19

20 **Abstract**

21 *Saccharomyces cerevisiae* is an important unicellular yeast species within the biotechnological and

22 food and beverage industries. A significant application of this species is the production of ethanol,

23 where concentrations are limited by cellular toxicity, often at the level of the cell membrane. Here,

24 we characterize 61 *S. cerevisiae* strains for ethanol tolerance and further analyse five representatives

25 with varying ethanol tolerances. The most tolerant strain, AJ4, was dominant in co-culture at 0% and

26 10% ethanol. Unexpectedly, although it does not have the highest NIC or MIC, MY29 was the

27 dominant strain in co-culture at 6% ethanol, which may be linked to differences in its basal lipidome.

28 Whilst relatively few lipidomic differences were observed between strains, a significantly higher PE

29 concentration was observed in the least tolerant strain, MY26, at 0% and 6% ethanol compared to the

30 other strains that became more similar at 10%, indicating potential involvement of this lipid with

31 ethanol sensitivity. Our findings reveal that AJ4 is best able to adapt its membrane to become more

32 fluid in the presence of ethanol and lipid extracts from AJ4 also form the most permeable membranes.

33 Furthermore, MY26 is least able to modulate fluidity in response to ethanol and membranes formed

34 from extracted lipids are least leaky at physiological ethanol concentrations. Overall, these results

35 reveal a potential mechanism of ethanol tolerance and suggests a limited set of membrane

36 compositions that diverse yeast species use to achieve this.

37

38 **Importance**

39 Many microbial processes are not implemented at the industrial level because the product yield is

40 poorer and more expensive than can be achieved by chemical synthesis. It is well established that

41 microbes show stress responses during bioprocessing, and one reason for poor product output from

42 cell factories is production conditions that are ultimately toxic to the cells. During fermentative

43 processes, yeast cells encounter culture media with high sugar content, which is later transformed

44 into high ethanol concentrations. Thus, ethanol toxicity is one of the major stresses in traditional and

45 more recent biotechnological processes. We have performed a multilayer phenotypic and lipidomic

46 characterization of a large number of industrial and environmental strains of *Saccharomyces* to

47 identify key resistant and non-resistant isolates for future applications.

48

49 **Keywords**: ethanol, *S. cerevisiae*, membrane properties

50

51 **Introduction**

52 *Saccharomyces cerevisiae* is a unicellular eukaryotic microorganism that has been employed as a

53 model organism to study diverse relevant phenomena in biology at molecular level (1). Due to its

54 high fermentative capability, it is also widely used in the biotechnology field for the performance of

55 industrial fermentations of products such as wine, beer or bread (2) or traditional Latin American

56 beverages like pulque, masato, chicha, tequila, or cachaça (3–7). *S. cerevisiae* also has a relevant role

57 in bioethanol production (8). *S. cerevisiae* has been isolated from different sources and environments

58 all over the world, including fruits, soils, cactus, insects, oak, and cork tree barks (9, 10). The

59 physiological and genetic diversity among the *Saccharomyces* genus is high, due to their colonization

60 of different environments; the most studied species are those associated with industrial processes of

61 economic importance as wine production (11–17), cider (18) and beer (11). *Saccharomyces* yeasts

62 that have been selected to carry out these fermentations in a controlled manner show particular

63 characteristics, as selective pressures imposed by the fermentative environment, such as low pH and

64 the high ethanol levels in the media, favor yeasts with the most efficient fermentative catabolism,

65 particularly *S. cerevisiae* strains, but there are species in the *Saccharomyces* genus which are also

66 found spontaneously in these fermentation products including *S. uvarum*. Depending on the

67 fermentation process, other factors apart from alcohol concentration, as temperature, can be

68 considered stress factors (19–21).

69 Ethanol (CH_3CH_2OH) is a small molecule containing a methyl group and a hydroxyl group and

70 consequently it is soluble in both aqueous and lipidic phases. Because of these properties, it can

71 penetrate inside cells, which generates important stresses; incorporation into the cell membrane can

72 increase fluidity, which is a fundamental driver of membrane properties (22, 23).

73 This fluidity change induces a loss of membrane integrity, becoming more permeable (24). Ethanol

74 causes other detrimental effects to the cells, including alterations on mitochondrial structure, reducing

75 ATP levels and respiratory frequency and favoring acetaldehyde and reactive oxygen species (ROS)

76 generation, which can cause lipid peroxidation, DNA damage and oxidative stress (25, 26). As a

77 consequence, a notable reduction in cellular viability occurs. Cell membranes are composed of lipids

78 (mainly phospholipids and sterols, but also sphingolipids and glycolipids) and proteins. Membrane

79 lipids are amphipathic, possessing hydrophobic (apolar) and hydrophilic (polar) regions. Embedded

80 membrane proteins are strongly associated with the apolar core of the bilayer and peripheral proteins

81 are more loosely associated with the membrane via several mechanisms. A key factor contributing to

82 membrane fluidity is the fatty acids and sterol composition of the membrane (27).

83 The molecular structure of ethanol allows passive diffusion across the membrane and likely

84 incorporation into the bilayer structure (28). When this happens, van der Waals attractive forces

85 decrease, increasing membrane fluidity (29). Using fluorescence anisotropy studies a direct

86 relationship between plasma membrane fluidity and ethanol concentration has been reported (30, 31).

87 This increase in fluidity, together with the loss of structural integrity previously mentioned, result in

88 loss of various intracellular components including amino acids and ions (24), producing alterations

89 in a cellular homeostasis.

90 The alterations in membrane properties are fundamental in the mechanism of ethanol toxicity but the

91 physical changes that the membrane structure undergoes as a result of ethanol presence in the media

92 have not been completely described. It is widely accepted that ethanol is intercalated in lipidic heads

93 of the membrane, with the OH group of the ethanol associated with the phosphate group of the lipidic

94 heads and the hydrophobic tails aligned with the hydrophobic core of the membrane. When this

95 interaction takes place, ethanol molecules substitute interfacial water molecules, generating lateral

96 spaces between polar heads, and, as a consequence, spaces in the hydrophobic core (32). These gaps

97 result in unfavorable energy, so the system tries to minimize it by creating an interdigitated phase.

98 This modification in the membrane causes a decrease in its thickness of at least 25% (33, 34) and as

99 a consequence of this thinning, alterations in membrane protein structure and function can occur,

100 leading to cellular inactivation during the fermentation process (35).

