Abstract

The focus of this work is to construct theoretical methods or approaches to tackle computationally challenging problems in quantum chemistry. The primary topic of the work will focus on efficient theories that allow for capturing electron-correlation in semiconductor or metallic nanoparticles. These systems are computationally challenging due to the size of the systems, the number of electrons per atom, and the degeneracy of the particle-hole states. Three methods presented here are aimed at providing novel theoretical methods towards computationally inexpensive electronic excited state calculations. The frequency-dependent geminal-screened electron-hole interaction kernel (FD-GSIK) method provides a real-space approach towards eliminating the virtual space reducing the computational effort present in most excited state methods. Dressed molecular orbital basis is presented to compress the configuration space in metallic nanoparticles, resulting in a cheap multi-reference approach to obtaining electron-correlation. Finally, the moment generated molecular orbital basis is derived to provide an alternative approach that utilizes moments of the reference function to decouple particle and hole states. A secondary focus within this work is to provide efficient Monte Carlo sampling techniques for modeling and integration. Monte Carlo provides an efficient pathway to sampling experimental models and evaluation of complicated integrals which are normally computationally costly. The theoretical developments presented in this work allow for understanding theoretical properties in semiconductor or metallic nanoparticles which normally would be computationally prohibited.

I want to begin by thanking my advisor Ari for his support and guidance through my Ph.D. career. His willingness to educate me in quantum mechanics, mathematics and computer science in my pursuit towards achieving this goal was phenomenal. Ari is a truly remarkable educator who ultimately wants the best for his students, setting them up to be prepared for the rigors of this field. As I approach the end of my education at Syracuse University I feel confident as a scientist and researcher thanks to Ari.

I next want to thank my parents and siblings who have always been there encouraging me on this path. They have been supporting me from afar, curious of my well-being to support in anyway they could. I appreciate the weekly calls from my dad as that gave me time to relax and contemplate my week and future. It is a ritual that I look forward too. Additionally, my mom was always there to accept a phone call whenever I need to decompress or discuss any of my troubles. My parents influence on my life and time here is appreciated beyond words.

I would like to thank my fiancé, Molly for her endless support during this journey. I want to thank her for kind and selfless nature, as my best friend. I am excited to continue our life together as we both venture out into the world beyond our academic careers.

I want to thank my labmates: Dr. Michael Bayne, Dr. Jeremy Scher and Nicole Spanedda that have helped me in my Ph.D. career with the invigorating and thorough discussions that made the days enjoyable. In particular, I want to thank Elyse Kleist who has been a friend through thick and thin since we both started at Syracuse. As well as Dr. Shawn Kowal, for our friendship that provided joy and laughter during our time here. Also, I want to provide special thanks to all the people in the chemistry main office and graduate school at Syracuse University for all their help throughout the years.

Lastly, I would like to thank my committee members, Dr. Pranav Soman, Dr. Weiwei Zheng, Dr. Joseph Chaiken, Dr. Timothy Korter, and Dr. John Franck for taking their time to be a part of my committee. All have you shown interest in my work and have provided me with guidance throughout my Ph.D. career. Either through research or teaching, each of you have impacted my

overall education and Ph.D. career.

There are numerous people who have further contributed to supporting me throughout my Ph.D. career. But I wanted to personally acknowledge all the people mentioned here for their efforts in assisting me to reach this accomplishment.

Chapter 1

Introduction

1.1 Scope

Quantum chemistry is an area within chemistry that focuses on obtaining theoretical insight into chemical systems with the use of quantum mechanics. In general, quantum chemistry research lies in obtaining answers accurately and efficiently. Accuracy in quantum chemistry begins by trying to minimize the energy within the system to match the ground-state energy or lowest energy state. But in addition, efficiency is of high importance within quantum chemistry to obtain results as quickly as possible. Where efficiency is measured by the computational effort needed for the theoretical investigation for the particular system. Typically, computational effort refers to the memory requirements, floating point operations, or speed of the calculation, method or algorithm. Throughout this presented work, path to efficient algorithms or computational methods is of key importance towards advancing the field of quantum chemistry.

A foundation within quantum chemistry is the Hartree-Fock method which provides a framework for calculating the energy of the chemical system from a wave-function and the Schrödinger equation. Hartree-Fock method captures about 99% of the total electronic energy of the system, and 95% of the wavefunction thereby contributing as a primary starting point for more advance quantum chemistry methods. [1] The goal of advance methods are to collect the remaining 1% of energy to complete the theoretical understanding of the system, and accuracy. In general, the en-

ergy differences in chemical and spectroscopic properties of interest are smaller than the missing 1% of electronic energy therefore it is crucial to develop methods that correct for the remaining energy. The energy that is not obtained in the Hartree-Fock method is the correlation energy and is defined as the energy missing from the Hartree-Fock model to matching the exact energy. The Hartree-Fock method is an introductory method and key baseline for much of quantum chemistry and provides the starting point for much of the presented work and discussed in [Chapter 2](#) along with the correlation energy.

A key aspect to appreciating and understanding the presented work comes from comprehension of the mathematical notation within the theory. I dedicate all of [Chapter 3](#) to second quantization which is a useful representation in quantum mechanics. It provides a simplistic notation towards more complicated equations and is used throughout the presented work. Once I have provided second quantization I will immediately use it to provide brief insight into many popular and commonly used electronic excited state methods, in [Chapter 4](#). The chapter will not be in-depth derivations of each method, but provide a primer to key mathematical expressions that define the methods. This chapter sets up the main motivation of the presented work, along with the problems faced towards obtaining correlation energy in modern quantum chemistry. Background material provided in [Chapter 2](#), [Chapter 3](#), and [Chapter 4](#) will allow for understanding of the presented work in [Chapter 5](#), [Chapter 6](#), [Chapter 7](#), and [Chapter 9](#).

In [Chapter 5](#), the frequency-dependent geminal-screened electron-hole interaction kernel (FD-GSIK) method for describing electron-hole correlation in electronically excited many-electron systems is presented. The FD-GSIK is a parameter-free, first-principle method derived from excited state wavefunction that was both frequency-dependent and r12-explicitly correlated. The FD-GSIK avoids using unoccupied orbitals for kernel construction by performing an infinite-order summation of particle-hole excitation and representing it as a compact real-space operator. It bypasses the computationally demanding steps of evaluation, storage, and transformation of atomic-orbital integrals by directly evaluating molecular orbital integrals in real space using the stratified Monte Carlo method. This chapter will demonstrate and discuss the advantages of this method by presenting excitation and electron-hole binding energies of large nanoparticles in-

cluding $\text{Pb}_{140}\text{S}_{140}$, $\text{Pb}_{140}\text{Se}_{140}$, $\text{Cd}_{144}\text{Se}_{144}$, and $\text{Cd}_{72}\text{S}_{72}$. This work was recently accepted for publication in *Journal of Chemical Theory and Computation* DOI:10.1021/acs.jctc.9b01238.

In **Chapter 6**, a dressed molecular orbital basis approach will be presented. I present a dressed particle-hole basis that allows for compression of the configuration space, allowing for a computationally efficient representation for investigation of multi-reference characteristics in electronic excitations. Multi-reference wavefunctions are approximations to the full configuration interaction (FCI) wavefunction, which is desirable since it provides an exact solution to the many-electron problem. The FCI is in practice computationally prohibitive for many-electron systems due to the number of excited determinants. In general, truncation of the configuration space is limited to the singly or doubly excited determinants for construction of the multi-reference wavefunction. Or by limiting the active space of the occupied or unoccupied orbitals thereby limiting the number of possible excited determinants. The objective of the presented work is to construct a molecular orbital basis that includes information for all particle-hole orbitals as well as compressing the configuration space without the use of truncation. The derived basis will be used in conjunction with the developed frequency-dependent geminal-screened electron-hole kernel (FD-GSIK) method to obtain electron-correlated excitation energies in silver nanowires, Ag_n where $n = 2, 4, 6, 8, 10, 12, 20, 40, 60, 80, 100$. These metallic like systems are of great interest due to their electronic properties but are computationally challenging due to the number of electrons and their highly degenerate molecular orbitals. The presented work aims to provide an approach that can efficiently understand multi-reference excitation characteristics within this system. This work is in preparation for submission to *The Journal of Chemical Physics*.

In **Chapter 7**, a derivation for a moment generated molecular orbital basis for obtaining electron-correlation is presented. This approach serves as an alternative to the frequency-dependent geminal-screened electron-hole interaction kernel reported in previous chapters. The operators in the method are the moments of the ground state particle or hole state, enabling a simplistic operator for decoupling the single particle-hole reference state. The benefit of the derived method would be that the operator is not limited by the choice of reference states.

In **Chapter 8**, I will briefly present the permutation sampling Monte Carlo integration method

and focus on the computational implementation of the method. The primary goal of the method is to decouple the dimensionality in integration to provide an efficient and accurate evaluation of numerical integrals. Within quantum chemistry numerical integration is ever-present and a key computational bottleneck within calculations. The main focus within this chapter will be the theory and computer science in efficient implementation of the permutation sampling Monte Carlo method. Providing insight into design decisions towards programming efficient software that is general purpose for future development but versatile in functionality. The use of permutation sampling Monte Carlo towards understanding a 12+1 dimensional Green's function integral is in preparation for journal submission.

In **Chapter 9**, various theoretical investigations within collaborative projects will be presented. These studies are centered around nanoparticles, which are of huge interest amongst many groups of science, including chemistry, biology and engineering. These nanoparticles that contain a large number of electrons are computationally limited with commercial electronic structure software packages. Therefore theoretical properties are a challenge to obtain and often avoided. The presented work will focus on the development of quantum chemical calculations for these large chemical systems. The first investigation will present the preliminary results for the collaborative investigation of Ag nanoclusters. The Ag nanoclusters were formed in a polymer film by direct-laser writing. It was found that these nanoclusters exhibited unique optical properties. This investigation will present theoretical insight on the HOMO-LUMO gap energies for large Ag nanoclusters to support the experimental observations. The next work will provide an insight into the theoretical works provided for understanding Mn^{2+} dopant migration in CdS/ZnS quantum dots. The goal of the theoretical investigation is to provide insight into dopant migration versus dopant ejection within these systems. The presented work will focus on the theoretical method developed towards understanding the thermodynamics of this molecular system in a computationally efficient manner. The work with Mn^{2+} dopant migration in CdS/ZnS quantum dots was recently accepted into *The Journal of Physical Chemistry Letters*.

Finally, **Chapter 10** will cover an overall conclusion to the presented work within this thesis and the future investigations of this work.

Chapter 2

Quantum Chemistry Background

2.1 Hartree-Fock approximation

I begin by briefly introducing the Hartree-Fock method as this is the foundation for most of the work that I have developed. The common nomenclature and conventions for describing many-electron wave functions for quantum chemists is a single Slater determinant, Φ ,

$$\Phi = \frac{1}{\sqrt{N!}} \begin{vmatrix} \chi_1(1) & \chi_2(1) & \cdots & \chi_N(1) \\ \chi_1(2) & \chi_2(2) & \cdots & \chi_N(2) \\ \vdots & \vdots & \ddots & \vdots \\ \chi_1(N) & \chi_2(N) & \cdots & \chi_N(N) \end{vmatrix} \quad (2.1)$$

$$= A |\chi_1(1)\chi_2(2)\cdots\chi_N(N)|. \quad (2.2)$$

In [Equation 2.1](#), there is a normalization factor, $\frac{1}{\sqrt{N!}}$, the antisymmetrizer, A , and a spin orbital, $\chi_i(\mu)$. The spin orbital describes both the spatial distribution and spin of the μ th electron. Electrons can have either be spin up (α) or spin down (β) within a spin orbital. The Slater determinant is the initial convention of choice for a physical wave function for several crucial reasons. First, the antisymmetry rule is followed by construction of the determinant. The antisymmetry rule is simply that interchange of both space and spin of two electrons must be opposite wave functions,

$$\begin{vmatrix} \chi_1(1) & \chi_2(1) & \cdots & \chi_N(1) \\ \chi_1(2) & \chi_2(2) & \cdots & \chi_N(2) \\ \vdots & \vdots & \ddots & \vdots \\ \chi_1(N) & \chi_N(N) & \cdots & \chi_N(N) \end{vmatrix} = - \begin{vmatrix} \chi_1(2) & \chi_2(2) & \cdots & \chi_N(2) \\ \chi_1(1) & \chi_2(1) & \cdots & \chi_N(1) \\ \vdots & \vdots & \ddots & \vdots \\ \chi_1(N) & \chi_N(N) & \cdots & \chi_N(N) \end{vmatrix} \quad (2.3)$$

Where by interchanging the first two rows in [Equation 2.1](#) yields a negative sign. The next reason is that a Slater determinant follows the Pauli exclusion principle, which is that two electrons can not occupy the same spin orbital. This occurs in a Slater determinant when two columns are exactly equal, which results in the determinant being zero.

The Hartree-Fock equation, in atomic units allows for optimization of the spin orbitals through minimization of the spin orbital energies,

$$\hat{f}\chi_i = \varepsilon_i\chi_i. \quad (2.4)$$

With the Fock operator \hat{f} ,

$$\hat{f} = \hat{h} + \hat{v}^{HF} \quad (2.5)$$

$$\hat{f} = \hat{h} + \sum_{j=1}^{N_{elec.}} (\hat{J}_j - \hat{K}_j) \quad (2.6)$$

containing the one-electron Hamiltonian,

$$\hat{h} = [\hat{t} + \hat{v}^{ne}] \quad (2.7)$$

$$\hat{h} = -\frac{1}{2}\nabla_i^2 - \sum_{A=1}^M \frac{Z_A}{r_{iA}} \quad (2.8)$$

and the two-electron Coulomb (\hat{J}) and exchange (\hat{K}) operators,

$$\hat{J}_j(1)\chi_i(1) = \langle \chi_j(2) | \frac{1}{r_{12}} | \chi_j(2) \rangle \chi_i(1) \quad (2.9)$$

$$\hat{K}_j(1)\chi_i(1) = \langle \chi_j(2) | \frac{1}{r_{12}} | \chi_i(2) \rangle \chi_j(1). \quad (2.10)$$

The Coulomb and exchange operators are an effective one-electron potential operator called the Hartree-Fock potential,

$$v^{HF} = \sum_{j=1}^{N_{elec.}} (J_j - \hat{K}_j) \quad (2.11)$$

The v^{HF} is simply an average potential felt by the μ th electron from the other electrons. By minimizing the energy of the spin orbitals a Slater determinant is obtained that is a good first approximation to electronic wave function. [2, 1]

The truth is that the exact wave function, χ_{exact} , for a many-electron interacting system is not a single Slater determinant but a combination of Slater determinants as there are many combinations of Slater determinants which can be formed. The use of one single Slater determinant is a good approximation to the ground state of a many-electron system for which the N electrons occupy the lowest N spin orbitals but neglects correlation effects.

2.2 Electron Correlation

Electron correlation is the correction to the Hartree-Fock wave function that is needed to obtain the exact wave function,

$$\Psi_{\text{exact}} = \Phi_{\text{HF}} + \chi_{\text{Corr}} \quad (2.12)$$

In general, interest lies with trying to obtain the correlation energy, which is the energy required to correct the Hartree-Fock energy, E_{HF} to the exact energy E_{exact} ,

$$\Delta E_{\text{corr}} = E_{\text{exact}} - E_{\text{HF}} \quad (2.13)$$

Since the instantaneous correlation of the electrons due to their repulsion is missing within the Hartree-Fock model, where the motion of the electron is described by an average field with respect to the other electrons. This limitation of the Hartree-Fock model is easily seen in bond dissociation energies, for which it fails. [2, 1, 3]

Chapter 3

Second quantization

A formulation that will be used throughout the presented work is second quantization. This formulation allows for a compact and convenient notation of representing wave-functions (*i.e.* Slater determinants) and operators, while providing a simplified way of manipulating the functions and operators.

3.1 Creation and Annihilation operators

Let's begin with the a normalized Slater determinant,

$$\Phi = \Phi_{ijk\dots N} \equiv A|\chi_i\chi_j\chi_k\dots\chi_N| \equiv |\chi_i\chi_j\chi_k\dots\chi_N\rangle \equiv |ijk\dots N\rangle \quad (3.1)$$

with the antisymmetrizer A , and a spin orbital χ , for each particle. The above notations ([Equation 3.1](#)) are all equivalent but the last notation will be of primary use throughout this work when utilizing second quantization formulation. This notation is just the simplest notation by dropping χ symbol for every spin orbital. It is important to note that occupancy within second quantization is denoted by the presence of a basis spin orbital in the determinant, for example the spin orbitals $ijk\dots N$ are occupied in [Equation 3.1](#) and all other spin orbitals are unoccupied.

