355 arrow heads indicate dentate thickening.

356

357 Fig. 2. (a) Original NIR spectra of heartwood and sapwood from *P. densiflora* and *P.*  
358 *thunbergii* designated as KYOw13942 and 00030, which were included in calibration set. (b)  
359 Second derivative spectra obtained from the 4 spectra in (a).

360

361 Fig. 3. Histograms of the class values computed by PLS-DA on the basis of the second  
362 derivative spectra for wavenumbers of 7300–4000  $\text{cm}^{-1}$  and obtained from (a) a mixture of  
363 sapwood and heartwood, (b) sapwood, and (c) heartwood.

364

365 Fig. 4. Optical micrographs of the radial sections acquired from wood samples from Chion-In  
366 temple. The images in (a)–(i) correspond to KYO\_ID\_5165, 5166, 5168, 5170, 5173, 5175,  
367 5185, 5189, and 5252, respectively, which were identified as being of *P. densiflora*. The  
368 images in (j)–(l), which were acquired from KYO\_ID\_5187, 5192, and 5197, respectively,  
369 were identified as being of *P. thunbergii*. The arrow heads indicate dentate thickening.

370

371 Fig. 5. (a) The principal components analysis (PCA) scores plotted on the first and second  
372 principal components on the basis of the second derivative NIR spectra in the 7300–4000  
373  $\text{cm}^{-1}$  region.

374 (b) The spectrum obtained from PC1 loading in PCA. The bands at 5970, 5800, and 5220  
375  $\text{cm}^{-1}$  are assigned to lignin, hemicellulose, and the absorbed water, respectively.

376 (c) Second derivative spectra obtained from unaging heartwood and aging wood of *P.*  
377 *thunbergii* designated as KYOw19176 and KYO\_ID\_5197.