101 It has been demonstrated that membrane thickness affects membrane protein functionality, in which

102 maximum activity takes place with a defined thickness (36, 37). If this thickness changes, exposure

103 of hydrophobic amino acid residues in integral membrane proteins can take place, resulting in a

3

104 phenomenon known as hydrophobic maladjustment (35), that can lead to aggregation of membrane
105 proteins to minimize the exposition of their hydrophobic parts in the aqueous media (38). Studies that
106 use membrane models formed by phosphatidylcholine and ergosterol that are exposed to different
107 ethanol concentrations have demonstrated that lipid composition protects the membrane because
108 interdigitated phase formation is delayed (39).
109 In Arroyo-López et al. (40) different S*accharomyces* species were characterized for their ethanol
110 tolerance, identifying *S. cerevisiae* as the most ethanol tolerant. In the present work, we have selected
111 61 *S. cerevisiae* strains, from different origins and isolation sources. The purpose of this study was to
112 establish differences in the behavior of strains that represent the different *S. cerevisiae* groups, to
113 determine the most resistant ones, so they are better to perform industrial fermentations. With this
114 aim, we both monitored the growth in a liquid medium with different ethanol concentrations, using
115 absorbance measurements, and in a solid media, carrying out drop test analysis on ethanol plates.
116 Growth data were statistically analyzed for each of the *S. cerevisiae* strains and strains showing a
117 different behavior under ethanol stress were selected to conduct membrane studies that allow
118 correlations of lipid composition in yeast populations with responses to environmental stress such as
119 ethanol.
120
121 **Results**
122 **Ethanol tolerance of the strains in solid media.**
123 A total of 61 yeast strains belonging to *S. cerevisiae* were selected to assess ethanol tolerance. The
124 strains have been identified by sequencing of the D1/D2 26S, sequencing of the D1/D2 26S rRNA
125 gene was deposited in GenBank with the accession numbers MW559910-MW559970. All the strains
126 have been identified as *S. cerevisiae* with the exception of MY62 that is a *S. cerevisiae* strain
127 containing a limited amount of *S. kudriavzevii* genome. 21 are industrial strains and were selected for
128 their use in winemaking and 40 of them belong to the IATA-CSIC collection. The sources from which
129 these 40 strains were retrieved are diverse: agave, beer, bioethanol, chicha, cider, cocoa, honey water,
130 masato, sake, sugar cane, wine, natural wild strains, etc. *S. cerevisiae* yeast strains' ethanol tolerance
131 was first assessed in plates with GPY + different ethanol percentages. To observe the influence of
132 ethanol on these strains we performed four biological replicates of each strain growth in 6 different
133 media. One biological replicate for each of the strains and media can be seen in Fig. S1. With the
134 growth data of each of the strains and taking into account, the 4 replicates values of growth for each
135 strain, a heatmap with the growth data in ethanol was constructed (Fig. 1). This heatmap is
136 hierarchically clustered into two big clusters with different subclusters. The first cluster is made up
137 of the strains which are more tolerant of ethanol (a total number of 22 of the 61 strains) and another
138 one with the rest of the strains which show intermediate and low growth with this compound (39

4

139 strains). Among the first cluster, with the most tolerant strains, it is interesting that 19 of the 22 strains

140 belong to commercial wine strains. The other 3 strains which are included in this heatmap are AJ4, a

141 Lallemand commercial strain, which is also one of the most tolerant strains of all the screened ones,

142 MY48, a cachaça strain and MY43, a cider yeast strain.

143 The other cluster, with the 39 intermediate-low tolerant strains, appears to be divided into two

144 subclusters too. One of the subclusters is composed of MY33 and MY34, which are the less ethanol

145 tolerant strains, and belong to the sake group. It is interesting to note that in the other subcluster, there

146 are strains with different behaviors. As an example, strains MY46 (cachaça) and MY44 (cider) growth

147 in ethanol media are affected by low ethanol concentrations (ethanol percentage of 6%), but they can

148 grow (at a low rate) until 16% of ethanol is present in solid media. On the other hand, there are other

149 strains, such as MY37 (Masato) and MY22 (natural), whose growth is not affected until 10% of

150 ethanol is present in GPY solid media but in the next ethanol step (14%) they do not grow at all.

151

152 **Ethanol tolerance of the strains in liquid media.**

153 Ethanol tolerance of the set of *S. cerevisiae* strains was evaluated in minimal YNB liquid media at

154 28ºC. Yeast growth was evaluated by OD_{600} determination in microtiter plates containing this media

155 with different ethanol concentrations and for each strain, the area under the curve during these

156 growths was calculated. With the area under the curve reduction due to the addition of ethanol, NIC

157 (non-inhibitory concentration) and MIC (minimum inhibitory concentration) parameters were

158 calculated for 57 of the 61 strains. Not all of the 61 strains could be evaluated following this method:

159 the data obtained with flor strains MY28 and MY31 could not be used because these strains flocculate

160 and the data obtained with them are not reproducible. The data obtained with the strains MY55 and

161 MY56 were not used as they have problems growing in minimal media YNB. The complete list with

162 the NIC and MIC values for each one of the selected strains can be found in Table S1. Fig. 2 depicts

163 a graph representing these values for each one of the strains.

164

165 **Strain selection**

166 After performing the phenotypic characterization in ethanol of our collection of 61 strains, to further

167 characterize some representatives of the different behaviors we decided to select 5 of them as they

168 showed a range of tolerances: AJ4, MY3, MY14, MY26, and MY29. Fig. 3A shows the results of the

169 drop test in GPY+ethanol media of these 5 strains and Fig. 3B the NIC and MIC parameters of growth

170 in YNB liquid media+ethanol.

171 AJ4 shows high NIC and MIC values during YNB growth in liquid media, and in solid media in GPY

172 + ethanol it clusters amongst the most tolerant *S. cerevisiae* strains too. This strain is a Lallemand

173 commercial strain that has been reported as a highly tolerant ethanol strain (41). It has a high NIC

174   value 11.62% ± (0.33%), which means that a high concentration of ethanol is needed to affect its

175   growth.

176   MY29, which is a flor strain isolated from sherry wine, is classified within the second cluster with

177   the strains that show an intermediate growth in GPY+ethanol in solid media. It grows well until 14%

178   ethanol; however, viability is reduced in 16% ethanol, and it is unable to grow at 18% ethanol.

179   Regarding the liquid assay in YNB+ethanol, its MIC value is amongst the highest MIC values of all

180   the strains (15.41% ± 2.93%), but its NIC value (7.5% ± 1.48%) can be classified as a medium-low

181   value. This result shows that MY29 is a *S. cerevisiae* strain whose behaviour can be classified as

182   intermediate in ethanol conditions. Moreover, MY29 is the most tolerant sherry wine strain of the

183   five strains analyzed.