The creation or annihilation of a particle represent the addition or removal of a spin orbital through the creation and annihilation operators. The creation operator is designated by the dagger

symbol, (\dagger) and creates a particle in a specific spin orbital at the beginning of the Slater determinant. The removal of a particle from the determinant is done through the annihilation operator on a specific spin orbital. The notations for creation and annihilation:

$$\text{creation operator for spin orbital } \chi_i, \quad i^\dagger \quad (3.2)$$

$$\text{annihilation operator for spin orbital } \chi_i, \quad i \quad (3.3)$$

These operators can be used on the Slater determinant, $|jk\dots N\rangle$, as follows:

$$i^\dagger |jk\dots N\rangle = |ijk\dots N\rangle \quad (3.4)$$

$$i |ijk\dots N\rangle = |jk\dots N\rangle \quad (3.5)$$

thereby creating a particle in i (Equation 3.4), then removing that particle from i (Equation 3.5). It is relevant to point out that creating a particle in an already occupied spin orbital or annihilating a particle that does not exist within the Slater determinant will result in a invalid determinant.

$$i^\dagger |ijk\dots N\rangle = 0 \quad (3.6)$$

$$i |jk\dots N\rangle = 0 \quad (3.7)$$

In general a lexical order of the spin orbitals is convenient,

$$|ijk\dots N\rangle, \quad \text{where } i < j < k < \dots < N \quad (3.8)$$

but we must discuss the creation and annihilation of a particle that is out of lexical order, for example creation/annihilation of p . The consequences of this is demonstrated below,

$$p^\dagger |ijk\dots N\rangle = |pijk\dots N\rangle = (-1)^{\sigma(p)} |ijk\dots p\dots N\rangle \quad (3.9)$$

$$p |ijk\dots p\dots N\rangle = (-1)^{\sigma(p)} |pijk\dots N\rangle = (-1)^{\sigma(p)} |ijk\dots N\rangle \quad (3.10)$$

where $(-1)^{\sigma(p)}$ is needed to maintain the antisymmetry principle in Slater determinants for which an interchange of the spin orbital p with the other spin orbitals $ijk\dots$ results in a negative sign occurring $\sigma(p)$ times. With all this points we can now define a *vacuum* Slater determinant, denoted as $|\rangle$, which is a determinant with no spin orbitals. This can be constructed through successive operations on a Slater determinant,

$$ijk\dots N|ijk\dots N\rangle = |\rangle \quad (3.11)$$

We can also create a Slater determinant from the *vacuum* Slater determinant through successive creation operations. [2, 1]

$$i^\dagger j^\dagger k^\dagger \dots N^\dagger |\rangle = |ijk\dots N\rangle \quad (3.12)$$

3.2 Anticommutation relations

With the definition of creation and annihilation operators let us now look at anticommutation relations of these operators. Let us first consider the creation operators p^\dagger and q^\dagger . The order of which these two operators can performed are as follows:

$$p^\dagger q^\dagger |ijk\dots\rangle = |pqijk\dots\rangle \quad (3.13)$$

$$q^\dagger p^\dagger |ijk\dots\rangle = |qpijk\dots\rangle = -|pqijk\dots\rangle \quad (3.14)$$

This is valid for any Slater determinant for which χ_p or χ_q does not exist in $|ijk\dots\rangle$, as the product would be zero. We then get the anticommutation relation for the two creation operators as,

$$p^\dagger q^\dagger = -q^\dagger p^\dagger \quad (3.15)$$

$$[p^\dagger, q^\dagger]_+ \equiv p^\dagger q^\dagger + q^\dagger p^\dagger = 0 \quad (3.16)$$

which can be generically written as:

$$[\hat{A}, \hat{B}]_+ \equiv \hat{A}\hat{B} + \hat{B}\hat{A} \quad (3.17)$$

is the anticommutator of \hat{A} and \hat{B} and commonly written as $\{\hat{A}, \hat{B}\}$. It is important to point out the case of $p = q$ this relation still holds true because $p^\dagger p^\dagger = 0$ (Equation 3.6). The creation anticommutation relation is unique as $[\hat{A}, \hat{B}]_+ = [\hat{B}, \hat{A}]_+$ which for a normal commutator $[\hat{A}, \hat{B}]_+ = -[\hat{B}, \hat{A}]_+$.

Now we can move onto the anticommutation relations for the annihilation operator. Let us now consider the annihilation operators p and q :

$$pq|qpikj\dots\rangle = p|pikj\dots\rangle = |ikj\dots\rangle \quad (3.18)$$

$$qp|qpikj\dots\rangle = -qp|qpikj\dots\rangle = -p|pikj\dots\rangle = -|ikj\dots\rangle \quad (3.19)$$

Note that if χ_p or χ_q are in the interior of the Slater determinant then a sign change will occur as described in Equation 3.10, for both cases of above equations (Equation 3.18, Equation 3.19). If χ_p and/or χ_q are not present within the Slater determinant the resulting determinant is zero. (Equation 3.7) Therefore we arrive at the anticommutator relation for the annihilation operator,

$$pq = -qp \quad (3.20)$$

$$[p, q]_+ = 0 \quad (3.21)$$

The last case to consider is a creation and annihilation operator pair, $p^\dagger q$ when $p \neq q$:

$$p^\dagger q|qijkl\dots\rangle = p^\dagger|ijkl\dots\rangle = |pijkl\dots\rangle \quad (3.22)$$

$$qp^\dagger|qijkl\dots\rangle = q|pqijkl\dots\rangle = -q|qpijkl\dots\rangle = -|pijkl\dots\rangle \quad (3.23)$$

This operation removes the particle from spin orbital q to put it into spin orbital p but there is

difference of a negative sign between the two expressions. Therefore we have the relation:

$$[p^\dagger, q]_+ = 0 \quad (p \neq q) \quad (3.24)$$

Let us now look at the case when $p = q$ in which p does or doesn't exist within the initial Slater determinant,

$$p^\dagger p |pijkl\dots\rangle = p^\dagger |ijkl\dots\rangle = |pijkl\dots\rangle \quad (3.25)$$

$$pp^\dagger |pijkl\dots\rangle = 0 \quad (3.26)$$

$$p^\dagger p |ijkl\dots\rangle = 0 \quad (3.27)$$

$$pp^\dagger |ijkl\dots\rangle = p^\dagger |pijkl\dots\rangle = |ijkl\dots\rangle \quad (3.28)$$

Which generalized shows that,

$$\left(p^\dagger p + pp^\dagger \right) |\dots\rangle = |\dots\rangle \quad (3.29)$$

For which we obtain the relation:

$$[p^\dagger, p]_+ = [p, p^\dagger]_+ = 1 \quad (3.30)$$

In the case of a creation and annihilation operator pair we then have the final anticommutation relation,

$$[p^\dagger, q]_+ = [p, q^\dagger]_+ = \delta_{pq} \quad (3.31)$$

that contains the Kronecker-delta operator, δ_{pq} . The Kronecker-delta operator is a commonly used operator that differentiates the expression for the instances when $p \neq q$ or $p = q$ resulting in zero or 1, respectively.[2, 1, 4]

In summary there are three anticommutation relations for creation and annihilation operators,

$$[p^\dagger, q^\dagger]_+ = 0 \quad (3.32)$$

$$[p, q]_+ = 0 \quad (3.33)$$

$$[p^\dagger, q]_+ = [p, q^\dagger]_+ = \delta_{pq} \quad (3.34)$$

3.3 Second quantized operators

The benefit with second quantization as presented so far allows is that we have presented a notation for a many-electron wave function without the need of Slater determinants. We can now represent a many-electron wave function simply through creation and annihilation operators, anticommutation relations, and the vacuum state. Our focus now shifts to the second quantization representation of many-particle operators, \mathcal{O}_1 and \mathcal{O}_2 for one-particle and two-particle operators, respectively. This will allow for representation of theory of many-electron systems without the use of Slater determinants by obtaining the second quantization equivalent of the matrix elements of $\langle K | \mathcal{O} | L \rangle$.

The second quantization expression for \mathcal{O}_1 , which will be the sum of one-electron operators ([Equation 2.5](#)) and for \mathcal{O}_2 the total coulomb repulsion between electrons are:

$$\mathcal{O}_1 = \sum_i^N \hat{h}(i) \implies \sum_{ij} \langle i | \hat{h} | j \rangle i^\dagger j \quad (3.35)$$

$$\mathcal{O}_2 = \frac{1}{2} \sum_{i \neq j}^{N^2} \hat{K}(i, j) \implies \frac{1}{2} \sum_{ijkl} \langle ij | kl \rangle i^\dagger j^\dagger lk \quad (3.36)$$

The left expression in [Equation 3.35](#) and [Equation 3.36](#) are the wave function representation of the operators, where the right hand side are the second quantization representation. The eloquence and benefit of second quantization is easily expressed from these expressions in terms of the summation of over the spin orbitals. For the wave function representation operators depend on the summation of each particle, where for second quantization the number of particles is independent of number of particles. This is one of the main benefits of second quantization as the expressions are not

limited by number of particles, on the other hand with wave function representation expressions depend on the number of particles. Therefore when dealing with large many-electron systems, the expressions in second quantization are simple while becoming burdensome in wave function representation.[1]

3.4 Particle-hole formulation

We are now able to fully describe theory of many-electron wave functions and operators in terms of second quantization. The reference state that we have constructed up to this point is a vacuum Slater determinant, Equation 3.11 and Equation 3.12. It will be more convenient if we had a fixed reference state that contained occupied spin orbitals, where all other Slater determinants can be constructed from this reference. The reference state that we will use is the Fermi vacuum defined as,

$$|0\rangle \equiv |\Phi_0\rangle = |ijk\dots N\rangle \quad (3.37)$$

The Fermi vacuum is typically the ground state determinant obtained from Hartree-Fock. Within the particle-hole formulation the spin orbitals i, j, k, \dots, N , in Equation 3.37 are the hole states(occupied orbitals). Particle states (unoccupied orbitals) are defined as a, b, c, \dots , the indices p, q, r, s, \dots are used to describe states that can be either hole or particle states.

The construction of the Fermi vacuum can easily be demonstrated through Figure 3.1. Starting with the many-particle picture there is a ground state which contains particles filling spin orbitals χ_i , according to the Pauli exclusion principle. The highest filled orbital is then designated the Fermi level, as ϵ_F . There is an example of an excited state for the many-particle picture, where the particle below the Fermi level, χ_3 has been excited above the Fermi level, χ_9 . Applying the Fermi vacuum as the reference, the ground state in the particle-hole picture appears empty. But in the particle-hole formulation we are only interested in changes from the ground state reference. Therefore the depiction of the excited state in the particle-hole picture contains a particle in χ_9 and

a hole (the empty circle) in χ_3 as these are the only changes from the Fermi vacuum.

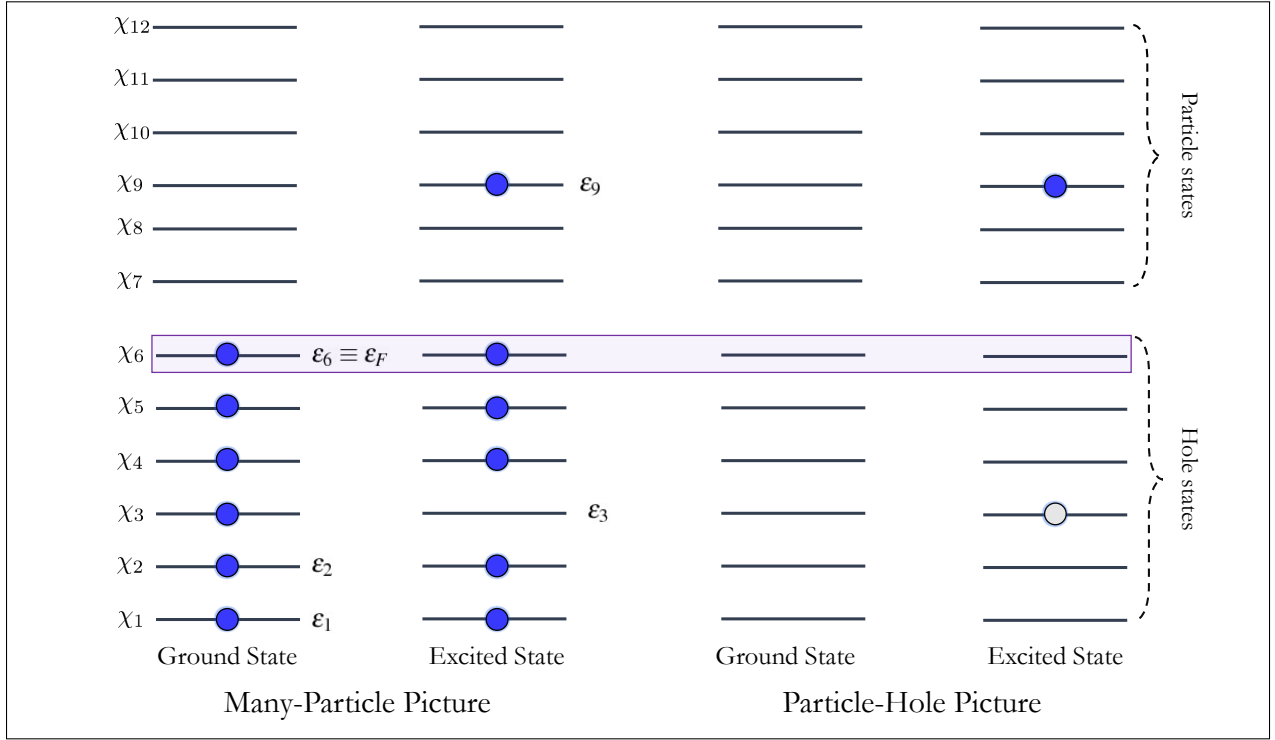

Figure 3.1: Diagram of the particle-hole representation. The left side is the many-particle picture for the ground state and excited state. While the right shows the particle-hole picture for the same ground and excited state of the many-particle picture.

This now allows us to describe excited state determinants with respect to the Fermi vacuum,

$$\text{(single excitation)} \quad |\Phi_i^a\rangle \equiv a^\dagger i|0\rangle = |ajk\dots N\rangle \quad (3.38)$$

$$\text{(double excitation)} \quad |\Phi_{ij}^{ab}\rangle \equiv a^\dagger b^\dagger ji|0\rangle = |abk\dots N\rangle \quad (3.39)$$

$$\text{(electron removal)} \quad |\Phi_i\rangle \equiv i|0\rangle = |jk\dots N\rangle \quad (3.40)$$

$$\text{(electron attachment)} \quad |\Phi^a\rangle \equiv a^\dagger|0\rangle = |aijk\dots N\rangle \quad (3.41)$$

with particle-hole representation operators that are hole or particle creators and annihilators.

$$i^\dagger - \text{hole annihilator} \quad (3.42)$$

$$i - \text{hole creator} \quad (3.43)$$

$$a^\dagger - \text{particle creator} \quad (3.44)$$

$$a - \text{particle annihilator} \quad (3.45)$$

It is important to note that a hole can not be annihilated if the hole doesn't exist within the reference state, that is,

$$i^\dagger |ijk\dots N\rangle = 0 \quad (3.46)$$

also a particle can not be destroyed if it doesn't exist,

$$a |ijk\dots N\rangle = 0 \quad (3.47)$$

Therefore, when describing a single excitation in particle-hole formalism like in [Equation 3.38](#), first a hole is created in i by removing the particle from spin orbital i , then that particle is created in spin orbital a . This has allowed for creation of single excited state determinant that only contains a hole annihilator, particle creator and the Fermi vacuum reference state. Likewise in describing a double excitation ([Equation 3.39](#)) the hole states are creating first by removing i then j , and creating the particles in b then a .

The order which these operators occur is through normal ordering of the pseudo-creation operators to the left of all pseudo-annihilation operators. The pseudo-creation operators are the operators in the particle-hole formalism that create, i and a^\dagger . These are referenced as pseudo-creation operators because they both create but both do not contain the \dagger symbol, which referees to creation in [section 3.1](#). The opposite is true for the pseudo-annihilation operators, i^\dagger and a as these operators annihilate. The process of moving all the pseudo-creation operators to left of the pseudo-annihilation operators is done through the anticommutation relations described in [Equation 3.32-Equation 3.34](#),

$$[p^\dagger, q^\dagger]_+ = 0 \quad (3.48)$$

$$[p, q]_+ = 0 \quad (3.49)$$

$$[p^\dagger, q]_+ = [p, q^\dagger]_+ = \delta_{pq} \quad (3.50)$$

which were also written as,

$$p^\dagger q^\dagger = -q^\dagger p^\dagger \quad (3.51)$$

$$pq = -qp \quad (3.52)$$

$$p^\dagger q = \delta_{pq} - qp^\dagger \quad (3.53)$$

as these will relations keep track of the sign changes that occur during the reordering of the operators. Let us start with this simple example,

$$p^\dagger q \implies p^\dagger q \quad (3.54)$$

in this case the operators are already in normal order, therefore no sign change is required. Now consider the follow case,

$$qp^\dagger \implies -p^\dagger q \quad (3.55)$$

following the anticommutation relation in [Equation 3.53](#) a negative sign is obtained during the normal ordering. Normal ordering particle-hole operators is crucial when evaluating matrix elements in second quantization.[\[1\]](#)

Chapter 4

Electronic Excited State Methods

A key component of the present work is to develop excited state methods to obtain electron-correlation energy to correct for the Hartree-Fock approximation to the exact Schrödinger wave-function. Within this chapter I will be presenting the underlying theory of many common excited state methods to serve as a introduction to the challenges addressed within the presented work after I have derived the linear response matrices. The derivation of each of these formulations nor their ranking in terms of accuracy are within the nature of this work, but their overall computational performance for excited state calculations is our primary interest and will be summarized towards the end.