184   MY26, which is an agave strain, is among the least tolerant strains in solid media and is also the strain

185   that shows the lowest growth among the three agave strains that we selected for our study. In liquid

186   media, its NIC value is also low, being affected by an ethanol concentration of 7.24% ±0.77 (%) but

187   its MIC value is high (15.34% ± 0.4%). This strain shows similar behavior in liquid media as MY29,

188   but in solid media, it proved to be less tolerant as it was not able to grow in 14% ethanol plates, and

189   MY26 could grow in this condition too.

190   MY3 and MY14 are commercial wine strains, which are classified in the cluster of the most tolerant

191   strains regarding their growth on ethanol plates. Nevertheless, MY14 appears to be affected by the

192   ethanol at low concentrations (NIC value of 6.787% ± 0.337% and MIC value of 13.93% ± 0.91%)

193   and MY3 seems to start being affected by ethanol at higher concentrations but has a low range, as it

194   has a low MIC value (NIC 8.89% ± 1.26% and MIC 12.97% ± 0.13%).

195

196   **Competition fermentations**

197   These five strains, AJ4, MY3, MY14, MY26, and MY29 were selected for their different behavior

198   regarding ethanol susceptibility. They were inoculated into mixed culture fermentations to assess the

199   correlation between ethanol tolerance and competition capacity under different ethanol

200   concentrations (0%, 6%, and 10%). As one GPY fermentation would be insufficient for observing

201   domination of the culture by one single strain, we followed a method in which we inoculated a sample

202   of the culture after sugar depletion into new fresh media with the corresponding ethanol

203   concentration.

204   After the tenth pass, AJ4 completely dominated the 0% and the 10% fermentations. However, in 6%

205   fermentations, MY29 strain completely dominated one of the three replicate fermentations and clearly

206   dominated the other two. The other 2 strains which are present in this 6 % fermentation when sugar

207   is depleted are AJ4 and MY14, although in low proportion. Neither MY3 nor MY26 colonies were

208   found in any of the fermentation (Fig. 4). AJ4 dominating high ethanol concentration cultures was

6

209 quite an expected result regarding its ethanol tolerance determined in the present work. However, it

210 does not seem clear why MY29 dominates 6% ethanol cultures, given its moderate tolerance

211 compared to other strains such as AJ4, MY3 or even MY14. Here, probably, complex interaction

212 among strains play an important role in domination, which has been studied previously for another

213 set of strains (42), and demonstrated to be of importance together with growth capacity under the

214 studied media conditions (43).

215

216 **Lipid composition and membrane properties**

217 Several studies have demonstrated that yeasts can adapt their membrane composition in response to

218 ethanol stress (44–46). To better understand the effects of ethanol upon the yeast strains, we

219 investigated the properties of the membranes in the presence and absence of ethanol. We determined

220 the total lipid composition of each of the strains by mass spectrometry (Table S2 and S3). The number

221 of species identified for major lipid classes for strains grown in media containing 0% or 6% ethanol

222 is shown in Fig. 5. For the strains grown in the absence of ethanol, for ceramide 1-phosphates (CerP),

223 there were significantly fewer species observed in MY29 (109.6 ± 6.61) compared to AJ4 and MY3

224 (128.2 ± 1.49 and 130 ± 0.55), where $P < 0.01$ (two-way anova and Tukey's multiple comparisons

225 test) and MY14 (126.6 ± 1.86) where $P < 0.05$. For cardiolipin species (CL), there were significantly

226 fewer observed in AJ4 and MY3 (3.0 ± 0.45 and 3.0 ± 0.31); ($P < 0.01$), and MY14 and MY26 ($4.2

227 ± 1.3 and 4.0 ± 0.55); ($P < 0.05$) when compared to MY29 (9.67 ± 1.8). There were fewer

228 diacylglycerols observed in MY29 compared to MY3 (180.2 ± 1.93 and 193.0 ± 1.41); ($P < 0.05$).

229 For glycerophosphatidicacid (GPA) species, there were significantly fewer species identified for

230 MY29 (126.4 ± 15.17) compared to AJ4 (178.0 ± 2.28; $P < 0.0001$), MY3 (175.0 ± 1.05; $P < 0.001$),

231 MY14 (170.4 ± 5.30; $P < 0.001$), and MY26 (167.8 ± 6.67; $P < 0.01$). There were also fewer

232 glycerophosphatidylethanolamine GPEth species identified for MY29 compared to each of the strains

233 ($P < 0.01$ in each case) (259.6 ± 3.2 AJ4; 258.4 ± 1.36 MY3; 254.8 ± 2.85 MY14; 252.4 ± 3.26 MY26

234 and 186.2 ± 35.034 for MY29). For glycerophosphoserine species (GPSer), there were fewer species

235 in MY29 (120.0 ± 12.99) compared to AJ4 and MY3 (157.6 ± 2.50 and 159 ± 1.41; $P < 0.001$), MY14

236 (151.6 ± 3.41; $P < 0.01$) and MY26 (147.4 ± 3.94; $P < 0.05$). Lastly, there were less monoacylglycerols

237 (MG) species observed in MY29 (19.0 ± 0.84) than for MY3 (24.6 ± 0.51; $P < 0.01$).

238

239 There were no significant differences observed between the species grown in the presence of 6%

240 ethanol; however, significant changes were seen between the 0% and 6% ethanol samples. For CL,

241 there were significantly fewer species observed for MY29 grown in 6% compared to 0% ethanol ($3.0

242 ± 0.44 and 9.66 ± 1.80; $P < 0.01$). For DG, there were more species in 0% MY3 than 6% ($193.0 \pm

243 1.41 and 178.4 ± 2.13; $P < 0.05$), for GPA there were significantly fewer species in MY29 at 0%

244 compared to 6% (126.4 ± 15.17 and 157.0 ± 4.03; P < 0.05), and for GPEth there were also

245 significantly fewer species in MY29 at 0% compared to 6% ethanol (186.2 ± 35.04 and 241.2 ± 1.82;

246 P < 0.05). There were significantly more MG species in MY3 at 0% (24.6 ± 0.51 and 20 ± 1.22; P <

247 0.05) and more TG species in MY3 at 0% compared to 6% ethanol (73.2 ± 1.39 and 66.6 ± 1.03; P <

248 0.01). Strikingly, MY29 seems to have the most different total lipid composition at 0% ethanol and

249 to remodel this most dramatically, in terms of species diversity, at 6%. However, at 6% ethanol,

250 species diversity in MY29 is similar to the other strains, perhaps indicating an optimal membrane

251 composition for ethanol tolerance.