4.1 Configuration Interaction Singles

Configuration interaction singles (CIS) is the most simplistic wave-function based *ab initio* method for electronic excited states, both conceptually and computationally. We will first start with our best single Slater determinant,

$$|\Phi_0\rangle = |\chi_1\chi_2\cdots\chi_N\rangle \tag{4.1}$$

where χ_i corresponds to a spin orbital with N number of electrons. $|\Phi_0\rangle$ is obtained by solving the time-independent HF equation, [Equation 2.5](#),

$$\hat{F}|\Phi_0\rangle = E_0|\Phi_0\rangle \quad (4.2)$$

where,

$$\hat{F} = \sum_i^{N_{elec.}} \hat{f}_i \quad (4.3)$$

In configuration interaction singles, the electronic wave-function is a combination of the singly excited determinants generated through all possible single particle creator and single hole creator operators.

$$|\Psi_{CIS}\rangle = \sum_{ia} c_i^a a^\dagger i |\Phi_0\rangle \quad (4.4)$$

$$|\Psi_{CIS}\rangle = \sum_{ia} c_i^a |\Phi_i^a\rangle \quad (4.5)$$

The summation in [Equation 4.4](#) is over all ia pairs which have a size of number of occupied ($N_{occ.}$) times number of virtual orbitals ($N_{vir.}$), commonly referred to as the configuration space. This many-body wave function is then substituted into the exact time-independent electronic Schrödinger equation,

$$\hat{H}|\Psi\rangle = [\hat{T} + \hat{V}_{elec-nucl} + \hat{V}_{elec-elec}] |\Psi\rangle = E|\Psi\rangle \quad (4.6)$$

where the electronic Hamiltonian contains the kinetic energy operator, (\hat{T})

$$\hat{T} = - \sum_i^{N_{elec.}} \frac{1}{2} \nabla_i^2 \quad (4.7)$$

the electron-nuclei attraction, ($\hat{V}_{\text{elec-nucl}}$)

$$\hat{V}_{\text{elec-nucl}} = - \sum_i^{N_{\text{elec}}} \sum_K^{N_{\text{nuc}}} \frac{Z_K}{|\mathbf{r}_i - \mathbf{R}_K|} \quad (4.8)$$

where i is iterating through all electrons and K runs over all nuclei, that have a nuclear charge, Z_K .

Finally the electron-electron interaction term, ($\hat{V}_{\text{elec-elec}}$)

$$\hat{V}_{\text{elec-elec}} = \sum_i^{N_{\text{elec}}} \sum_{j>i}^{N_{\text{elec}}} \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|} \quad (4.9)$$

Then by projecting onto [Equation 4.6](#) or multiplication of $\langle \Phi_j^b |$ on the right hand side,

$$\sum_{i,a}^{N_{\text{occ.}}, N_{\text{vir}}} \langle \Phi_j^b | \hat{H} | \Phi_i^a \rangle c_i^a = E_{\text{CIS}} \sum_{i,a}^{N_{\text{occ.}}, N_{\text{vir}}} c_i^a \delta_{ij} \delta_{ab} \quad (4.10)$$

where a single term within the left summation is

$$\langle \Phi_j^b | \hat{H} | \Phi_i^a \rangle = (E_0 + \varepsilon_a - \varepsilon_i) \delta_{ij} \delta_{ab} + \langle ij | f_H(\mathbf{r}_1, \mathbf{r}_2) | ab \rangle_A \quad (4.11)$$

where $f_H(\mathbf{r}_1, \mathbf{r}_2) = 1/|\mathbf{r}_1 - \mathbf{r}_2|$ is the Hartree kernel. The full expression is then defined as,

$$\sum_{i,a}^{N_{\text{occ.}}, N_{\text{vir}}} \{ (E_0 + \varepsilon_a - \varepsilon_i) \delta_{ij} \delta_{ab} + \langle ij | f_H(\mathbf{r}_1, \mathbf{r}_2) | ab \rangle_A \} c_i^a = E_{\text{CIS}} \sum_{ia}^{N_{\text{occ.}}, N_{\text{vir}}} c_i^a \delta_{ij} \delta_{ab} \quad (4.12)$$

which can be simplified with the equation for the excitation energy $\omega_{\text{CIS}} = E_{\text{CIS}} - E_0$,

$$\sum_{i,a}^{N_{\text{occ.}}, N_{\text{vir}}} \{ (\varepsilon_a - \varepsilon_i) \delta_{ij} \delta_{ab} + \langle ij | f_H(\mathbf{r}_1, \mathbf{r}_2) | ab \rangle_A \} c_i^a = \omega_{\text{CIS}} \sum_{ia}^{N_{\text{occ.}}, N_{\text{vir}}} c_i^a \delta_{ij} \delta_{ab} \quad (4.13)$$

in the above expression ε is the orbital energy of the χ_a or χ_i orbitals, and $\langle ij | f_H(\mathbf{r}_1, \mathbf{r}_2) | ab \rangle_A$ is the antisymmetrized two-electron integrals defined as,

$$\langle ij | f_H(\mathbf{r}_1, \mathbf{r}_2) | ab \rangle_A = \langle ij | f_H(\mathbf{r}_1, \mathbf{r}_2) | ab \rangle - \langle ij | f_H(\mathbf{r}_1, \mathbf{r}_2) | ba \rangle \quad (4.14)$$

$$\langle ij|f_H(\mathbf{r}_1, \mathbf{r}_2)|ab\rangle = \int \int d\mathbf{r}_1 d\mathbf{r}_2 \chi_i^*(\mathbf{r}_1) \chi_j^*(\mathbf{r}_2) f_H(\mathbf{r}_1, \mathbf{r}_2) \chi_a(\mathbf{r}_1) \chi_b(\mathbf{r}_2) \quad (4.15)$$

$$\langle ij|f_H(\mathbf{r}_1, \mathbf{r}_2)|ba\rangle = \int \int d\mathbf{r}_1 d\mathbf{r}_2 \chi_i^*(\mathbf{r}_1) \chi_j^*(\mathbf{r}_2) f_H(\mathbf{r}_1, \mathbf{r}_2) \chi_b(\mathbf{r}_1) \chi_a(\mathbf{r}_2) \quad (4.16)$$

The expression [Equation 4.13](#) can be more conveniently written in matrix notation,

$$\mathbf{A}\mathbf{X} = \omega\mathbf{X} \quad (4.17)$$

as an eigenvalue equation that uses \mathbf{A} for the matrix representation of [Equation 4.11](#). ω is the diagonal matrix of the excitation energies, and \mathbf{X} is the matrix of the CIS expansion coefficients.

The matrix elements of \mathbf{A} are,

$$A_{ia,jb} = (\varepsilon_a - \varepsilon_i) \delta_{ij} \delta_{ab} + \langle ij|f_H(\mathbf{r}_1, \mathbf{r}_2)|ab\rangle_A \quad (4.18)$$

The excitation energies can be obtained by,

$$(\mathbf{A} - \omega)\mathbf{X} = 0 \quad (4.19)$$

or diagonalization of \mathbf{A} .[\[3\]](#)

4.2 Linear Response Matrices

4.2.1 Casida Equations

Within [section 4.1](#) the derivation of \mathbf{A} matrix was the primary focus. This matrix is of key importance for linear response theory for excited state calculations. The \mathbf{A} matrix is only one component of what is commonly referred to as the Casida equations or linear response matrices,[\[5, 3\]](#)

$$\begin{bmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{B}^* & \mathbf{A}^* \end{bmatrix} \begin{bmatrix} \mathbf{X} \\ \mathbf{Y} \end{bmatrix} = \omega \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \begin{bmatrix} \mathbf{X} \\ \mathbf{Y} \end{bmatrix} \quad (4.20)$$

From the perspective of Time-dependent Hartree-Fock (TD-HF) the matrix elements are defined as follows,

$$A_{ia,jb} = (\epsilon_a - \epsilon_i) \delta_{ij} \delta_{ab} + \langle ij | f_H(\mathbf{r}_1, \mathbf{r}_2) | ab \rangle_A \quad (4.21)$$

$$B_{ia,jb} = \langle ib | f_H(\mathbf{r}_1, \mathbf{r}_2) | aj \rangle_A \quad (4.22)$$

or more generically written and known as,

$$A_{ia,jb} = (\epsilon_a - \epsilon_i) \delta_{ij} \delta_{ab} + K_{ia,jb} \quad (4.23)$$

$$B_{ia,jb} = K_{ia,bj} \quad (4.24)$$

with the electron-hole interaction kernel (K_{eh}) or coupling matrix,

$$K_{pq,rs} = \langle pr | \hat{K}_{eh} | qs \rangle - \langle pr | \hat{K}_{eh} | sq \rangle \quad (4.25)$$

Where we have seen the terms for the \mathbf{A} matrix which describes the resonant coupling between the excitations, but now have a non-resonant coupling matrix in the form of \mathbf{B} between the excitations and de-excitations. It is very common to set $\mathbf{B} = 0$ in Equation 4.20, this is commonly referred to as the Tamm-Dancoff approximation (TDA)[4, 6]. When the TDA is applied to Equation 4.20 it reduces to the CIS formulation Equation 4.17. The last term in both the matrices is response of the nonlocal HF exchange potential, which yields a Coulomb-like term.

4.2.2 Limitations

It is important to note some key computational cost features of these response matrices as these are a primary focus of the present research. The first being the size of these matrices, they are $(N_{occ.})^2 \times (N_{vir.})^2$ in size, where $N_{occ.}$ and $N_{vir.}$ is the number of occupied molecular orbitals and number of virtual orbitals, respectively. The size of these matrices are inherently linked to the square of the occupation space of the system, because ia iterates through all single particle ex-

citation's in the system. The next computational cost arises in the construction of the coupling matrix, where the atomic-orbital to molecular-orbital (AO-to-MO) integral transformation is required. Where the integral transformation is,

$$[\chi_p(\mathbf{r}_1)\chi_q(\mathbf{r}_1)|\hat{K}_{\text{eh}}|\chi_r(\mathbf{r}_2)\chi_s(\mathbf{r}_2)] = \sum_{\mu=1}^{N_{AO}} \sum_{\nu=1}^{N_{AO}} \sum_{\lambda=1}^{N_{AO}} \sum_{\sigma=1}^{N_{AO}} C_{\mu p} C_{\nu q} C_{\lambda r} C_{\sigma s} [\phi_{\mu}(\mathbf{r}_1)\phi_{\nu}(\mathbf{r}_1)|\hat{K}_{\text{eh}}|\phi_{\lambda}(\mathbf{r}_2)\phi_{\sigma}(\mathbf{r}_2)] \quad (4.26)$$

For which the linear combination of atomic orbitals (LCAO) is a summation over the number of atomic orbitals (N_{AO}). This transformation has the scaling of $O(N_b^5)$, where N_b is the number of basis functions for the system. [2] To put these limitations into perspective, Table 4.1 shows some numerical data to better describe the computational effort for the response matrices. The

Table 4.1: Size of excited state calculation based on basis function and active electrons

Molecule	Number of Active Electrons	Basis Functions	Singly Exited Configurations	Two-Electron Transformation
H ₂ O	10	19 (6-31G*)	140	2,476,099
CdSe	18	26 (LANL2DZ)	153	11,881,376
Cd ₁₂ Se ₁₂	216	312 (LANL2DZ)	22,032	2,956,466,552,832
Cd ₂₅₀ Se ₂₅₀	4,500	6,750 (LANL2DZ)	10,125,000	14,012,604,492,187,500,000

data provided in Table 4.1 shows the unfavorable scaling of the singly excited configurations and two-electron integral transformation for a system of experimental interest, Cd₂₅₀Se₂₅₀ which is approximately a 2 nm quantum dot. A key limitation to also take note of is the computational effort in regards to storage of this information which can greatly exceed general use devices rapidly.

In the following sections I will go over how various other excited state methods reduce the computational effort examined here in the Hartree-Fock linear response matrices. Each method can arrive at the Casida equations but I will only be presenting the form of the **A** and **B** matrices.

4.3 Time-Dependent Density Funtional Theory

Time-dependent density functional theory (TD-DFT) is a very common excited state method due to the widespread use of DFT for ground state calculations. Since the ground state reference is

constructed through DFT, there requires a treatment of the exchange-correlation (xc) functional which has replaced the HF exchange potential. In LR-TD-DFT the \mathbf{A} and \mathbf{B} matrices are defined as,

$$A_{ia,jb} = (\varepsilon_a - \varepsilon_i) \delta_{ij} \delta_{ab} + \langle ij | f_H(\mathbf{r}_1, \mathbf{r}_2) | ab \rangle + \langle ij | f_{xc} | ab \rangle \quad (4.27)$$

$$B_{ia,jb} = \langle ib | f_H(\mathbf{r}_1, \mathbf{r}_2) | aj \rangle + \langle ib | f_{xc} | aj \rangle \quad (4.28)$$

where the last term is the response of the chosen xc potential. The response to the xc potential is the second functional derivative of the exchange-correlation energy, known as the xc kernel,

$$\langle ij | f_{xc} | ab \rangle = \int d^3\mathbf{r}_1 d^3\mathbf{r}_2 \chi_i^*(\mathbf{r}_1) \chi_j^*(\mathbf{r}_2) \frac{\partial^2 E_{ex}}{\partial \rho(\mathbf{r}_1) \partial \rho(\mathbf{r}_2)} \chi_a(\mathbf{r}_1) \chi_b(\mathbf{r}_2) \quad (4.29)$$

The limitations of LR-TD-DFT are still consistent with those described in [subsection 4.2.2](#) regarding the size of the \mathbf{A} and \mathbf{B} matrices, along with the AO-to-MO transformation. But in addition there is now the computational effort in calculation and storage of the xc kernel. Also, since the exact xc potential is not know, but approximated in use the choice of density functional is an inherited limitation of using DFT based excited state methods.[3]

4.4 GW Bethe-Salpeter equation

The GW formulation is a correction to the ground state Kohn-Sham(KS) DFT orbitals utilizing the energy-dependent $\Sigma(E)$ self-energy as follows,[7, 8, 9]

$$\varepsilon_n^{GW} = \varepsilon_n^{KS} + \langle \phi_n^{KS} | \Sigma(\varepsilon_n^{GW}) - V^{xc} | \phi_n^{KS} \rangle \quad (4.30)$$

where V^{xc} is the DFT exchange-correlation potential. Where the self energy is defined as follows,

$$\Sigma(\mathbf{r}, \mathbf{r}'; E) = \frac{i}{2\pi} \int d\omega e^{i\omega 0^+} G(\mathbf{r}, \mathbf{r}'; E + \omega) W(\mathbf{r}, \mathbf{r}'; \omega) \quad (4.31)$$

$$G(\mathbf{r}, \mathbf{r}'; E) = \sum_n \frac{\phi_n(\mathbf{r}) \phi_n^*(\mathbf{r}')}{E - \varepsilon_n + 0^+ \times \text{sgn}(\varepsilon_n - E_f)} \quad (4.32)$$

$$W(\mathbf{r}, \mathbf{r}'; \omega) = v(\mathbf{r}, \mathbf{r}') + \int d\mathbf{r}_1 d\mathbf{r}_2 v(\mathbf{r}, \mathbf{r}_1) P_0(\mathbf{r}_1, \mathbf{r}_2; \omega) W(\mathbf{r}_2, \mathbf{r}'; \omega) \quad (4.33)$$

$$P_0(\mathbf{r}, \mathbf{r}'; \omega) = \sum_{i,j} (f_i - f_j) \frac{\phi_i^*(\mathbf{r}) \phi_j(\mathbf{r}) \phi_j^*(\mathbf{r}') \phi_i(\mathbf{r}')}{\varepsilon_i - \varepsilon_j - \omega - i0^+} \quad (4.34)$$

containing a screened Coulomb potential W , where $v(\mathbf{r}, \mathbf{r}')$ is the bare Coulomb potential, G is the time-ordered one-body Green's function, P_0 the independent-electron susceptibility, 0^+ is an infinitesimally small positive number, and $\{f\}$ are occupation numbers.[10] The above equations obtain corrected ground state orbitals, through construction of the self-energy. But the best Σ will be the one in which the left and right ε_n^{GW} in Equation 4.30 are equal, therefore self-consistent. The computational effort needed to construct the ground state reference in GW is important in terms of understanding overall computational cost in calculation of excited state excitations as the self energy is a 6-dimensional integral. With the construction of the ground state reference it is at this point that the Bethe-Salpeter equations (BSE) are used to obtain the linear response matrices,

$$A_{ia,jb} = \left(\varepsilon_a^{GW} - \varepsilon_i^{GW} \right) \delta_{ij} \delta_{ab} + \langle ij | f_H(\mathbf{r}_1, \mathbf{r}_2) | ab \rangle + \langle ij | W | ab \rangle \quad (4.35)$$

$$B_{ia,jb} = \langle ib | f_H(\mathbf{r}_1, \mathbf{r}_2) | aj \rangle + \langle ib | W | aj \rangle \quad (4.36)$$

which look familiar to the LR-TD-DFT formulation except for the last term, which instead of the response the xc functional, there is now a response to the screened Coulomb potential, W . With GW-BSE the ground state reference is corrected but the excited state calculations have not gained much in terms of computational cost reduction. The size of \mathbf{A} and \mathbf{B} are still linked to number of singly excited states and the cost of the AO-to-MO integral transformation has not been addressed.