252

253 Acyl chain length and saturation have been shown to be important factors in regulating membrane

254 fluidity and ethanol tolerance in yeast (44–46). We therefore investigated this for AJ4, MY3, MY14,

255 MY26 and MY29 strains in both 0% and 6% ethanol. While there were no significant changes in

256 average carbon length of the acyl chains for each of the strains grown in 0% compared to 6% ethanol

257 (Fig. S2), there were significant differences in saturation (Fig. 6). For the strains grown in 0% ethanol

258 (Fig. 6A), DG species contained a significantly lower percentage saturated acyl chains in MY29

259 compared to AJ4 (37.95 ± 0.35 and 40.22 ± 0.30; P < 0.01). There was a significantly higher

260 percentage of monounsaturated CL species in MY29 (30 ± 7.83) compared to AJ4 and MY3 (0 ± 0.0

261 in both cases; P < 0.01), and MY26 (3.33 ± 3.33; P < 0.05). For GPA, there was a significantly higher

262 percentage saturated chains in MY29 (34.51 ± 1.07) compared to MY14 (31.30 ± 0.88); P < 0.05. For

263 GPEth, there were more saturated chains in MY29 compared to AJ4, MY3, MY14, and MY26 (31.21

264 ± 3.79; 25.30 ± 0.24; 24.92 ± 0.16; 24.96 ± 0.26; 24.38 ± 0.26; P < 0.05 in each case). There was a

265 significantly greater number of saturated GPSer species in MY29 compared to MY26 (32.44 ± 1.70

266 and 29.24 ± 0.22; P < 0.05) and a lower number of monounsaturated species in MY29 (40.07 ± 2.20)

267 compared to MY3 and MY14 (45.11 ± 0.62 and 44.7 ± 0.59; P < 0.05). Lastly, there was a

268 significantly higher percentage of MG species containing two unsaturations in MY29 (10.59 ± 0.40)

269 compared to MY3 (8.14 ± 0.17) (P < 0.05). Once again, MY29 is the most different in terms of

270 saturated species at 0% ethanol and remodels its membrane to be more similar to the other strains at

271 6%.

272

273 There were no significant differences observed between strains for 6% ethanol samples (Fig. 6B), but

274 there were between strains grown in 0% compared to 6% ethanol. There was a significantly higher

275 percentage of saturated DG species for AJ4 at 0% than 6% ethanol (40.22 ± 0.30 and 38.08 ± 0.44),

276 and a lower percentage of monounsaturated species for AJ4 (32.80 ± 0.09 and 34.75 ± 0.38; P <

277 0.001) and MY3 (33.06 ± 0.21 and 34.54 ± 0.25; P < 0.05) at 0% compared to 6% ethanol. For

278 saturated GPEth species, there was a significantly higher percentage in 0% MY29 than 6% MY29

279 (31.21 ± 3.79 and 24.65 ± 0.26; P < 0.05), and significantly fewer monounsaturated species in 0%

280 MY29 compared to 6% (40.23 ± 0.55 and 41.94 ± 0.42; P < 0.05). There were significantly more

281 monounsaturated GPGro species in MY29 at 0% compared to 6% ethanol (19.12 ± 4.95 and 12.37±

282 1.05). In addition, there were significantly fewer monounsaturated GPSer species in 0% MY29 than

283 in 6% (40.07 ± 2.20 and 44.77 ± 0.23). Lastly, for TG species, there were significantly more saturated

284 species in MY14 at 0% ethanol than in MY14 at 6% (35.94 ± 0.58 and 30.86 ± 1.16; P < 0.001), more

285 monounsaturated species in AJ4 6% (26.33 ± 0.503; P < 0.01), MY14 6% (6.24 ± 0.55; P < 0.01), and

286 MY26 6% (25.73 ± 0.26; P < 0.05) compared to the 0% samples (23.40 ± 0.64; 23.60 ± 0.40 and

287 23.55 ± 0.25 respectively), and fewer species containing two unsaturations in MY3 (26.50 ± 0.47; P

288 < 0.01) and MY14 at 0% (26.98 ± 0.55; P < 0.05) compared to 6% (29.43 ± 0.68 and 29.39 ± 0.48)

289 samples.

290

291 To assess variation in overall lipid unsaturation the unsaturation index (UI) was calculated at the lipid

292 level by lipid class for species identified in each strain at 0% and 6% ethanol (Table 2) using the

293 percentage of lipids weighted by the number of unsaturated bonds: UI = % with one unsaturation +

294 (2 x % with two unsaturations) + (3 x % with three unsaturations) + (4 x % with four unsaturations).

295 The UI for DG was significantly lower for AJ4 compared to MY29 at 0% ethanol (86.76 ± 0.64 and

296 90.03 ± 0.61, P < 0.01) and higher for GPEth species in the 0% AJ4, MY14, MY26 strains compared

297 to MY29 (108.72 ± 0.35, 108.72 ± 0.28, 109.36 ± 0.60 and 97.36 ± 7.13 respectively, where P < 0.05

298 in each case). The UI for MY29 at 0% was also significantly lower than at 6% ethanol (108.73 ± 0.92,

299 P < 0.05). Lastly, the UI for MG species at 0% ethanol was significantly lower for MY3 compared to

300 MY29 (73.30 ± 16.58 and 83.27 ± 18.95, P < 0.05), and the UI for MY29 at 0% ethanol was

301 significantly higher compared to 6% MY29 (83.27 ± 18.95 and 78.74 ± 1.52, P < 0.05).

302

303 Due to changes observed in phosphatidylethanolamine (PE) and phosphatidylserine (PS) species

304 diversity in Fig. 5, we undertook quantitative TLC analysis of these lipids. This showed significant

305 differences in the abundance of PE in MY26 grown in 0% ethanol (0.41 ± 0.02), where the abundance

306 was higher compared to AJ4 (0.03 ± 0.01; P < 0.0001), MY3 (0.08 ± 0.01; P < 0.0001), MY14 (0.17

307 ± 0.01; P < 0.0001) and MY29 (0.18 ± 0.04; P < 0.0001) grown in 0% ethanol as illustrated by Fig.

308 7. There was also a significantly greater abundance of PE in 6% MY26 (0.41 ± 0.05) compared to

309 6% AJ4 (0.08 ± 0.03; P < 0.05), MY3 (0.07 ± 0.02; P < 0.0001), MY14 (0.09 ± 0.01; P < 0.0001) and

310 MY29 (0.13 ± 0.01; P < 0.0001). In addition, there was a lower abundance of PE in MY26 at 10%

311 ethanol (0.20 ± 0.06) compared to MY26 at both 0% (0.41 ± 0.02) and 6% ethanol (0.41 ± 0.051); P

312 < 0.001). There was a significantly lower abundance of PS in AJ4 at 0% ethanol (0.06 ± 0.01)

313 compared to MY14 and MY29 (0.36 ± 0.06 and 0.30 ± 0.09; P < 0.01 and P < 0.05, respectively).

314 There was also a significantly lower abundance of PS in MY3 compared to MY14 at 0% ethanol

315 (0.09 ± 0.01 and 0.36 ± 0.06; $P < 0.05$). It is notable that MY26, the least tolerant strain, is the most

316 different at 0% and 6% ethanol, but has a similar composition to the other strains at 10%.

317

318 We next examined the effect of ethanol upon the fluidity of the yeast membranes as they grew in

319 cultures with and without ethanol. We utilized the fluorescent dye, Laurdan, which has been used to

320 study phase properties of membranes as it is sensitive to the polarity of the membrane environment

321 (47). GP (Generalized Polarization) values, which correlate inversely with fluidity, were calculated

322 at six timepoints during the growth of AJ4, MY3, MY14, MY26 and MY29 strains in GPY, GPY

323 containing 6% ethanol and GPY containing 10% ethanol. The assay suggests that the fluidity of the

324 yeast membranes decreases with culture time as shown by the increase in GP (Fig. 8). AJ4 and MY14

325 strains demonstrated large changes in fluidity when treated with 10% ethanol (AJ4 showed a GP value

326 change of -0.0002 ± 0.0009 at 10% and a GP value change of 0.0233 ± 0.0025 at 0% and MY14

327 showed a GP value change of -0.0101 ± 0.002 at 10% and a GP value change of 0.009 ± 0.002 at 0%)

328 ($P < 0.001$ and $P < 0.01$, respectively). MY29 also became significantly more fluid at 10% ethanol

329 (GP value change of -0.0016 ± 0.0011 at 10% and a GP value change of 0.0084 ± 0.0019 at 0%) ($P <$

330 0.05). However, these strains did not show any increases in fluidity with 6% ethanol. The other strains

331 showed no significant differences to fluidity with ethanol treatment. It is notable that the most tolerant

332 strains show the largest increases in membrane fluidity in response to ethanol exposure.

333

334 To examine membrane permeability, we investigated the integrity of liposomes composed of lipids

335 extracted from each of the strains and loaded with carboxyfluorescein (CF) dye. The liposomes were

336 challenged with increasing concentrations of exogenous ethanol, and the fluorescence increase from

337 CF dye release was measured. The data in Fig. 9 shows that the liposomes containing lipids extracted

338 from AJ4 demonstrated a significantly greater increase in fluorescence at high ethanol concentrations

339 than those composed of lipids from the other strains (ANOVA and Tukey's multiple comparisons test

340 (90.98 ± 4.29 fluorescence increase; $P < 0.001$). MY3 and MY26 liposomes were less "leaky" overall

341 (46.38 ± 2.97 and 47.41 ± 7.84 of fluorescence increase). This increase in fluorescence indicates

342 increased "leakiness" of the membranes.

343

344 **Principal component analysis**

345 With the aim of grouping the 5 selected strains based on their lipid composition and their ethanol

346 tolerance, the data obtained in the previous sections was used to perform a PCA (Fig. 10). The data

347 from the variables NIC, MIC, and the drop test growth value at 14% and 16% of ethanol in the plates,

348 related to the ethanol tolerance were used. For the lipid composition, the data of the

10

349   carboxyfluorescein release at the last time point; the data from the Laurdan experiments of the

350   differential GP value at 10% of ethanol and when no ethanol is present in the last time point, and the

351   PE abundance at 0% and 6% of ethanol in the media was used. The two commercial wine strains

352   MY3 and MY14 group together, and MY26 (the most sensitive to ethanol) and AJ4 (the most tolerant)

353   are the two strains that demonstrate the most differences among them. It is interesting to note that

354   MY26 is associated in the PCA with an accumulation of PE in the membrane at low ethanol

355   concentration and a higher membrane rigidity, and the most tolerant stain, AJ4, associated with a high

356   membrane fluidity in the presence of ethanol.

357

358   **Discussion**

359   In this study, we investigated the membrane properties of the selected yeast strains to try to understand

360   their different levels of ethanol tolerance. The mass spectrometry analysis of the lipid composition of

361   each strain in the absence of ethanol highlighted differences, in particular between MY29 and the

362   other strains, not only in the variety of species observed for the lipid classes but also in their saturation.

363   MY29 is a flor yeast. These yeasts constitute a separate phylogenetic group within *S. cerevisiae*

364   species. They are characterized by forming a layer on top of wine known as flor, which allows them

365   to access the oxygen during the fermentation of sherry wines, so they show different behavior and

366   thus physiological characteristics to wine yeast. Moreover, they have been reported to survive under

367   extreme conditions (ethanol content over 15%) (48, 49), which could relate to their membrane

368   structure.

369   Upon treatment with 6% ethanol, the lipid composition of MY29 underwent significant changes; the

370   composition was then found to be more similar to that of the other strains, suggesting that the

371   membrane of MY29 underwent more drastic changes than the other strains in response to ethanol.

372   The lack of significant differences at 6% ethanol suggests that each of the strains move towards a

373   more common lipid composition in response to ethanol. However, despite the fewer differences to

374   lipid composition at 6% ethanol between the strains, MY29 dominated the fermentation at this

375   concentration. In addition, the lipid composition of AJ4 was not significantly different from the other

376   strains at 6% ethanol, although it is the most tolerant to ethanol. It is possible that there may be further

377   adaptation of the membrane at higher ethanol concentrations than were investigated in this study, but

378   it is likely that other factors contribute to the ethanol tolerance of these strains.

379   Indeed, this has been suggested by other studies, where the relationship between H^+-ATPase activity

380   and ergosterol content as well as the sterol to phospholipid and protein to phospholipid ratios are

381   important (45, 50, 51). Ethanol tolerance is a complex phenotype, and different mechanisms may lead

382   to improved tolerance. Fluidisation of the yeast membranes by ethanol is also known to activate the

383   unfolded protein response (UPR), and it is speculated that a better response could lead to greater

384   tolerance (52). Moreover, yeast cells can increase their tolerance to ethanol by other mechanisms,

385   such as the increase the biosynthesis of some amino acids, as tryptophan (53)

386   and trehalose accumulation (54).