4.5 Coupled-Cluster methods

Couple cluster methods deal with the coupled-cluster (CC) wave-function,[1, 11]

$$\Psi = e^{\hat{T}} |0\rangle \quad (4.37)$$

where $|0\rangle$ is the reference wave-function and

$$\hat{T} = \hat{T}_1 + \hat{T}_2 + \hat{T}_3 + \dots \quad (4.38)$$

Which are m -body cluster operators given as,

$$\hat{T}_m = \frac{1}{(m!)^2} \sum_{\substack{ij\dots \\ ab\dots}} t_{ij\dots}^{ab\dots} \left\{ a^\dagger i b^\dagger j \dots \right\} \quad (4.39)$$

where m is the pairs of creation and annihilation operators, producing m -fold excitations. The benefit of this exponential *ansatz* is that if expanded in a Taylor series,

$$e^{\hat{T}} = 1 + \frac{1}{2}\hat{T}^2 + \frac{1}{3!}\hat{T}^3 + \dots \quad (4.40)$$

and then by expanding \hat{T} ,

$$\Psi = |0\rangle + \hat{T}_1|0\rangle + \hat{T}_2|0\rangle + \dots \quad (4.41)$$

$$+ \frac{1}{2!}\hat{T}_1^2|0\rangle + \hat{T}_1\hat{T}_2|0\rangle + \frac{1}{2!}\hat{T}_2^2|0\rangle + \dots \quad (4.42)$$

$$+ \frac{1}{3!}\hat{T}_1^3|0\rangle + \frac{1}{2!}\hat{T}_1^2\hat{T}_2|0\rangle + \frac{1}{2!}\hat{T}_1\hat{T}_2^2|0\rangle + \frac{1}{3!}\hat{T}_2^3|0\rangle + \dots \quad (4.43)$$

$$+ \dots \quad (4.44)$$

for which one can obtain a wave-function that has m -tuple excitations from a single ground state reference Slater determinant. This is the general description of a CC wave-function, in practice the excitation operator is limited to singles and/or doubles as the expansion in \hat{T} can be costly, but provides a quality description of the ground state reference. With the ground state reference in CC described I present the response matrices,

$$A_{ai,bj} = \left(\epsilon_a^{CC} - \epsilon_i^{CC} \right) \delta_{ij} \delta_{ab} + \langle ij | f_H(\mathbf{r}_1, \mathbf{r}_2) | ab \rangle_A \quad (4.45)$$

$$B_{ai,bj} = \langle ib | f_H(\mathbf{r}_1, \mathbf{r}_2) | aj \rangle_A \quad (4.46)$$

for which look similar to that obtained in TDHF but the wave-functions are CC wave-functions, therefore contain more information on the m -tuple excitations in \hat{T} .

4.6 Multi-Reference

Multi-reference (MR) approaches deal with construction of a wave-function from a collection of Slater determinants mainly from the Full CI wave-function,

$$|\Psi\rangle = c_0|\Phi_0\rangle + \sum_{ia} c_i^a |\Phi_i^a\rangle + \left(\frac{1}{2!}\right)^2 \sum_{ijab} c_{ij}^{ab} |\Phi_{ij}^{ab}\rangle + \left(\frac{1}{3!}\right)^2 \sum_{ijkabc} c_{ijk}^{abc} |\Phi_{ijk}^{abc}\rangle + \dots \quad (4.47)$$

which fully permutes the lowest Slater determinant to n -tuply excited determinants. The number of n -tuply excited determinants is determined by the number of spin orbitals ($2K$), number of occupied orbitals, $N_{occ.}$ with $N_{vir.} = 2K - N_{occ.}$, number of virtual orbitals. Since we can also choose from $N_{vir.}$ the number of n -tuply excited determinants is,

$$\binom{N_{occ.}}{N_{vir.}} \binom{2K - N_{occ.}}{N_{vir.}} \quad (4.48)$$

which for many-electron systems with a large number of one-electron basis sets result in poor computational scaling, [2] recall the scaling of the just the singly excited determinants in [Table 4.1](#).

The MR approach that I wish to discuss briefly is the complete active space (CAS) approach, which constructs a CI like wave-function through restriction of the number of excitations in the expansion. Within CAS the molecular orbital space is separated into subspaces containing: inactive, active and secondary (virtual) orbitals. Where the inactive space are doubly occupied orbitals, typically core orbitals and the virtual orbitals are unoccupied in all possible configurations. Finally the active orbitals have variable occupancy of 0, 1 or 2. The CI space then contains all possible determinants that can be constructed from the active orbitals. Therefore when utilizing CAS there is an inherited choice in the active space for construction of the wave-function.

4.7 Summary

The limitations and computational cost of these methods reduce to several components: *a)* form of the reference wave function, *b)* size of configuration space, *c)* number of excitation permutations, *d)* limit of the virtual space, *e)* two-electron integral transformation, see [Table 4.2](#)

Table 4.2: Non-linear scaling of various excited state methods.

Method	Exponential Scaling of basis functions
CIS	$O(N^4)$ [3]
TD-DFT	$O(N^4)$ [3]
EOM-CCS(D)	$O(N^4)$ ($O(N^6)$) [12]
GW-BSE	$O(N^4)$ [7]
CASPT2	$O(N^4)$ [13]
LPNO	$O(N^5)$ [14]

The reference wave function can be as simple as the HF/DFT wave function or in the case of MR or CC methods a set of configurations. All configurations in a many-electron system consist of all possible permutations of electron-hole n -tuple excitations. But often these reference configurations are reduced to a set of single, double or triple electron-hole excitations near the Fermi level.[11, 15] Which in practice leads to complications with user-experience in choosing appropriate active spaces.[16, 17] This reference configuration is then subject to n -tuple excitations up to the limit of the virtual space, which is restricted by the size of the basis set. When for the exact solution the virtual space is infinite.[2] Each of the configurations are formed through an atomic orbital to molecular orbital transformation, (AO-to-MO), which is limited by the two-electron integral transformation. The two-electron transformation is in general the slowest computational step with a $O(N^5)$ scaling, with N related to the number of basis functions.[2, 3, 18, 5, 19] In some methods there is a basis transformation from molecular orbitals basis to a different basis that can reduce computational scaling, like pair natural orbitals (PNOs).[20] While some methods utilize the resolution-of-the-identity (RI) approximation to reduce the scale of the transformation.[21, 3, 5]

Chapter 5

Compact real-space representation of excited states using frequency-dependent explicitly-correlated electron-hole interaction kernel

5.1 Introduction

Accurate treatment of electron-hole interaction and inclusion of electron-correlation effect is central for describing electronic excitation states. Development of efficient theoretical methods for excited states continues to be an active field of research. The construction of the electron-hole interaction kernel $K_{\text{eh}}(\omega)$ is the main source of difference for various approaches including: configuration interaction (CI),[\[3, 22\]](#) coupled-cluster (CC),[\[12, 23\]](#) GW-Bethe-Salpeter equation (GW-BSE), [\[24, 25, 26, 27\]](#) time-dependent density functional theory (TDDFT), [\[28, 29, 30, 31\]](#) multireference (MRCI), [\[15\]](#) pair natural orbitals (PNO), [\[32, 33\]](#) and explicitly-correlated Hartree-Fock methods.[\[34, 35, 36, 37\]](#)

The steep computational cost originates from various components including: *a*) treatment of electron-electron correlation, *b*) number of particle-hole excitations, *c*) form of the $K_{\text{eh}}(\omega)$, and *d*) two-electron AO-to-MO integral transformation. The number of particle-hole states affects the size of the *A* and *B* response matrices, that arise in various theories including, TDDFT, GW-BSE, EOM-CCSD, and CIS methods.[\[5, 3\]](#) Various strategies exist to obtain a compact repre-

sentation of the basis. Information from the polarization propagator,[38] 1-particle reduced density matrix, [32, 33] and Cholesky decomposition (CD)[39] have been used for calculation of excited states. A different strategy using stochastic basis functions has been demonstrated in GW-BSE,[40, 41] many-body perturbation theory (MBPT),[42] and TDDFT formulations.[43, 44] Another alternative approach is to move away from occupation-number representation and use real-space representation.[45, 37] Methods such as reduced-density matrix,[46] electron-hole explicitly-correlated Hartree-Fock,[34, 35, 36] geminal screened electron-hole interaction kernel,[45, 37] electron-correlator method, [47] and geminal-augmented MCSCF[48] have successfully demonstrated the efficacy of real-space representation.

The goal of this work is to present an efficient and practical method to account for electron-hole correlation in large semiconductor NPs without using a large number of particle-hole states. Using Löwdin’s partitioning technique,[49] we have derived a real-space, frequency-dependent, explicitly-correlated, electron-hole interaction kernel (FD-GSIK method) that is capable of describing the dynamical screening of electrons and holes in a many-electron system. The method was implemented by performing real-space Monte Carlo (MC) integration for computation of all matrix elements. We demonstrate that the FD-GSIK method provides a compact representation of $K_{\text{eh}}(\omega)$ while avoiding the steep N^5 computational cost of performing AO-to-MO integral transformation, and circumventing storing and evaluating frequency-dependent AO integrals. The FD-GSIK addresses the need for a first-principle excited-state method that does not exhibit the steep scaling of the computational cost with increasing system size.

5.2 Theory

5.2.1 Construction of frequency-dependent electron-hole-interaction kernel

The effective many-body electron-hole Hamiltonian has the general form [50, 51, 52, 35, 53, 54]

$$H_{\text{eh}} = H_{\text{e}}^0 + H_{\text{h}}^0 + V_{\text{ee}} + V_{\text{hh}} + V_{\text{eh}} \quad (5.1)$$

where

$$H_e^0 = \sum_{e_1 e_2} \langle e_1 | f^e | e_2 \rangle e_1^\dagger e_2 \quad (5.2)$$

$$H_h^0 = \sum_{h_1 h_2} \langle h_1 | f^h | h_2 \rangle h_1^\dagger h_2 \quad (5.3)$$

$$V_{ee} = \sum_{e_1 e_2 e_3 e_4} \langle e_1 e_2 | w_{ee} | e_4 e_3 \rangle e_1^\dagger e_2^\dagger e_3 e_4 \quad (5.4)$$

$$V_{hh} = \sum_{h_1 h_2 h_3 h_4} \langle h_1 h_2 | w_{hh} | h_4 h_3 \rangle h_1^\dagger h_2^\dagger h_3 h_4 \quad (5.5)$$

$$V_{eh} = \sum_{h_1 h_2 e_1 e_2} \langle e_1 h_1 | v_{eh} | e_2 h_2 \rangle e_1^\dagger h_1^\dagger h_2 e_2 \quad (5.6)$$

where e^\dagger and h^\dagger are particle and hole creation operators, and f_e and f_h are the Fock operators. The electron-hole Hamiltonian can be factored into a sum of non-interaction terms and interaction terms. For a 1-particle 1-hole state, further simplification can be achieved and the total Hamiltonian can be expressed as

$$H_{eh} = H_{eh}^0 + V_{eh} \quad (5.7)$$

The non-interacting Hamiltonian H_{eh}^0 is obtained from the Fock operator whose eigenfunctions are (uncorrelated) particle-hole excited states

$$H_{eh}^0 = \omega_p^0 |P\rangle = (\varepsilon_a - \varepsilon_i) |\chi_i^h \chi_a^e\rangle \quad (5.8)$$

We are interested in calculating the many-body correction to ω_p^0 due to electron-hole correlation in the system. We start by defining the zeroth-order approximation of the electron-hole wavefunction as,

$$|\Psi_X\rangle^{(0)} = |P\rangle \quad (5.9)$$

and the correlated electron-hole wavefunction Ψ_X is defined as

$$|\Psi_X\rangle = C_P|P\rangle + C_\perp|P_\perp\rangle \quad (5.10)$$

where C_P and C_\perp are expansion coefficients and P_\perp is the correlated wavefunction that exists in the orthogonal subspace of P . This is a very general form of the wavefunction and both MBPT and CI wavefunctions can be expressed in this form, where choice and construction of P_\perp differentiates between treatment of electron-hole correlation within different methods. Here, we will define an electron-hole correlator operator Λ and express the P_\perp as,

$$|\Psi_X\rangle = C_P|P\rangle + C_Q\Lambda(\omega, r_{\text{eh}})|Q\rangle \quad (5.11)$$

where C_P and C_Q are expansion coefficients, $|P\rangle$ and $|Q\rangle$ are two eigenvectors of H_{eh}^0 operators with eigenvalues ω_p^0 and ω_Q^0 , respectively and $\langle P|Q\rangle = 0$. These two eigenvectors represent two different particle-hole excitation of the form $|P\rangle = |\chi_i^h \chi_a^e\rangle$ and $|Q\rangle = |\chi_j^h \chi_b^e\rangle$ which are obtained from applying the following particle-hole excitation operators $\{a^\dagger i\}$ and $\{b^\dagger j\}$, as shown in [Figure 5.1](#). The central quantity of interest is the $\Lambda(\omega, r_{\text{eh}})$ operator, a frequency-dependent, r12-explicitly correlated operator which operates simultaneously on both particle and hole states and is responsible for capturing electron-hole correlation. Construction of Λ and determination of $|Q\rangle$ are presented in [subsection 5.2.4](#) and [subsection 5.2.2](#), respectively. In this section, we will focus on the construction of the $K_{\text{eh}}(\omega)$ and its derivation is independent of the specific form of Λ . The two conditions that Λ must satisfy are: (1) frequency-dependent, and (2) explicitly-correlated. Both the expansion coefficients (C_P, C_Q) and $\Lambda(\omega, r_{\text{eh}})$ are obtained from the solution of the resulting

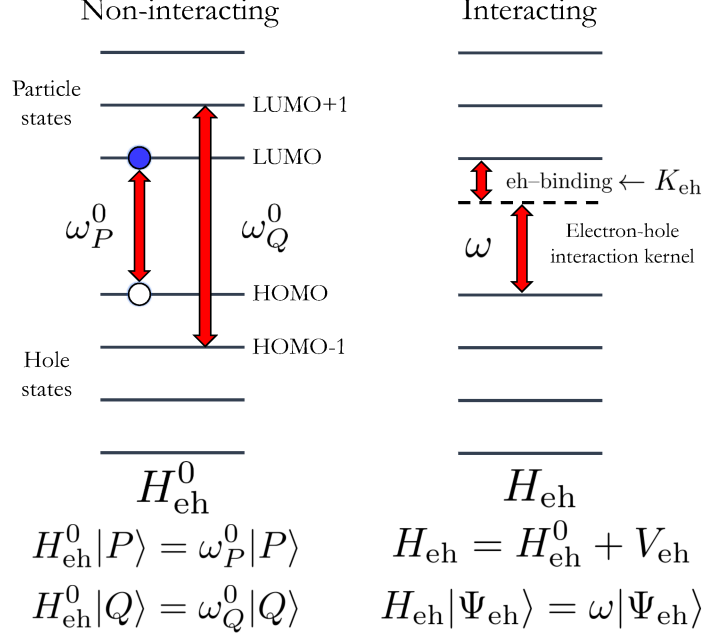

Figure 5.1: Interacting and non-interacting Hamiltonian

electron-hole pseudo eigenvalue equation,

$$H_{\text{eh}}|\Psi_X(\omega)\rangle = \omega|\Psi_X(\omega)\rangle \quad (5.12)$$

where,

$$|\Psi_X\rangle = C_P|P\rangle + C_Q\Lambda(\omega)|Q\rangle \quad (5.13)$$

and $|P\rangle$ and $|Q\rangle$ are eigenkets of the non-interacting electron-hole Hamiltonian H_{eh}^0 .

$$H_{\text{eh}}^0|P\rangle = \omega_P^0|P\rangle \quad (5.14)$$

$$H_{\text{eh}}^0|Q\rangle = \omega_Q^0|Q\rangle \quad (5.15)$$

Because $\Lambda(\omega, r_{\text{eh}})$ is frequency-dependent and depends on the eigenvalue ω , the solution is obtained iteratively. We have used the Löwdin's partitioning scheme[49] to obtain the analytical expression of $K_{\text{eh}}(\omega)$ in terms of the relevant matrix elements associated with V_{eh} and $\Lambda(\omega, r_{\text{eh}})$. The step-by-step derivation of the frequency-dependent electron-hole interaction kernel using Löwdin's

partitioning technique is presented below. We start with projection on the subspace of $\langle P|$ and $\langle Q|$, and using orthonormalization of $\langle P|Q\rangle = \delta_{PQ}$ we get,

$$\begin{bmatrix} \langle P|H_{\text{ch}}|P\rangle & \langle P|H_{\text{ch}}\Lambda(\omega)|Q\rangle \\ \langle Q|H_{\text{ch}}|P\rangle & \langle Q|H_{\text{ch}}\Lambda(\omega)|Q\rangle \end{bmatrix} \begin{bmatrix} C_P \\ C_Q \end{bmatrix} = \omega \begin{bmatrix} 1 & \langle P|\Lambda(\omega)|Q\rangle \\ 0 & \langle Q|\Lambda(\omega)|Q\rangle \end{bmatrix} \begin{bmatrix} C_P \\ C_Q \end{bmatrix} \quad (5.16)$$