387   Nevertheless, it is striking that yeast strains with different membrane compositions in the absence of

388   ethanol become more similar upon exposure, suggesting a common, or limited number, of membrane

389   compositions that maximize tolerance to ethanol.

390   Incorporation of longer acyl chains and a decrease in shorter chains has previously been shown to

391   occur in yeast in response to ethanol (46, 55); however, we did not observe any significant changes

392   in chain length. Our study does suggest that there were significant differences in saturation between

393   the species upon ethanol treatment. These changes occurred in GPGro and GPEth in MY29, and

394   occurred predominantly in DG and TG for the other strains, with shifts towards increased saturation

395   for AJ4 and increased unsaturation for MY3 and MY14. These changes appear to be complex and

396   specific to each strain. Documented changes to the membrane of yeast upon ethanol challenge are

397   conflicting (56); while some studies have shown that increased levels of unsaturated fatty acids are

398   linked to improved ethanol tolerance (46), changes to the unsaturation index may not necessarily be

399   associated with improved tolerance, or lead to the expected changes in membrane fluidity, and it is

400   rather the potential of the cell to alter its composition (45, 57). The lipid membrane is a highly

401   complex environment and multiple factors can influence membrane fluidity and permeability. Further

402   study of these strains is required to determine if their different compositions have similar biophysical

403   properties.

404   We investigated the fluidity of the membranes and the Laurdan assay demonstrated that the fluidity

405   of the membranes for each strain decreased over the duration of the fermentation, which has been

406   observed previously (58), and may be linked to nutrient depletion and changes in the growth rate of

407   the cells. In our study, the most tolerant strain, AJ4, underwent the largest changes in fluidity, where

408   the membranes were significantly more fluid at 10% ethanol than in the other conditions. AJ4 lipid-

409   containing liposomes were also the "leakiest" when compared to the other strains. This strain may

410   therefore be better able to tolerate the fluidizing effects of ethanol upon the membrane or to modulate

411   its membrane composition to lead to an increase in fluidity; this more fluid composition may allow

412   more efficient movement of ethanol across the membrane. The membranes of one of the least tolerant

413   strains, MY26, did not alter in fluidity in any of the conditions and liposomes comprised of MY26

414   lipids were less leaky when challenged with ethanol. In addition, our analysis of PE abundance shows

415   that MY26 contained significantly more PE than the other strains in both 0% and 6% ethanol, while

416   the most tolerant strain, AJ4, contained less PE in general than other strains. PE has a small headgroup

417   and can form hydrogen bonds with adjacent PE molecules (59). It influences lipid packing and

418   therefore membrane fluidity, where increased PE content results in less fluid membranes (60, 61),

419   consistent with our hypothesis. Lower PE content in relation to PC has been correlated with more

420   tolerant strains (46, 62). These findings suggest that more tolerant strains are more fluid and

421   permeable, while less tolerant strains are more rigid and less permeable. Several studies have

422   correlated membrane fluidity and ethanol tolerance, and many of these point to increased fluidity

423   being associated with more tolerant strains (45, 57), although another study suggests that less fluid

424   membranes are associated with more tolerant strains (58). In this study, we provide further support

425   for the concept that low PE content is beneficial for ethanol tolerance. This result can guide

426   engineering to improve ethanol tolerance towards the reduction of PE synthesis. This compound is

427   produced by four separate pathways, but the Psd pathway, which utilizes PS as a substrate is

428   predominant in *S. cerevisiae* (63,64), so future works can be addressed in this direction.

429   In summary, the lipid composition of most of the yeast strains in this study were comparable but there

430   were significant differences between these and the MY29 strain. Upon ethanol treatment, this

431   composition changed significantly and a more similar composition was reached, suggesting an

432   adaptation mechanism in common with the other strains. Changes in saturation were observed for

433   each of the strains upon ethanol treatment, but it is not clear if these changes have a direct impact

434   upon fluidity and tolerance, and it is likely that other factors beyond the scope of this study play a

435   critical role and further investigation is needed. The PE abundance of the least tolerant strain, MY26,

436   was significantly higher than in the other strains. Our investigation therefore suggests that the

437   membranes of more tolerant strains are more fluid and contain less PE. Overall, our results point to a

438   reduced set of desirable membrane compositions and features that promote ethanol tolerance with

439   increased fluidity and permeability appearing to be key.

440

441

442   **Material and methods**

443   **Strains and media conditions.**

444   The *Saccharomyces cerevisiae* yeast strains used in this study are listed in Table 1. A total number of

445   61 strains from different isolation sources were selected. These strains were maintained in GPY-agar

446   medium (%w/v: yeast extract 0.5, peptone, 0.5, glucose 2, agar 2). Yeast identity was confirmed by

447   sequencing the D1/D2 domain of the 26S rRNA gene (65).

448

449   **Drop test experiments. Assay in ethanol plates**

450   To assess yeast strains' ethanol tolerance, drop test experiments were carried out. Rectangular GPY

451   plates supplemented with different ethanol percentages (0, 6, 10, 14, 16 and 18%) were prepared.

452   Yeast cells were grown overnight at 28ºC on GPY media and diluted to an $OD_{600}= 0.1$ in sterile water.

453   Then, serial dilutions of cells (10^{-1} to 10^{-3}) were transferred on the plates with replicates and incubated

13

454 at 28ºC for ten days with the plates wrapped in parafilm to avoid ethanol evaporation. Each strain

455 was inoculated twice on the same plate but at different positions, and an exact replicate of the plate

456 was made. With this method, four biological replicates of each strain were performed. Growth values

457 were assigned to each of the replicates: 0 no growth, 1 weak growth, 2 intermediate growth and 3

458 remarked growth. Median growth values were assigned for each ethanol concentration. Hierarchical

459 clustering used in heatmap plot was elaborated using www.heatmapper.ca tool, (66) with Euclidean

460 distance measurement method and group clustering was based on growth in different ethanol media

461 averages (average linkage).