Performing Löwdin's partitioning,

$$H_{PP}C_P + \tilde{H}_{PQ}C_Q = \omega C_P + \omega \tilde{S}_{PQ}C_Q \quad (5.17)$$

$$H_{QP}C_P + \tilde{H}_{QQ}C_Q = \omega \tilde{S}_{QQ}C_Q \quad (5.18)$$

where the tilde terms are defined as:

$$\tilde{S}_{PQ} = \langle P|\Lambda(\omega)|Q\rangle \quad (5.19)$$

$$\tilde{S}_{QQ} = \langle Q|\Lambda(\omega)|Q\rangle \quad (5.20)$$

$$\tilde{H}_{PQ} = \langle P|H_{\text{ch}}\Lambda(\omega)|Q\rangle = \omega_P^0 \tilde{S}_{PQ} - \langle P|r_{12}^{-1}\Lambda(\omega)|Q\rangle \quad (5.21)$$

$$\tilde{H}_{QQ} = \langle Q|H_{\text{ch}}\Lambda(\omega)|Q\rangle = \omega_Q^0 \tilde{S}_{QQ} - \langle Q|r_{12}^{-1}\Lambda(\omega)|Q\rangle \quad (5.22)$$

Rearranging [Equation 5.17](#) and [Equation 5.18](#),

$$H_{PP}C_P + [\tilde{H}_{PQ} - \omega \tilde{S}_{PQ}] C_Q = \omega C_P \quad (5.23)$$

$$[\tilde{H}_{QQ} - \omega \tilde{S}_{QQ}] C_Q = -H_{QP}C_P \quad (5.24)$$

Therefore,

$$C_Q = -\frac{H_{QP}}{\tilde{H}_{QQ} - \omega\tilde{S}_{QQ}}C_P \quad (5.25)$$

We obtain the equation for the electron-hole interaction kernel,

$$[H_{PP} + K_{PP}(\omega)]C_P = \omega C_P \quad (5.26)$$

where $K_{PP}(\omega)$ is the electron-hole interaction kernel and is defined as

$$K_{PP}(\omega) = -\frac{[\tilde{H}_{PQ} - \omega\tilde{S}_{PQ}]H_{QP}}{\tilde{H}_{QQ} - \omega\tilde{S}_{QQ}} \quad (5.27)$$

Substituting the definitions of the tilde operators defined in [Equation 5.19](#) - [Equation 5.22](#), the closed-form analytical expression for $[K_{\text{eh}}(\omega)]_{PP}$ is given by

$$K_{PP}(\omega) = -\frac{[\langle P|r_{12}^{-1}\Lambda(\omega)|Q\rangle_A - (\omega_P^0 - \omega)\langle P|\Lambda(\omega)|Q\rangle] \langle Q|r_{12}^{-1}|P\rangle_A}{\langle Q|r_{12}^{-1}\Lambda(\omega)|Q\rangle_A + (\omega_Q^0 - \omega)\langle Q|\Lambda(\omega)|Q\rangle} \quad (5.28)$$

where $\langle \dots \rangle_A$ represents anti-symmetrized matrix elements. The expression for $[K_{\text{eh}}(\omega)]_{PP}$ can be further simplified by performing Gram - Schmidt orthogonalization to make $\langle P|\Lambda|Q\rangle = 0$. This can be achieved by replacing

$$\Lambda|Q\rangle \rightarrow \Lambda|Q\rangle - \langle P|\Lambda|Q\rangle|P\rangle \quad (5.29)$$

in the expression for K_{PP} in [Equation 6.27](#). The orthogonalization procedure imposes intermediate normalization condition for the electron-hole wave

$$\langle P|\Psi_X\rangle = 1 \quad (5.30)$$

The $[K_{\text{eh}}(\omega)]_{PP}$ terms has two sources of frequency-dependency. The first are the $(\omega_P^0 - \omega)$ and $(\omega_Q^0 - \omega)$ terms from the operator inversion step in the Löwdin's partitioning. The second is the

frequency-dependency from $\Lambda(\omega, r_{\text{eh}})$ and this feature is the main content of this article. Indeed, setting $\Lambda = 1$ results in a simple 2×2 configuration-interaction singles (CIS) expression.

5.2.2 Determination of the $|Q\rangle$ state

The zeroth-order electron-hole wavefunction is given by $|\Psi_X\rangle^{(0)} = |P\rangle$ and the choice of the $|Q\rangle$ plays an important role in accurate description of electron-hole correlation and calculation of electron-hole binding energies. In this work, we determine $|Q\rangle$ by minimizing the trace $T[Q]$ of the 2×2 uncorrelated Hamiltonian.

$$\mathbf{H}_{PQ} = \begin{bmatrix} \langle P|H_{\text{eh}}|P\rangle & \langle P|H_{\text{eh}}|Q\rangle \\ \langle Q|H_{\text{eh}}|P\rangle & \langle Q|H_{\text{eh}}|Q\rangle \end{bmatrix} \quad (5.31)$$

where, the trace is given by

$$T[Q] = \omega_P^0 + \omega_Q^0 + \langle P|v_{\text{eh}}|P\rangle + \langle Q|v_{\text{eh}}|Q\rangle \quad (5.32)$$

and the search for Q is only restricted to states $\omega_P^0 \leq \omega_Q^0$. Since, Q is a uncorrelated particle-hole state, the last two terms in the previous expression, can be written in terms of particle and hole densities,

$$T[\rho_P^{\text{h}}, \rho_Q^{\text{e}}] = \omega_P^0 + \omega_Q^0 - \langle \rho_P^{\text{h}} \rho_P^{\text{e}} r_{\text{eh}}^{-1} \rangle - \langle \rho_Q^{\text{h}} \rho_Q^{\text{e}} r_{\text{eh}}^{-1} \rangle \quad (5.33)$$

The search for the optimal Q scales $N_{\text{occ}} \times N_{\text{vir}}$ and requires searching over all 1p-1h states $|\chi_j \chi_b\rangle$. To reduce the computational cost, we define an approximate trace operator given by \tilde{T}

$$\tilde{T}[\tilde{\rho}_Q^{\text{h}}, \tilde{\rho}_Q^{\text{e}}] = \omega_P^0 + \omega_Q^0 - \langle \rho_P^{\text{h}} \rho_P^{\text{e}} r_{\text{eh}}^{-1} \rangle - \langle \tilde{\rho}_Q^{\text{h}} \tilde{\rho}_Q^{\text{e}} r_{\text{eh}}^{-1} \rangle \quad (5.34)$$

which uses approximate densities $\tilde{\rho}_Q^h \tilde{\rho}_Q^e$. The densities $\tilde{\rho}_Q^h \tilde{\rho}_Q^e$ are the Gaussian approximation to the true densities $\rho_Q^h \rho_Q^e$

$$\tilde{\rho}_Q^{e,h} = \frac{1}{\sigma_Q^{e,h} \sqrt{2\pi}} e^{-\frac{1}{2} \left(\frac{r - \mu_Q^{e,h}}{\sigma_Q^{e,h}} \right)^2} \quad (5.35)$$

and are obtained by minimizing the Kullback–Leibler divergence[55] between the true densities $\rho_Q^h \rho_Q^e$ and the Gaussian probability distribution functions.

$$D_{\text{Kullback–Leibler}} = \int_V d\mathbf{r} \rho_Q^{e,h} \ln \left[\frac{\rho_Q^{e,h}}{\tilde{\rho}_Q^{e,h}} \right] \quad (5.36)$$

The computational effort for determination of approximate densities $\tilde{\rho}_Q^h \tilde{\rho}_Q^e$ scales linearly with $(N_{\text{occ}} + N_{\text{vir}})$ and the calculation of $\langle \tilde{\rho}_Q^h \tilde{\rho}_Q^e r_{\text{eh}}^{-1} \rangle$ is performed analytically. Both of these steps allow us search for the optimal $|Q\rangle$ state at a reduced computational cost.

5.2.3 Reducing the number of particle-hole states

The $\Lambda(\omega, r_{\text{eh}})$ operator introduces the electron-hole correlation and add correction beyond the zeroth-order approximation to the electron-hole wavefunction. Motivated by both CIS and MBPT theory for excited states, we represent Λ in project space of 1p-1h states as

$$\Lambda = \sum_{ij}^{\text{Nocc}} \sum_{ab}^{\infty} \Lambda_{ijab} \{a^\dagger i\} |0\rangle \langle 0| \{j^\dagger b\} \quad (5.37)$$

The action of $\Lambda(\omega, r_{\text{eh}})$ in the electron-hole wavefunction can be interpreted as a compact representation of an infinite-order particle-hole excitation operator in the occupation-number representation [37]

$$\Lambda(\omega, r_{\text{eh}})|Q\rangle = \sum_{K=0}^{\infty} c_K^\Lambda(\omega)|K\rangle \quad (5.38)$$

where the expansion coefficient $c_K^\Lambda(\omega)$ is a functional of Λ and are calculated from the matrix element $\langle K|\Lambda|Q\rangle$. In the present work, we will use the explicitly-correlated Slater-geminal function for constructing the Λ operator in real-space representation. Both Slater-geminal and Gaussian-geminal functions have been used extensively for many-electron,[56, 48, 47] electron-proton[57, 58], and electron-hole systems[34, 35, 36, 45, 37] and provide a compact representation for construction of correlated many-particle wavefunction. The correlation operator, $\Lambda(\omega, r_{\text{eh}})$ has the general form of,

$$\Lambda(\omega, r_{\text{eh}}) = \frac{(\omega_p^0 - \omega)}{\gamma} e^{-r_{\text{eh}}\gamma} \quad (5.39)$$

where $\gamma = \langle P|r_{\text{eh}}^{-1}|P\rangle$. *The most important feature of the above expression for Λ is the complete absence of any adjustable parameters.* All quantities needed to define the operator are calculated during the course of the calculations. The explicit correlation comes from the Slater-geminal function $e^{-\gamma r}/\gamma$. We have made γ proportional to the Coulomb interaction of the electron-hole pair in $|P\rangle$ by setting $\gamma = \langle P|r_{\text{eh}}^{-1}|P\rangle$. The Slater-geminal is scaled by the $(\omega_p^0 - \omega)$ and is the frequency dependence of Λ . Although ω_p^0 is known before start of the calculation, ω is the final result and therefore, determination of ω requires a self-consistent solution of the equation derived in [Equation 5.12](#).

5.2.4 Eliminating the AO-to-MO integral transformation

One of the principle computational bottleneck in performing first-principle excited state calculation is the evaluation of matrix elements. Traditionally, for atom-centered basis functions, the integrals are evaluated in AO representation and are later transformed in MO basis after the SCF step. This is an expensive transformation that scales as N^5 . In this work, such a procedure is impractical because of three reasons. First, the scaling of the AO-to-MO is computationally impractical for large NPs that have > 200 heavy atoms with > 1000 basis functions. Second, as shown in [Equation 6.28](#), the matrix elements depends on Slater-geminal function which are more complicated than the conventional 2-electron integrals and further adds to the already high computational cost. Third,

the matrix elements depend on the final solution ω and consequently needs to be evaluated multiple times during the course of the calculations. In this work, we have addressed all these challenges by calculating the necessary integrals directly in the MO basis using MC numerical integration procedure. Specifically,

$$\langle \psi_r(\mathbf{r})\psi_s(\mathbf{r}) | \Lambda(r_{12}, \omega) | \psi_u(\mathbf{r})\psi_v(\mathbf{r}) \rangle = \int d\mathbf{r}_1 d\mathbf{r}_2 \psi_r(\mathbf{r}_1)\psi_s(\mathbf{r}_2)\Lambda(r_{12}, \omega)\psi_u(\mathbf{r}_1)\psi_v(\mathbf{r}_2) \quad (5.40)$$

$$= (\omega_p^0 - \omega) \int d\mathbf{r}_1 d\mathbf{r}_2 F(\mathbf{r}) \quad (5.41)$$

$$= \frac{(\omega_p^0 - \omega)}{N_{\text{sample}}} \sum_{\mathbf{r}_i \in \rho_{\text{pdf}}} \left[\frac{F(\mathbf{r}_i)}{\rho_{\text{pdf}}(\mathbf{r}_i)} \right] \quad (5.42)$$

where the MOs at any point in \mathbf{r} in 3D space is obtained by $\psi_r(\mathbf{r}) = \sum_{\mu=1}^{N_{\text{AO}}} C_{\mu r} \phi_{\mu}(\mathbf{r})$. The MC step can be performed either using importance or stratified sampling and the details of the MC procedure used in this work has been described earlier, Bayne et. al.[59]. Additionally, the knowledge of analytic solution of the AO integrals using the explicitly correlated function is not needed and the method is not restricted by the choice of explicitly correlated function used in Λ .

5.2.5 Summary of steps in the overall calculation

Step 1 - Performing Hartree-Fock calculation: The first step involved the calculation of single-particle states and orbital energies which provided the zeroth-order description of the electronic excitation. We demonstrate the overall procedure using the Hartree-Fock (HF) method, however, both Kohn-Sham and pseudo-potential methods can be used as well.

Step 2 - Selection of the zeroth-order state: The next step involved selection of the P and Q states. Here, we are interested in investigating the effect of electron-hole correlation on the lowest excitation energy and therefore the HOMO-LUMO excitation in the non-interaction system was selected. Specifically, $|P\rangle$ was set to $P = \chi_{\text{HOMO}}^h \chi_{\text{LUMO}}^e$. The orthogonal space $|Q\rangle$ was selected using the procedue described in [subsection 5.2.2](#). The zeroth-order excitation energy ω_p^0 is given by the HOMO-LUMO gap. It is important to note that this is a conventional HF procedure using

conventional AO integrals. No explicitly-correlated integrals were evaluated in this step.

Step 3 - Evaluation of spatial molecular orbitals at point \mathbf{r} : The MC integration required evaluation of the spatial MOs $\psi(\mathbf{r})$ at any point in 3D space and was achieved by pre-computing the values of the MOs on a spatial grid before the start of the MC step. This made the implementation portable and demonstrated universal applicability, as it did not require source-code modification of electronic structure packages.

Step 4 - Performing the 1st Monte Carlo integration for construction of Λ : After the MOs were obtained on a 3D grid, MC integration was performed to calculate $\langle P|r_{\text{eh}}^{-1}|P\rangle$. This quantity is needed for construction of the explicitly-correlated function in Λ as shown in [Equation 6.28](#). In this work, we advocate the stratified-sampling approach and used the combined control-variate stratified sampling method (CCVSS) for evaluating two-electron integrals. [\[59\]](#)

Step 5 - Performing the 2nd Monte Carlo integration for construction $H[\Lambda(\omega)]$ and $S[\Lambda(\omega)]$: After $\Lambda(\omega)$ was constructed from ω_p^0 and $\langle P|r_{\text{eh}}^{-1}|P\rangle$, the matrix elements in [Equation 6.27](#) were calculated numerically using the MC integration method described above. Since both P and Q states are eigenvectors of H_{eh}^0 , matrix elements involving the reference Hamiltonian were obtained analytically. The remaining matrix elements are of the general form $\langle *|r_{\text{eh}}^{-1}|*\rangle$, $\langle *|\Lambda|*\rangle$, $\langle *|r_{\text{eh}}^{-1}\Lambda|*\rangle$, and were evaluated simultaneously in a single MC integration step.

Step 6 - Calculation of the excitation energy from the iterative solution of the projected equation: In the final step, matrix elements calculated previously were used to construct the $K_{\text{eh}}(\omega)$ using [Equation 6.27](#). The excitation energy ω was obtained iteratively by evaluation of the left-hand-side of [Equation 5.26](#) by setting $\omega = \omega_p^0$ as the starting guess.

5.3 Results

5.3.1 Chemical system and system setup

The FD-GSIK method was used to calculate excitation energy on a series of common NPs: PbS, PbSe, CdS, and CdSe up to 2.5 nm in diameter. The chemical formulas for the NPs investigated range from Pb_4S_4 - $\text{Pb}_{140}\text{S}_{140}$, Pb_4Se_4 - $\text{Pb}_{140}\text{Se}_{140}$, Cd_3S_3 - $\text{Cd}_{87}\text{S}_{87}$, Cd_3Se_3 - $\text{Cd}_{144}\text{Se}_{144}$, totaling in 48 unique structures. Details of the NPs including (1) chemical formula, (2) ω_p^0 energies, (3) electron-hole binding energies, (4) $\omega_{\text{FD-GSIK}}$ excitations, (5) standard deviation of $\omega_{\text{FD-GSIK}}$, and (6) computational cost are presented in Appendix A. Geometries for the NPs were generated by cutting dots of the desired size from bulk solid structure: for PbS and PbSe using the rock-salt crystal structure, while for CdS and CdSe the wurtzite crystal structure. The ground state single-particle states were obtained using the Q-CHEM package[60] using LANL2DZ basis and ECP. The 3D spatial grid for the MOs was generated with 100 points per dimension to generate a 10^6 point grid to obtain a dense grid for the integral evaluation. The grid boundary was determined by imposing a cutoff of $|\psi(\mathbf{r})| \leq 10^{-12}$ at the grid edges. The quality of the 3D spatial grid was verified by evaluating the normalization integral $\langle \psi | \psi \rangle$ before start of the MC calculations.

5.3.2 Scaling of FD-GSIK cost

The computational effort of the FD-GSIK method was compared to CIS calculation (Figure 5.2), for a series of PbS quantum dots ($\text{Pb}_4\text{S}_4 - \text{Pb}_{80}\text{S}_{80}$). Unsurprisingly, we found evidence of $O(N^5)$ -scaling of computational cost for the CIS calculations. In contrast, the FD-GSIK method exhibited linear-scaling of the computational cost with increasing system size. Comparison of the excitation energies between FD-GSIK and CIS (Table 5.1) shows that the FD-GSIK energies are always lower than the CIS values. This trend is consistent with both MBPT and coupled-cluster formulations where we expect inclusion of electron-hole correlation to decrease the excitation energies.

Figure 5.2: The single-core timing comparison of CIS and FD-GSIK calculations for the PbS series ($\text{Pb}_4\text{S}_4 - \text{Pb}_{80}\text{S}_{80}$) using LANL2DZ basis.

Table 5.1: Comparison of the first excitation energy (eV) obtained from CIS and the FD-GSIK method for PbS nanoparticles.

Chemical Formula	ω_{CIS}	$\omega_{\text{FD-GSIK}}$
Pb_4S_4	3.7386	3.2915
$\text{Pb}_{16}\text{S}_{16}$	3.1944	2.4134
$\text{Pb}_{28}\text{S}_{28}$	3.1370	2.8188
$\text{Pb}_{44}\text{S}_{44}$	3.3432	3.0030
$\text{Pb}_{68}\text{S}_{68}$	2.4257	1.6547
$\text{Pb}_{80}\text{S}_{80}$	3.1582	3.1496

Table 5.2: Comparison of electron-hole binding energies (eV) obtained from EOM-CCSD, ADC(3), and FD-GSIK method for PbS nanoparticles.

Chemical Formula	EOM-CCSD		ADC(3)		FD-GSIK	
	Electron-hole binding eV	Time hour	Electron-hole binding eV	Time hour	Electron-hole binding eV	Time hour
Pb_4S_4	5.5922	0.0137	4.4832	0.008	5.0621	0.129
$\text{Pb}_{16}\text{S}_{16}$	4.5701	127.311	3.2128	1.372	3.9938	0.144
$\text{Pb}_{28}\text{S}_{28}$	—	—	3.3213	13.333	3.6390	0.132

5.3.3 Comparison of FD-GSIK with correlated methods

To further inspect the impact of electron-hole correlation operator in the FD-GSIK method, we performed calculations on a small subset of the PbS nanoparticles using EOM-CCSD and ADC(3)

methods [61, 62] and the comparison of the electron-hole binding energies are presented in [Table 5.2](#). These results showed two key insights; first, that FD-GSIK is successfully able to capture electron-hole correlation within the same magnitude as other correlated methods. Specifically, as compared to EOM-CCSD, the FD-GSIK method was found to capture 91% and 87% of the electron-hole binding energies. Second, the total time needed to perform the FD-GSIK calculations for these systems scales sub-linearly with respect to increasing system size. The FD-GSIK results were also compared with GW-BSE calculations[63] for CdSe clusters ([Table 5.3](#)) and were found to be in good agreement with the GW-BSE results. The results from [Table 5.2](#) and [Table 5.3](#) demonstrate that the FD-GSIK is able to capture electron-hole correlation that is comparable to high-level many-body methods at a significantly low computational cost that has a favorable scaling with respect to system size.

Table 5.3: Comparison of excitation energy (eV) obtained from FD-GSIK method and GW-BSE[63] for small CdSe nanoparticles.

Chemical Formula	$\omega_{\text{FD-GSIK}}$	$\omega_{\text{GW-BSE}}$ [63]
Cd ₃ Se ₃	3.75	3.99
Cd ₆ Se ₆	3.31	3.33

5.3.4 Electron-hole binding energy

The FD-GSIK method was used to calculate electron-hole binding energies for PbS, PbSe, CdS, and CdSe NPs of varying sizes and the results are presented in [Figure 5.3](#) as a function of ω_p^0 energies. The complete list of excitation energies and electron-hole binding energies for these NPs is also available in Appendix A. We found that electron-hole binding energy exhibit a strong correlation with the non-interaction excitation energy (ω_p^0) and increased with increasing HOMO-LUMO gap.

5.3.5 Error analysis of the FD-GSIK method

The relationship between unbiased estimation of numerical error in the integral from the standard deviation of the integration kernel in MC method is well-known[59]. In the FD-GSIK method,

Figure 5.3: Electron-hole binding energy obtained using FD-GSIK method for $\text{Pb}_4\text{S}_4\text{-Pb}_{140}\text{S}_{140}$, $\text{Pb}_4\text{Se}_4\text{-Pb}_{140}\text{Se}_{140}$, $\text{Cd}_3\text{S}_3\text{-Cd}_{87}\text{S}_{87}$, and $\text{Cd}_3\text{Se}_3\text{-Cd}_{144}\text{Se}_{144}$ as a function of ω_p^0 .

Table 5.4: Maximum and minimum standard deviation (eV) of FD-GSIK excitation energy for each nanoparticle series.

Standard Deviation	PbS	PbSe	CdS	CdSe
Maximum	0.018	0.042	0.064	0.059
Minimum	0.002	0.002	0.005	0.006

this relationship allows us to monitor and reduce the error in the calculated excitation energies. In [Table 5.4](#), the maximum and minimum standard deviation is provided for each semiconducting NP series. The results from the standard deviation demonstrate the FD-GSIK method is able to achieve meV level of accuracy for all the NPs investigated in this work. The detailed description of errors for each NPs are presented in Appendix A.

5.3.6 Summary of results from the FD-GSIK calculations

5.4 Discussion

5.4.1 Low-scaling excited state method

In this work we present a frequency-dependent electron-hole interaction kernel that does not exhibit steep scaling of computational cost with increasing system size. Traditional occupation-

Table 5.9: Largest clusters investigated using LANL2DZ basis.

Cluster	Diameter (nm)	Number of AOs	Number of 1p-1h states
Cd ₁₄₄ Se ₁₄₄	2.5	3744	3.17×10^6
Cd ₈₇ S ₈₇	2.0	1392	1.16×10^6
Pb ₁₄₀ Se ₁₄₀	2.5	2240	1.08×10^6
Pb ₁₄₀ S ₁₄₀	2.5	2240	1.08×10^6

number approaches that use particle-hole excitation basis for excitation energy calculation suffer from high computational cost because the number of basis functions increase as $(N_{\text{occ}} \times N_{\text{vir}})$. As an example, this point is illustrated in [Table 5.9](#) for the largest NPs investigated in this work. The last column of [Table 5.9](#) shows that for all systems investigated in this work, use of the conventional method would require a particle-hole basis that is at least 10^6 or higher in size. In addition to that, the number of 2-electron integrals needed to construct the A – matrix increases as $(N_{\text{occ}} + N_{\text{vir}})^2$ which further contributes to the increasing the cost of the calculation. Finally, the AO-to-MO integral transformation which scales as $(N_{\text{occ}} + N_{\text{vir}})^5$ is a major contributor to the computational cost. All these factors contribute to the steep increase in the overall computational cost and is captured in [Figure 5.2](#), where CIS line shows the cost of the conventional CIS calculation. The FD-GSIK line in [Figure 5.2](#) showcases computation cost of the method developed in this work.

5.4.2 Frequency dependent kernel

The importance of frequency dependence for describing chemical systems is well-understood and have been studies extensively both in the context of MBPT[[38](#), [40](#), [41](#)] and TDDFT[[64](#), [65](#), [66](#), [67](#)]. In the FD-GSIK method, the frequency dependence in the interaction kernel allows the electron-hole interaction to change dynamically for different excitation and for different chemical systems.

The expression for the K_{eh} derived in Equation 6.27 is general and is applicable to a wide variety of choices for Λ by users.

5.4.3 Absence of adjustable parameters

Another significant feature of this work is that the kernel does not have adjustable parameters. The functional form presented here allows only two parameters, both of which are calculated during the course of the calculation. The inclusion on $(\omega_p^0 - \omega)$ makes the kernel dependent on the difference between the reference and the interacting system. The quantity $\langle P | r_{\text{eh}}^{-1} | P \rangle$ is equal to the first-order correction in Rayleigh-Schrödinger perturbation theory (RSPT). Both of these terms modify the kernel dynamically with respect to the strength of the electron-hole interaction.

5.4.4 Future directions and extensions

In terms of directions for future research, the FD-GSIK kernel presents opportunities for extensions in other excited state phenomenons. Specifically, it is well-known in linear-response treatment of excited states that frequency-dependence in the electron-hole interaction kernel is crucial for describing two-electron excitations[68] and the present method can be extended to study biexcitonic interactions in semiconductor nanoparticles. Application to biexcitonic systems will involve defining $|P\rangle$ as the non-interacting 2p-2h reference state. The state $|Q\rangle$ will be obtained from the search in orthogonal 2p-2h space similar to procedure described here for 1p-1h systems. The FD-GSIK method can also be combined with electron-hole multicomponent coupled-cluster theory (eh-mcCC)[53, 54] for studying biexcitonic and multiexcitonic states. The FD-GSIK in its present form is not size-consistent and combining it with eh-mcCC will require a size-consistent formulation of the method.

The FD-GSIK method can also be extended to study systems that exhibit high density of states near the HOMO-LUMO gap such as gold and silver metallic clusters and large quantum dots. The issue of performing excited-state calculations in the presence of high density of particle-hole states is challenging and would require modification of the method presented here. One promising strategy is to use an orbital-optimized version of the present method, where dressed particle and

hole state are obtained from a linear-combination of the bare particle-hole states.

$$|\tilde{h}\rangle = \sum_i c_i |i\rangle \quad (5.43)$$

$$|\tilde{e}\rangle = \sum_a c_a |a\rangle \quad (5.44)$$

where the \mathbf{c} are obtained by minimizing $\langle \tilde{h}\tilde{e} | H_0 + V_{\text{eh}} | \tilde{h}\tilde{e} \rangle$. Preliminary studies using this approach on gold nanoclusters were found to be promising and is currently being pursued.

5.5 Conclusions

In summary, the FD-GSIK method presented here implements a series of theoretical strategies to reduce the cost of an excited state calculation while maintaining the accuracy of the method. First, we have reduced the number of particle-hole states needed to describe the electron-hole interaction kernel by using an explicitly-correlated ansatz. Second, we have avoided the storage, evaluation, and transformation of atomic orbital integrals by performing evaluating the molecular orbitals integrals directly using the Monte Carlo method. Third, we have developed a frequency-dependent term in the electron-hole interaction kernel to account for dynamically screening. Finally, the FD-GSIK method is a first-principle method that is free of external parametrization and all required information is evaluated during the course of the calculation. The FD-GSIK method was applied to a series of quantum dots and the results from the calculations demonstrate the efficacy of the FD-GSIK method for reducing the scaling of computational effort with respect to system size.

Chapter 6

Investigation of Dense Manifold of Particle-Hole Excitations in Metallic Nanowires Using r_{12} -Correlated Frequency Dependent Electron-Hole Interaction Kernel

6.1 Introduction

Noble metal nanoparticles, in particular silver and gold are of great interest for their applications in biomedicine,[69, 70, 71, 72, 73] catalysis,[74] energy conversion,[75, 76, 77, 78] and sensing.[79, 80, 81, 82] The potential in the above applications stems from strong absorption peaks in the visible to near IR region called surface plasmon resonance (SPR). [83, 84] A SPR is collective oscillations of electronic transitions due to the density of states within these metallic-like systems. Noble metal nanoparticles have been extensively studied both experimentally[85, 86, 87, 88] and theoretically [89, 90] to better understand the plasmonic nature.

The effect of composition, [91, 92] environment, [93] size,[94, 95, 96] and shape [97, 98, 95, 96] of noble metal nanoparticles is of particular interest as these cause tunability in the absorption peaks. In particular, nanorods and nanowires are of great interest due to the impact on their optical properties as a function of increased length. [99, 100, 101] Where a longitudinal mode along the

main axis and a transverse mode perpendicular to the main axis are known to have varying effects due to increasing chain length. For which the longitudinal peak red shifts as length is increased and there is minimal effect of energy on the transverse peak.[102, 103]

A proper treatment of electron-correlation is then imperative towards better understanding these systems. Configuration interaction (CI) provides a simplistic method towards capturing electron-correlation. It is well known that with the limit of infinite basis, full configuration interaction (FCI) will exactly solve electron-correlation in the Schrödinger equation. The challenges are also well known with CI in the dramatically increasing computational cost for CI space. Tackling the challenge of size configuration space is a vast field of interest with various methods: Quantum Monte Carlo (QMC),[104] complete active space configuration interaction (CASCI) method, [105] geminal-projected configuration interaction (GP-CI) method,[45] many-body expanded full configuration interaction (MBE-FCI) method,[106, 107] multireference configuration interaction (MRCI), [108, 109, 110] multireference self consistent field (MR-SCF) theory,[111, 112] multireference second-order perturbation (MRMP2) theory, [113, 114] multi-state complete active space perturbation (MS-CASPT2) theory,[115] and rank-reduced full configuration interaction (RR-FCI).[116] The general goal within these methods and theories is to either restrict the the number of configurations through limiting the active space, or selecting only important configurations. The use of CI for nanoparticles is also limited by the cost of CI space, due to the number of single-particle states.[117, 118, 119] Time-dependent density-functional theory (TD-DFT) has demonstrated impactful insight into understanding the plasmon resonance within many noble metal nanowires and nanoparticles in obtaining electron-correlation.[120, 121, 122, 123, 124, 125, 126, 127, 128, 103] Though these TD-DFT studies have been useful, there still exist limitation for theoretical investigations for complex noble metal. There exists a class of "magic clusters" that are theoretically investigated simply due to the use of high-symmetry within the structure to eliminate computational effort.[129, 130, 96] In general, noble metal systems can contain many electrons which require the use of many basis functions, thereby increasing the number of single-particle excitations increasing the computational effort to obtain electron-correlation. The limitations with CI and TD-DFT to investigate plasmon resonance within truly unique noble metal nanoparticles

requires the development of new theoretical methods.[131]

In this work we will present an orbital-optimized dressed particle-hole basis, that allows us to compress the configuration space in a many-electron system but still capture the contribution to electron-hole correlation from all the single-particle excitations. The ideal of orbital-optimized excited states methods is not new, and is an area of interest with orbital-optimized Møller-Plesset perturbation (OO-MP) theory,[132, 133, 134] orbital-optimized coupled-cluster (OO-CC) methods,[135, 136] and various others theories.[137, 138, 139, 140, 141, 142] The goal of this work is to provide a formulation that captures the electron-hole correlation for plasmonic systems, or systems with highly degenerate orbitals with computational efficiency in mind by compression of the CI space. We will utilize our recently developed first-principle method, the frequency-dependent geminal-screened electron-hole interaction kernel method (FD-GSIK) to capture electron correlation which provides us a computational cost that is independent of system size. This work presented will not focus on the derivation of FD-GSIK but the formulation of our dressed molecular orbital basis and its application to silver nanowires to obtain correlated excitation energy for the longitudinal peak, the highest occupied molecular orbital (HOMO) to lowest unoccupied molecular orbital (LUMO) gap.