462

463 **Assay in liquid media.**

464 **Optical density measurements.**

465 GPY precultures of each strain were prepared and incubated at 28ºC overnight. These cultures were

466 washed with sterile water and adjusted to an $OD_{600}= 0.1$ in each one of the culture media (YNB liquid

467 media supplemented with different ethanol percentages (0, 1, 6, 8, 10, 13, 16 and 18 %)). YNB is

468 composed of 6.7 g/L of aminoacids and ammonium sulfate (YNB, Difco) and supplemented with 20

469 g/L of D-glucose as carbon source. Growth was monitored in a SPECTROstar Omega instrument

470 (BMG Labtech, Offenburg, Germany) at 28ºC. NuncTM MicroWellTM 96 well plates (ThermoFisher

471 Scientific) wrapped in parafilm and with water in each of its 4 repositories were employed.

472 Measurements were taken at 600 nm every 30min, with 10 seconds of preshaking before each

473 measurement until 64 hours of growth monitoring. All the experiments were carried out in triplicate.

474

475 **Estimation of the NIC and MIC parameters.**

476 The basis of the technique, used as in (40), is the comparison of the area under the OD–time curve of

477 positive control (absence of ethanol, optimal conditions) with the areas of the tested condition

478 (presence of ethanol, increasing inhibitory conditions). As the amount of inhibitor in the well

479 increases, the effect on the growth of the organism also increases. This effect on the growth is

480 manifested by a reduction in the area under the OD–time curve relative to the positive control at any

481 specified time.

482 Briefly, the areas under the OD–time curves were calculated by integration using GCAT software

483 (http://gcat-pub.glbrc.org/). Then, for each ethanol condition and strain replicate, the fractional area

484 (fa) was obtained by dividing the tested area between the positive control area (f a = (test area) /

485 (positive control area). The plot of the fa vs log10 ethanol concentration produced a sigmoid-shape

486 curve that could be well fitted with the modified Gompertz function for decay (67) fa =

487 $A+C\times\exp[-\exp(B(x - M)])$. After this modelling, the NIC (non-*inhibitory* concentration) and MIC

488 (Minimum Inhibitory Concentration) parameters could be estimated as in (66).

489   NIC = 10[M−(1.718/B)] MIC = 10[M+(1/B)]

490   To check for significant differences among yeast species for NIC and MIC parameters, an analysis of

491   variance was performed using the one-way ANOVA module of Statistica 7.0 software. Tukey's test

492   was employed for mean comparison. ggplot2 package (68) implemented in R software, version 3.2.2

493   (RDevelopment Core Team 2011) was employed for graphic representation of these NIC and MIC

494   values.

495   **Strains selection and competition fermentation**

496   Competition fermentations were carried out in 30 mL GPY, GPY+6% ethanol and GPY+10% ethanol

497   in triplicate. 0.1 OD of each of the 5 strains (AJ4, MY3, MY14, MY26, MY29) were inoculated in

498   every initial culture. Every 3/5 days 1 mL of the culture was transferred into the corresponding fresh

499   media. After 5 and 10 rounds, culture plates of samples from every tube were obtained. 20 colonies

500   from every plate were randomly picked for their identification. This was carried out by means of

501   mitochondrial digestion profile identification (69), which allowed differentiation of all the strains

502   except for MY14 and MY29, which shared the same exact profile. As an alternative, as we had

503   available the genome sequences of MY14 and MY29 (70), we identified a divergent region among

504   these two strains which encomprises gene *MMS1*. We amplified a region of gene *MMS1* with primers

505   *f1* (AACGGATCCTTTTTCCCAAC) and *r1* (CGGTCGCAAAAATTAACG) and used *RsaI*

506   digestion to differentiate specially these two strains. Theoretical results for digestion bands sizes in

507   an agarose gel were calculated based on Sanger sequencing of the amplicon for the strains of interest

508   (Figure S3).

509

510   **Lipid composition and membrane studies.**

511   **Lipid extraction and quantification by ammonium ferrothiocyanate assay**

512   Yeast precultures of each one of the five selected strains (AJ4, MY3, MY12, MY26 and MY29) were

513   first propagated in 25 mL of GPY media at 200 rpm and 28°C. The cultures were harvested after 24

514   h and total lipids were extracted using a modified Bligh and Dyer protocol (71). To quantify the lipids,

515   10 µL sample was taken from the above 100 µL reconstituted lipids in chloroform and added to 2 mL

516   chloroform with 1 mL of assay reagent (0.1M $FeCl_3.6H_2O$, 0.4 M ammonium thiocyanate) in a 15

517   mL glass tube. Samples were vortexed for 1 min and centrifuged at 14,500 g for 5 mins. The lower

518   layer was collected into quartz cuvettes. The absorbance was measured at 488 nm, and the

519   concentration of lipid was determined by comparison with a standard curve of a mixture of

520   phospholipid standards (POPC, POPE and POPG) (Sigma).

521

522   **Mass spectrometry of lipids present in the strains**

523   The lipids from each of the five yeast strains extracted as previously described were reconstituted in
524   100 µL chloroform to contain 5 µg/µL lipid as determined by ammonium ferrothiocyanate assay, and
525   then diluted 1 in 50 in solvent A (50:50 acetonitrile:H_2O, 5 mM ammonium formate and 0.1% v/v
526   formic acid). Analysis of 10 µL samples was performed by LCMS. LC was performed on a U3000
527   UPLC system (Thermo scientific, Hemel Hempstead) using a Kinetex C18 reversed phase column
528   (Phenomenex, 2.6 µm particle size, 2.1 mm x 150 mm), at a flow rate of 200 µL/min with a gradient
529   from 10% solvent B to 100% solvent B (85:10:5 isopropanol: acetonitrile: H_2O, 5 mM ammonium
530   formate and 0.1% v/v formic acid) with the following profile: t=0 10% A, t=20 86%A, t=22 96%A,
531   t=26 95%A. MS analysis was carried out in positive and negative ionization mode on a Sciex 5600
532   Triple TOF. Source parameters were optimized on infused standards. Survey scans were collected in
533   the mass range 250-1250 Da for 250 ms. MSMS data was collected using top 5 information dependent
534   acquisition and dynamic exclusion for 5 s, using a fixed collision energy of 35V and a collision energy
535   spread of 10V for 200 ms per scan. ProgenesisQI® was used for quantification and LipidBlast
536   (https://fiehnlab.ucdavis.edu/projects/LipidBlast) for identification. All data were manually verified
537   and curated. Data were analysed by two-way ANOVA and Tukey's multiple comparisons test, where
538   n = 5. Data sets were uploaded to: https://doi.org/10.17036/researchdata.aston.ac.uk.00000495
539
540   **TLC analysis.**
541   Yeast lipids extracted as above after 24 h growth were analysed by TLC. Briefly, 20 µg of lipid sample
542   and 10 µg phospholipid lipid standards (POPE and POPS) (Sigma) were loaded onto silica gel TLC
543   plates (Sigma) and separated using chloroform/methanol/acetic acid/water 25:15:4:2. The plates were
544   air dried and sprayed with ninhydrin reagent (0.2% ninhydrin in ethanol) (Sigma) and charred at
545   100°C for 5 mins. Images of plates were captured with a digital camera ad spot intensity was
546   determined using ImageJ software.
547
548   **Laurdan membrane fluidity assay.**
549   Yeast cultures were set up in GPY and incubated at 200 rpm and 28°C overnight. Then, 25 mL of
550   GPY media containing 0% ethanol, 6% ethanol or 10% ethanol was inoculated to an OD_{595} of 0.5.
551   Samples were taken at different time points during the fermentation, and live yeast were diluted to an
552   OD_{595} of 0.4 in GPY and incubated with 5 µM Laurdan (6-dodecanoyl-2-dimethylaminonaphthalene)
553   for 1 h. Fluorescence emission of these cells stained with Laurdan was taken using a microplate reader
554   (Mithras, Berthold) with the following filters; λex=460 λem=535. Generalized Polarization (GP),
555   derived from fluorescence intensities at critical wavelengths, can be considered as an index of
556   membrane fluidity and is calculated as GP = $(I_{460}-I_{535})/(I_{460}+I_{535})$. Data were analyzed by one-way
557   ANOVA and Tukey's multiple comparisons test, where n = 3.