6.2 Theory

6.2.1 Dressed Molecular Orbitals

The effective many-body electron-hole Hamiltonian has the general form [50, 51, 52, 35, 53, 54]

$$H_{\text{eh}} = H_{\text{e}}^0 + H_{\text{h}}^0 + V_{\text{ee}} + V_{\text{hh}} + V_{\text{eh}} \quad (6.1)$$

where

$$H_{\text{e}}^0 = \sum_{e_1 e_2} \langle e_1 | f^e | e_2 \rangle e_1^\dagger e_2 \quad (6.2)$$

$$H_h^0 = \sum_{h_1 h_2} \langle h_1 | f^h | h_2 \rangle h_1^\dagger h_2 \quad (6.3)$$

$$V_{ee} = \sum_{e_1 e_2 e_3 e_4} \langle e_1 e_2 | w_{ee} | e_4 e_3 \rangle e_1^\dagger e_2^\dagger e_3 e_4 \quad (6.4)$$

$$V_{hh} = \sum_{h_1 h_2 h_3 h_4} \langle h_1 h_2 | w_{hh} | h_4 h_3 \rangle h_1^\dagger h_2^\dagger h_3 h_4 \quad (6.5)$$

$$V_{eh} = \sum_{h_1 h_2 e_1 e_2} \langle e_1 h_1 | v_{eh} | e_2 h_2 \rangle e_1^\dagger h_1^\dagger h_2 e_2 \quad (6.6)$$

where e^\dagger and h^\dagger are particle and hole creation operators, and f_e and f_h are the Fock operators. The electron-hole Hamiltonian can be factored into a sum of non-interaction terms and interaction terms. For a 1-particle 1-hole state, further simplification can be achieved and the total Hamiltonian can be expressed as

$$H_{eh} = H_{eh}^0 + V_{eh} \quad (6.7)$$

The non-interacting Hamiltonian H_{eh}^0 is obtained from the Fock operator whose eigenfunctions are (uncorrelated) particle-hole excited states

$$H_{eh}^0 |P\rangle = \omega_P^0 |P\rangle = (\epsilon_a - \epsilon_i) |\chi_i^h \chi_a^e\rangle \quad (6.8)$$

We are interested in understanding the many-body correction to a collection of single-particle excitations $\{\omega_P^0\}$, which are made up from all possible single-particle excitations from a set of particle states and a set of hole states as described below.

$$\{I\} = \{i, j, \dots, N^h\} \quad (6.9)$$

$$\{A\} = \{a, b, \dots, N^e\} \quad (6.10)$$

$$\{\omega_P^0\} = \{\omega_{P_1}^0, \dots, \omega_{P_N}^0\} \quad (6.11)$$

The set of particle states ($\{I\}$) and set of hole states ($\{A\}$) do not have to contain all the particle or hole states, respectively, but in general consist of a subset of all particle/hole states. We then define the set of particle/hole states that do not exist in $\{I\}$ and $\{A\}$ as,

$$\{J\} = \{i', j', \dots, N^{h'}\} \quad (6.12)$$

$$\{B\} = \{a', b', \dots, N^{e'}\} \quad (6.13)$$

Note, that $\langle \{I\} | \{J\} \rangle = 0$ and that $\{I\}$ and $\{J\}$ contain all hole states for the system, these relations are the case for for the particle states as well. The wave-function for this collection of single-particle excitations is defined as,

$$|\tilde{P}\rangle = |he\rangle \quad (6.14)$$

$$|h\rangle = \sum_{i \in \{I\}} c_i |i\rangle \quad (6.15)$$

$$|e\rangle = \sum_{a \in \{A\}} c_a |a\rangle \quad (6.16)$$

in which we introduce a dressed uncorrelated molecular orbital , $|\tilde{P}\rangle$. Where the summations run over N_P^h and N_P^e number of hole orbitals and particle orbitals in set $\{I\}$ and $\{A\}$, respectively that contribute to the collective excitation for which we want to correct, along with coefficients c_i and c_a . Since we are interested in the collective excitation, the coefficients used in $|\tilde{P}\rangle$ are weighted so each particle/hole state contributes uniformly. From this point on in this presented work, a tilde will refer to dressed states as described in [Equation 6.14](#).

We start by defining the zeroth-order approximation of the electron-hole wavefunction as,

$$|\Psi_X\rangle^{(0)} = |\tilde{P}\rangle \quad (6.17)$$

We now define the correlated electron-hole wavefunction Ψ_X as

$$|\Psi_X\rangle = C_{\tilde{P}}|\tilde{P}\rangle + C_{\perp}|\tilde{P}_{\perp}\rangle \quad (6.18)$$

where $C_{\tilde{P}}$ and C_{\perp} are expansion coefficients and \tilde{P}_{\perp} is the correlated wavefunction that exists in the orthogonal subspace of \tilde{P} . This is a very general form of the wavefunction and both MBPT and CI wavefunctions can be expressed in this form, where choice and construction of \tilde{P}_{\perp} differentiates between treatment of electron-hole correlation within different methods. Here, we will define an electron-hole correlator operator Λ and express the \tilde{P}_{\perp} as,

$$|\Psi_X\rangle = C_{\tilde{P}}|\tilde{P}\rangle + C_{\tilde{Q}}\Lambda(\omega, r_{\text{eh}})|\tilde{Q}\rangle \quad (6.19)$$

where we define $|\tilde{Q}\rangle$ as,

$$|\tilde{Q}\rangle = |h'e'\rangle \quad (6.20)$$

$$|h'\rangle = \sum_{j \in \{J\}} c_j |j\rangle \quad (6.21)$$

$$|e'\rangle = \sum_{b \in \{B\}} c_b |b\rangle \quad (6.22)$$

where $|\tilde{Q}\rangle$ contains all particle-hole states not used in construction of $|\tilde{P}\rangle$ and $\langle \tilde{P} | \tilde{Q} \rangle = 0$.

6.2.2 Frequency-dependent geminal-screened electron-hole interaction kernel

At this point we have derived dressed molecular orbital basis and how we construct our correlated electron-hole wavefunction, Ψ_X as

$$|\Psi_X\rangle = C_{\tilde{P}}|\tilde{P}\rangle + C_{\tilde{Q}}\Lambda(\omega, r_{\text{eh}})|\tilde{Q}\rangle \quad (6.23)$$

and are interested in solving,

$$H_{\text{eh}}|\Psi_X\rangle = \omega|\Psi_X\rangle \quad (6.24)$$

In this next section we will discuss briefly the frequency-dependent geminal-screened electron-hole interaction (FD-GSIK) method in terms of our correlated wavefunction. Full details of the derivation are in our previous work. FD-GSIK starts by projecting of $\langle\tilde{P}|$ and $\langle\tilde{Q}|$ on the subspace and utilizing orthonormalization, $\langle\tilde{P}|\tilde{Q}\rangle = 0$ to obtain,

$$\begin{bmatrix} \langle\tilde{P}|H_{\text{eh}}|\tilde{P}\rangle & \langle\tilde{P}|H_{\text{eh}}\Lambda(\omega)|\tilde{Q}\rangle \\ \langle\tilde{Q}|H_{\text{eh}}|\tilde{P}\rangle & \langle\tilde{Q}|H_{\text{eh}}\Lambda(\omega)|\tilde{Q}\rangle \end{bmatrix} \begin{bmatrix} C_{\tilde{P}} \\ C_{\tilde{Q}} \end{bmatrix} = \omega \begin{bmatrix} 1 & \langle\tilde{P}|\Lambda(\omega)|\tilde{Q}\rangle \\ 0 & \langle\tilde{Q}|\Lambda(\omega)|\tilde{Q}\rangle \end{bmatrix} \begin{bmatrix} C_{\tilde{P}} \\ C_{\tilde{Q}} \end{bmatrix} \quad (6.25)$$

After performing Löwdin's partitioning, we are able to obtain a equation for the electron-hole interaction kernel,

$$[H_{\tilde{P}\tilde{P}} + K_{\tilde{P}\tilde{P}}(\omega)]C_{\tilde{P}} = \omega C_{\tilde{P}} \quad (6.26)$$

where we obtain a closed-form analytical expression for our electron-hole interaction kernel, $K_{\tilde{P}\tilde{P}}(\omega)$ is defined as,

$$K_{\tilde{P}\tilde{P}}(\omega) = -\frac{\left[\langle\tilde{P}|r_{12}^{-1}\Lambda(\omega)|\tilde{Q}\rangle_A - (\omega_{\tilde{P}}^0 - \omega)\langle\tilde{P}|\Lambda(\omega)|\tilde{Q}\rangle\right] \langle\tilde{Q}|r_{12}^{-1}|\tilde{P}\rangle_A}{\langle\tilde{Q}|r_{12}^{-1}\Lambda(\omega)|\tilde{Q}\rangle_A + (\omega_{\tilde{Q}}^0 - \omega)\langle\tilde{Q}|\Lambda(\omega)|\tilde{Q}\rangle} \quad (6.27)$$

where $\langle\dots\rangle_A$ represents anti-symmetrized matrix elements and $\Lambda(\omega, r_{\text{eh}})$ is,

$$\Lambda(\omega, r_{\text{eh}}) = \frac{(\omega_{\tilde{P}}^0 - \omega)}{\gamma} e^{-r_{\text{eh}}\gamma} \quad (6.28)$$

where $\gamma = \langle\tilde{P}|r_{\text{eh}}^{-1}|\tilde{P}\rangle$. Some key features to point out in FD-GSIK, first is the form of $\Lambda(\omega, r_{\text{eh}})$, which is absent of any adjustable parameters and is an infinite-order particle-particle excitation operator in real space representation.[37] Next is that our electron-hole interaction kernel has two

forms of frequency dependency, first were obtained through the Löwdin's partitioning and the second is in the $\Lambda(\omega, r_{\text{eh}})$ operator. Therefore obtaining ω is performed through the iterative solution of Equation 6.26 by utilizing a starting guess of $\omega = \omega_{\tilde{P}}^0$ in $K_{\tilde{P}\tilde{P}}(\omega)$.

6.2.3 Optimization of $|\tilde{Q}\rangle$ Dressing Coefficients

The zeroth-order electron-hole wavefunction is given by $|\Psi_X\rangle^{(0)} = |\tilde{P}\rangle$ and the choice of the $|\tilde{Q}\rangle$ plays an important role in accurate description of electron-hole correlation. In this work, we construct $|\tilde{Q}\rangle$ as,

$$|\tilde{Q}\rangle = |h'e'\rangle \quad (6.29)$$

$$|h'\rangle = \sum_{j \in \{J\}} c_j |j\rangle \quad (6.30)$$

$$|e'\rangle = \sum_{b \in \{B\}} c_b |b\rangle \quad (6.31)$$

where a coefficient is calculated as,

$$c_r = \frac{e^{-\alpha \Delta E_r^2}}{\sum_r e^{-\alpha \Delta E_r^2}} \quad (6.32)$$

with $\Delta E_r^2 = (\epsilon_s^0 - \epsilon_r)^2$ where ϵ_s^0 is the particle/hole energies from the lowest single-particle excitation (ω_Q^0) in $|Q\rangle$.

Determination of \vec{c} is done by minimizing the first-order corrected excitation energy of a given dressed molecular orbital,

$$\min_{\alpha} [\langle \tilde{Q} | H_{eh} | \tilde{Q} \rangle] = \omega_Q^0 + \langle \tilde{Q} | v_{eh} | \tilde{Q} \rangle \quad (6.33)$$

since \tilde{Q} is an uncorrelated particle-hole basis the last term can be expressed in terms of density,

$$\langle \tilde{Q} | v_{eh} | \tilde{Q} \rangle = \langle \rho_{\tilde{Q}} r_{eh}^{-1} \rangle \quad (6.34)$$

where the density, $\rho_{\tilde{Q}}$ is defined as,

$$\rho_{\tilde{Q}}(1,2) = \tilde{Q}(1,2)\tilde{Q}(1,2) \quad (6.35)$$

$$= h'(1)e'(2)h'(1)e'(2) \quad (6.36)$$

$$= h'(1)h'(1)e'(2)e'(2) \quad (6.37)$$

$$\rho_{\tilde{Q}}(1,2) = \rho_{h'}(1)\rho_{e'}(2) \quad (6.38)$$

which provides particle and hole densities of the dressed states. These particle and hole densities are obtained through,

$$\rho_{h'}(1) = \sum_{j \in \{J\}} c_j^2 \rho_j^{h'}(1) \quad (6.39)$$

$$\rho_{e'}(2) = \sum_{b \in \{B\}} c_b^2 \rho_b^{e'}(2) \quad (6.40)$$

using the particle and hole densities that eigenfunctions of the Fock operator. The search for the coefficients scales as $N_\alpha \times (N_{\tilde{Q}}^{h'} \times N_{\tilde{Q}}^{e'})$ requiring search over all states. We reduce the computational cost by approximating the true densities $\rho_j^{h'} \rho_b^{e'}$, through a Gaussian approximation such that,

$$\rho_r^{e,h} \approx \rho_r^{G:e,h} = \frac{1}{\sigma_r^{e,h} \sqrt{2\pi}} e^{-\frac{1}{2} \left(\frac{r - \mu_r^{e,h}}{\sigma_r^{e,h}} \right)^2} \quad (6.41)$$

and are obtained by minimizing the Kullback–Leibler divergence[55] between the true densities $\rho_j^{h'} \rho_b^{e'}$ and the Gaussian probability distribution functions.

$$D_{\text{Kullback–Leibler}} = \int_V d\mathbf{r} \rho_j^{h'} \rho_b^{e'} \ln \left[\frac{\rho_j^{h'} \rho_b^{e'}}{\rho_j^{G:h'} \rho_b^{G:e'}} \right] \quad (6.42)$$

The computational effort for determination of approximate densities $\rho_r^{G:h'}, \rho_r^{G:e'}$ scales linearly with $N_\alpha \times (N_{\tilde{Q}}^{h'} + N_{\tilde{Q}}^{e'})$ and the calculation of $\langle \rho_{\tilde{Q}} r_{\text{eh}}^{-1} \rangle$ is performed analytically. Where $N_{\tilde{Q}}^{h'}$ and $N_{\tilde{Q}}^{e'}$ are the number of particle/hole orbitals in set $\{J\}$ and $\{B\}$. Both of these steps allow us to search

for the optimal α in construction of the \vec{c} coefficients at a reduced computational cost. Once the coefficients are obtained construction of $|\tilde{Q}\rangle$ is performed numerically.

6.3 Results and Discussion

6.3.1 Computational Details

The current work utilizes the above derivation of orbital-optimized dressed molecular orbitals and our FD-GSIK method to obtain correlated excitation energies of Ag_n nanowires where $n = 2, 4, 6, 8, 10, 12, 20, 40, 60, 80, 100$ using FD-GSIK method. The nanowires were constructed using a bond distance of 3.51 Å which was obtained by using the central Ag-Ag bond distance obtained from a Hartree-Fock (HF) optimized Ag_{100} calculation with LANL2DZ basis and effective core potential (ECP). The uncorrelated ground state single-particle states were calculated using HF method and LANL2DZ basis and ECP for the nanowires with the TERACHEM package. [143] The spatial MOs, $\psi(\mathbf{r})$ were generated with 100 points per dimension to generate a 10^6 point grid to obtain a dense grid for construction of the dressed molecular orbitals, $\tilde{\psi}(\mathbf{r})$. The grid boundary was set by imposing a cutoff tolerance of $|\psi(\mathbf{r})| \leq 10^{-12}$. The Monte Carlo integration was performed in decuplicate for obtaining maximum and minimum errors on the order of meV. Within this work we performed two sets of calculations utilizing different $|\tilde{P}\rangle$ states. In the first set of calculations we were interested in only the HOMO-LUMO gap, therefore $|\tilde{P}\rangle = |P\rangle$. As this gap was either the highest or second highest oscillator strength for all Ag nanowires. The next set of calculations looked into $|\tilde{P}\rangle$ that included all the single-particle excitations that were within 1 eV of the HOMO-LUMO gap (ω_p^0). This therefore gave us a collection of single-particle excitations near the band edge of the system. The dressed molecular orbitals were calculated as described in [subsection 6.2.3](#) to obtain the $|\tilde{Q}\rangle$ state for FD-GSIK.

6.3.2 HOMO-LUMO Gap for Ag Nanowires

The first investigation utilizing dressed molecular orbitals was to obtain electron-correlation for a specific excitation, the HOMO-LUMO gap. Which is classified as the longitudinal peak in vari-

ous reported works,[102, 103] and known to red shift as length is increased. We are interesting in understanding this trend for longer Ag nanowires and comparing to results from the previously reported TD-DFT work of Guidez and Aikens.[144] Utilizing FD-GSIK allows for calculation of excitation energies where the computational cost is independent of system size, therefore if the ground state wavefunction can be obtained, FD-GSIK can provide correlated excitation energies. This allowed for an investigation up to Ag₁₀₀, Figure 6.1. The reported HOMO-LUMO gap (ω_p^{HF})

Figure 6.1: Excitation energy of Ag nanowires using FD-GSIK for the HOMO-LUMO gap in comparison to reported TD-DFT results. †[144]

shows a red shift in the energy as system size increases. In addition, the first order corrected excitation defined by $\omega_p^{(1)} = \omega_p^{HF} - \langle P|r_{12}^{-1}|P\rangle$, is reported. Also observed is that $\omega_p^{FD-GSIK}$ and ω_p^{TD-DFT} are in great agreement for the nanowires up to Ag₄₀, replicating the trend that is commonly reported for this small nanowire series. Interestingly as the number of Ag atoms increases the trend is non-convergent and there is an increase in energy, or a blue shift, in the excitation as the system approaches Ag₁₀₀. The use of dressed molecular orbitals and FD-GSIK has allowed for investigation of larger nanowires and demonstrates a non-obvious trend in the excitation energy with respect to system length. This was accomplished by the computationally efficient FD-GSIK

method which was developed for computationally challenging systems through the use of a compressed molecular orbital basis.