16

558

Carboxyfluorescein dye leakage assay

560 Lipids for each of the five selected yeast strains extracted as described previously were used to

561 generate 400 nm liposomes loaded with 100 mM Carboxyfluorescein (CF) in protein buffer (50 mM

562 tris, 50 mM NaCl, pH 7.4). Dye leakage assays were performed with at 0.125 mg/mL liposomes and

563 increasing concentrations of ethanol in protein buffer at room temperature, and the fluorescence

564 emission measured (λex= 492 nm, λem=512 nm). Liposomes were treated with 5% Triton X-100 to

565 fully disrupt them, and fluorescence measurements were normalized to the maximum reading for each

566 liposome composition. Data were analyzed by one-way ANOVA and Tukey's multiple comparisons

567 test, where n = 3.

568

PCA analysis

570 To visualize the relationships among different ethanol tolerance parameters and lipid composition of

571 the selected *S. cerevisiae* strains, a principal component analysis (PCA) was performed using the

572 prcomp function and ggbiplot (0.55 version) and ggplot (3.2.1 version) implemented in R.

573

Data availability

575 The sequencing of the D1/D2 26S rRNA gene of the strains was deposited in GenBank with the

576 accession numbers MW559910-MW559970 (73).

779

780   **Figure legends.**

781

782   **FIG 1.** Heatmap representation of growth values (from 0 to 3) of the analysed strains at plates with

783   increasing ethanol concentrations. Each line corresponds to a strain (AJ4, MY1-MY63) and each

784   column to a particular ethanol concentration (0%, 6%, 10%, 14%, 16% and 18%). The color key bar

785   at the top indicates growth values, from yellow (low growth value) to pink (high growth value).

786   Hierarchical clustering is showed on the left. Color dots on the right of the Figure indicate the

787   source/origin of each one of the strains and shapes their classification. In Fig. S1 can be seen one of

788   the four replicates from which these heatmap was constructed.

789

790   **FIG 2.** Representation of each strain NIC (yellow) and MIC (red) parameters of the selected strains

791   in relation with its ethanol tolerance (%). Values are averages from triplicate experiments and

792   standard deviation is represented too. Color dots on the right of the Figure indicate the source/origin

793   of each one of the strains and shapes their classification. Strains are ordered by MIC value.

794

795   **FIG 3**. Photograph of the drop tests in ethanol plates (A) and the NIC and MIC parameters (B) for

796   each one of the 5 selected strains.

797

798   **FIG 4**. Percentage of strains present in GPY+ethanol media determined by molecular identification

799   after 10 rounds of fermentations. Every biological replicate is indicated by letters *A*, *B* and *C* and

800   the ethanol concentration present in the media in the *X* axis.

801

802   **FIG 5.** Number of species identified by lipid class for AJ4, MY3, MY14, MY26 and MY29 strains

803   in the presence of 0% ethanol and 6% of ethanol. Lipids were extracted and analysed by LC-MS in

804   positive and negative ion mode (n = 5).

805

806   **FIG 6**. Percentage of saturated, monounsaturated and polyunsaturated chains by lipid class showing

807   significant changes for A) AJ4, MY3, MY14, MY26 and MY29 strains in the presence of 0%

808   ethanol, and B) AJ4, MY3, MY14, MY26 and MY29 strains in the presence of 6% ethanol. Lipids

809   were extracted and analysed by LC-MS in positive and negative ion mode (n = 5).

810

811   **FIG 7**. TLC analysis of phosphatidylethanolamine (PE) and phosphatidylserine (PS) abundance for

812   AJ4, MY3, MY14, MY26 and MY29 strains in the presence of 0%, 6% and 10% of ethanol.

23

813 Samples were loaded in triplicate and spot intensity was analyzed using ImageJ. Spot intensity is

814 plotted relative to phospholipid standards loaded onto each plate.

815

816 **FIG 8**. The effects of ethanol upon the fluidity of live yeast throughout the fermentation, measured

817 by changes to Laurdan generalized polarization (GP).

818

819 **FIG 9**. The effects of ethanol upon liposomes composed of lipids extracted from AJ4, MY3, MY14,

820 MY26 and MY29 strains normalized to the maximum amount of dye released upon treatment with

821 5% Triton X-100.

822

823 **FIG 10**. Plot of the first two factors of a Principal Component Analysis (PCA) of the five *S.*

824 *cerevisiae* strains regarding their lipid composition and their ethanol tolerance.

825 **TABLE 1.** List of the 61 *Saccharomyces* strains selected used in this work.

MY42	AQ2717	Lung, Spain	-

839
840 AQ (Amparo Querol collection),
841 [a] MY62 is a *S. cerevisiae* strain containing a limited amount of *S. kudriavzevii* genome (72, 73)
842 [b] kindly provided by Professor Sipiczki

27

843 **Table 2**. Unsaturation index (UI) for lipids identified in each strain was calculated using the percentage of lipids with each number of unsaturated bonds: one unsaturation + (2 x
844 two unsaturations) + (3 x three unsaturations) + (4 x four unsaturations). Statistically significant differences between strains and ethanol conditions are highlighted in bold (two-
845 way anova and Tukey's multiple comparisons test). Errors (SD) are shown in brackets, n = 5.