6.3.3 Collection of single-particle excitations for Ag Nanowires

In addition we were interested in the set of single-particle excitations near the HOMO-LUMO gap. As this set will give us insight into the effect of the multi-reference nature of high density of states near the HOMO-LUMO gap, this is easily observed for Ag₁₀₀ in, [Figure 6.2](#). Which shows

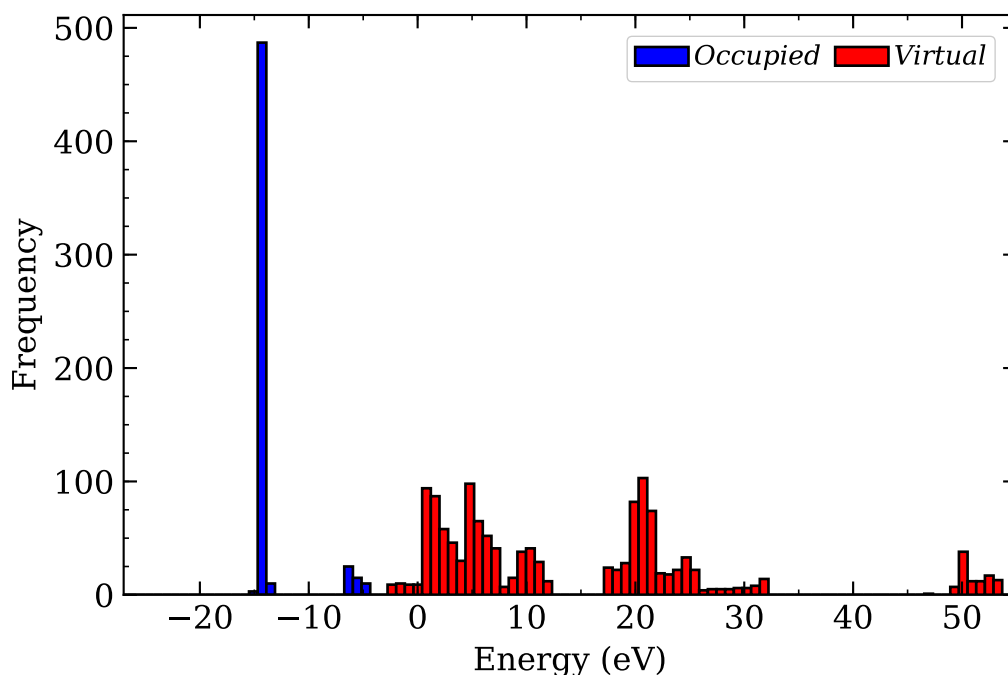

Figure 6.2: Histogram of molecular orbital energies for Ag₁₀₀ near the HOMO-LUMO gap.

a clear HOMO-LUMO gap but that there exist numerous orbitals that lie near each other around the HOMO-LUMO gap. Clear breaks in the continuum of energy is not observed until -10 eV and 15 eV for the occupied and virtual space, respectively. In this work we are mainly interested in the single-particle excitations that exist within 1 eV of the HOMO-LUMO gap, as these are the most contributing to the degeneracy near the HOMO-LUMO gap. This defines our $|\tilde{P}\rangle$ state, in which each unique hole/particle state is evenly weighted and $|\tilde{Q}\rangle$ consists of every particle-hole state not in $|\tilde{P}\rangle$. The results are shown in [Figure 6.3](#). Observed is a red shift in the collective excitation up to Ag₄₀ and then an increase in energy for Ag₆₀ and Ag₇₀ with a slight decrease in energy for Ag₁₀₀.

Figure 6.3: Comparison of the uncorrelated gap to the first-order corrected and FD-GSIK correlated excitation obtained for $|\tilde{P}\rangle$ in Ag nanowires.

The uncorrelated ground state energies are in general higher due to the multi-reference excitation energy used in construction of the dressed molecular orbital basis.

6.3.4 Error analysis and timing data

With FD-GSIK the use of Monte Carlo integration allows us to reduce the error in the excitation energies in a computationally efficient approach. Presented in [Table 6.1](#) and [Table 6.2](#) are the standard deviations of the FD-GSIK excitation energies for all the systems presented. In addition, the single-core total cumulative CPU time is reported for each system for the 1+10 MC integration's, one run to evaluate $\langle \tilde{P} | r_{12}^{-1} | \tilde{P} \rangle$ and then ten FD-GSIK integrations. These standard deviations result in meV errors, providing confidence in the reported energies. The error within a FD-GSIK calculation are systematically improvable through additional MC integrations, which can be performed in at low computational cost due to the construction of the dressed molecular orbital and FD-GSIK method.

Table 6.1: The standard deviation of $\omega_p^{FD-GSIK}$ from 1+10 runs of the Monte Carlo integration with total single-core CPU computational time.

Chemical Formula	$\omega_p^{FD-GSIK}$ (eV)	Standard Deviation (meV)	Total CPU Time (Hours)
Ag ₂	1.5835	3.68E-01	1.31
Ag ₄	1.2387	1.57E-01	1.35
Ag ₆	1.0766	1.97E-01	1.36
Ag ₈	0.8822	3.52E-01	1.35
Ag ₁₀	0.8690	2.62E-01	1.32
Ag ₁₂	0.7757	4.75E-01	1.33
Ag ₂₀	0.5217	3.70E-01	1.34
Ag ₄₀	0.4805	6.96E-01	1.32
Ag ₆₀	0.6695	5.50E-01	1.33
Ag ₈₀	0.8671	4.44E-01	1.35
Ag ₁₀₀	1.8456	2.59E-01	1.33

Table 6.2: The standard deviation of $\omega_{\bar{p}}^{FD-GSIK}$ from 1+10 runs of the Monte Carlo integration with total single-core CPU computational time.

Chemical Formula	$\omega_{\bar{p}}^{FD-GSIK}$ (eV)	Standard Deviation (meV)	Total CPU Time (Hours)
Ag ₁₀	2.7217	5.32E-02	1.34
Ag ₂₀	2.5120	9.68E-02	1.36
Ag ₄₀	2.3287	3.38E-01	1.34
Ag ₆₀	2.7574	1.30E-01	1.35
Ag ₈₀	2.8929	1.56E-01	1.34
Ag ₁₀₀	2.6626	1.84E-01	1.34

6.4 Conclusions

The dressed molecular orbital basis was presented to compress the configuration space for understanding multi-reference single-particle excitations. Allowing for a computationally efficient multi-reference molecular orbital basis that can tackle large many-electron systems which have many single-particle excitations. The use of dressed molecular orbitals allowed us to investigate a highly degenerate metallic like system, silver nanowires. But in general, this formulation can be used for other chemical systems in which multi-reference characteristics are of interest. In conjunction with the frequency-depend geminal-screened electron-hole interaction kernel (FD-GSIK) method we were able to obtain electron-correlated excitation energies for the HOMO-LUMO gap

and a collection of excitations near the HOMO-LUMO gap up to Ag_{100} . Observed within the presented work is a non-obvious trend in the energy of the HOMO-LUMO gap which blue shifts at longer nanowire lengths.

Chapter 7

Derivation of Moment Generated Molecular Orbital Basis

7.1 Introduction

Presented in this chapter is a derivation for the moment generated molecular orbital basis. The purpose of this derived work serves as an alternative to the frequency-dependent geminal-screened electron-hole interaction kernel presented in [Chapter 5](#) and [Chapter 6](#). The main limitation within FD-GSIK is that the $\Lambda(\omega, r_{eh})$ projection operator will not project to particle-hole states lower than the specified $|Q\rangle$ state. Therefore the selection of $|Q\rangle$ is limited to a particle-hole state that is in general the next particle-hole state after $|P\rangle$. The goal of the moment generate molecular orbital basis was to provide an electron-correlated approach that was free of the $\Lambda(\omega, r_{eh})$ projection operator and utilized the moments of the particle/hole states to capture electron-correlation. The body of this chapter is entirely the derivation of the method and will contain no results to validate the method.

7.2 Theory

The effective many-body electron-hole Hamiltonian has the general form

$$H_{\text{eh}} = H_{\text{e}}^0 + H_{\text{h}}^0 + V_{\text{ee}} + V_{\text{hh}} + V_{\text{eh}} \quad (7.1)$$

where

$$H_{\text{e}}^0 = \sum_{e_1 e_2} \langle e_1 | f^e | e_2 \rangle e_1^\dagger e_2 \quad (7.2)$$

$$H_{\text{h}}^0 = \sum_{h_1 h_2} \langle h_1 | f^h | h_2 \rangle h_1^\dagger h_2 \quad (7.3)$$

$$V_{\text{ee}} = \sum_{e_1 e_2 e_3 e_4} \langle e_1 e_2 | w_{\text{ee}} | e_4 e_3 \rangle e_1^\dagger e_2^\dagger e_3 e_4 \quad (7.4)$$

$$V_{\text{hh}} = \sum_{h_1 h_2 h_3 h_4} \langle h_1 h_2 | w_{\text{hh}} | h_4 h_3 \rangle h_1^\dagger h_2^\dagger h_3 h_4 \quad (7.5)$$

$$V_{\text{eh}} = \sum_{h_1 h_2 e_1 e_2} \langle e_1 h_1 | v_{\text{eh}} | e_2 h_2 \rangle e_1^\dagger h_1^\dagger h_2 e_2 \quad (7.6)$$

where e^\dagger and h^\dagger are particle and hole creation operators, and f_e and f_h are the Fock operators. The electron-hole Hamiltonian can be factored into a sum of non-interaction terms and interaction terms. For a 1-particle 1-hole state, further simplification can be achieved and the total Hamiltonian can be expressed as

$$H_{\text{eh}} = H_{\text{eh}}^0 + V_{\text{eh}} \quad (7.7)$$

The non-interacting Hamiltonian H_{eh}^0 is obtained from the Fock operator whose eigenfunctions are (uncorrelated) particle-hole excited states

$$H_{\text{eh}}^0 = \omega_p^0 |P\rangle = (\varepsilon_a^e - \varepsilon_i^h) |\Phi_0^h \Phi_0^e\rangle \quad (7.8)$$

We are interested in calculating the many-body correction to ω_p^0 due to electron-hole correlation in the system.

$$H_{\text{eh}} |\Psi_X\rangle = \omega |\Psi_X\rangle \quad (7.9)$$

We start by defining the zeroth-order approximation of the electron-hole wavefunction as,

$$|\Psi_X\rangle^{(0)} = |P\rangle \quad (7.10)$$

and the correlated electron-hole wavefunction Ψ_X is defined as

$$|\Psi_X\rangle = c_P |P\rangle + c_Q |Q\rangle \quad (7.11)$$

where,

$$|P\rangle = \Phi_0^h \Phi_0^e \quad (7.12)$$

$$|Q\rangle = \left(\Omega_h \Phi_0^h \right) \left(\Omega_e \Phi_0^e \right) \quad (7.13)$$

In this presented derivation $\Omega_{e,h}$ is a moment operator that is defined as $\Omega_{e,h} = \left(r_{e,h}^m - \langle r_{e,h}^m \rangle \right)$, where m is the moment. The moment operator has the following property,

$$\langle \Phi_0^{e,h} | \Omega_{e,h} | \Phi_0^{e,h} \rangle = 0 \quad (7.14)$$

$$\langle \Phi_0^{e,h} | \left(r_{e,h}^m - \langle r_{e,h}^m \rangle \right) | \Phi_0^{e,h} \rangle = \langle \Phi_0^{e,h} | r_{e,h}^m | \Phi_0^{e,h} \rangle - \langle r_{e,h}^m \rangle = 0 \quad (7.15)$$

therefore $\Omega_h\Omega_e$ in Equation 7.13 can be expanded as,

$$\Omega_h\Omega_e = (r_h^m - \langle r_h^m \rangle) (r_e^{m'} - \langle r_e^{m'} \rangle) \quad (7.16)$$

$$= \left(r_h^m r_e^{m'} + \langle r_h^m \rangle \langle r_e^{m'} \rangle - r_h^m \langle r_e^{m'} \rangle - \langle r_h^m \rangle r_e^{m'} \right) \quad (7.17)$$

where m and m' are different moments for the hole and particle state respectively. Projecting $\langle P|$ and $\langle Q|$ onto Equation 7.9 results in the following matrix expression,

$$\begin{bmatrix} \langle P|H_{ch}|P\rangle & \langle P|H_{ch}\Omega_h\Omega_e|Q\rangle \\ \langle Q|H_{ch}|P\rangle & \langle Q|H_{ch}\Omega_h\Omega_e|Q\rangle \end{bmatrix} \begin{bmatrix} C_P \\ C_Q \end{bmatrix} = \omega \begin{bmatrix} 1 & 0 \\ 0 & \langle Q|\Omega_h\Omega_e|Q\rangle \end{bmatrix} \begin{bmatrix} C_P \\ C_Q \end{bmatrix} \quad (7.18)$$

simplified as,

$$\begin{bmatrix} H_{PP} & H_{PQ} \\ H_{PQ} & H_{QQ} \end{bmatrix} \begin{bmatrix} C_P \\ C_Q \end{bmatrix} = \omega \begin{bmatrix} 1 & 0 \\ 0 & S_{QQ} \end{bmatrix} \begin{bmatrix} C_P \\ C_Q \end{bmatrix} \quad (7.19)$$

for which \mathbf{H} can be expanded as,

$$\begin{bmatrix} H_{PP} & H_{PQ} \\ H_{PQ} & H_{QQ} \end{bmatrix} = \begin{bmatrix} H_{PP}^0 & H_{PQ}^0 \\ H_{PQ}^0 & H_{QQ}^0 \end{bmatrix} + \begin{bmatrix} V_{PP} & V_{PQ} \\ V_{PQ} & V_{QQ} \end{bmatrix} \quad (7.20)$$

for which the definitions of the matrix elements are as follows:

$$V_{PP} = \langle \Phi_0^h \Phi_0^e | r_{12}^{-1} | \Phi_0^h \Phi_0^e \rangle \quad (7.21)$$

$$V_{PQ} = \langle \Phi_0^h \Phi_0^e | r_{12}^{-1} \Omega_h \Omega_e | \Phi_0^h \Phi_0^e \rangle \quad (7.22)$$

$$V_{QQ} = \langle \Phi_0^h \Phi_0^e | \Omega_h \Omega_e r_{12}^{-1} \Omega_h \Omega_e | \Phi_0^h \Phi_0^e \rangle \quad (7.23)$$

$$H_{PP}^0 = \omega_p^0 \quad (7.24)$$

$$H_{PQ}^0 = \langle P | H_{eh}^0 | Q \rangle = \omega_p^0 \langle P | Q \rangle = 0 \quad (7.25)$$

$$H_{QQ}^0 = \langle Q | H_{eh}^0 | Q \rangle = \langle \Omega_h \Phi_0^h \Omega_e \Phi_0^e | H_h^0 + H_e^0 | \Omega_h \Phi_0^h \Omega_e \Phi_0^e \rangle \quad (7.26)$$

$$= \langle \Omega_h \Phi_0^h | H_h^0 | \Omega_h \Phi_0^h \rangle \langle \Phi_0^e | \Omega_e \Omega_e | \Phi_0^e \rangle + \langle \Omega_e \Phi_0^e | H_e^0 | \Omega_e \Phi_0^e \rangle \langle \Phi_0^h | \Omega_h \Omega_h | \Phi_0^h \rangle \quad (7.27)$$

$$H_{QQ}^0 = \sum_k c_k^2 E_k^{0,h} \sum_k c_k^2 + \sum_k c_k^2 E_k^{0,e} \sum_k c_k^2 \quad (7.28)$$

with $c_k = \langle k | r^m | 0 \rangle$.

7.3 Conclusion

That concludes the derivation of moment generated molecular orbital basis which allows for obtaining electron-correlation for any given $|P\rangle$ and $|Q\rangle$ state. The advantage of the presented derivation is that the choice of $|P\rangle$ and $|Q\rangle$ is not restricted by the correlated operator, unlike the work presented in [Chapter 5](#) and [Chapter 6](#). The implementation and validation of the presented derivation is still in order, but the derivation in its presented form is still a novel approach for efficient implementation of electron-hole interaction kernel.

Chapter 8

Implementation of Permutation Sampling Monte Carlo Integration Method

8.1 Introduction

The permutation sampling Monte Carlo method is a universal integration technique that was developed within the Chakraborty research group to tackle the challenges of multi-dimensional integrals. Within the research group we are heavily interested in avoiding the atomic-orbital to molecular-orbital integral transformation. While developing new excited state methods for the grid based approaches, integrals become burdensome in higher dimensions. This chapter will focus on the computer science of the recent code implementation in C++ for permutation sampling Monte Carlo method as key decisions were made to program a code that was computationally efficient, portable, and multi-purpose.

8.2 Theory

The theory presented here is to briefly introduce the concepts of the permutation sampling Monte Carlo integration method which is a part of a larger investigation in ionization energies using

Green's function within the group. To begin, let us evaluate a simple 1-D Gaussian function,

$$\int_{-\infty}^{\infty} e^{-x^2} dx = \sqrt{\pi} \quad (8.1)$$

using Monte Carlo method of a million uniform random points. This is a simple enough task as we can easily evaluate these million points in a matter of seconds, the accuracy of the integral evaluation is very reasonable with error of 1×10^{-3} . Now lets move up to a 3-D Gaussian function,

$$\int_{-\infty}^{\infty} e^{-\mathbf{r}^2} d\mathbf{r} \quad (8.2)$$

where $\mathbf{r}^2 = x^2 + y^2 + z^2$, therefore the 3-D Gaussian integral is a product of three 1-D Gaussian functions.

$$\int_{-\infty}^{\infty} e^{-\mathbf{r}^2} d\mathbf{r} = \int_{-\infty}^{\infty} e^{-x^2} dx \times \int_{-\infty}^{\infty} e^{-y^2} dy \times \int_{-\infty}^{\infty} e^{-z^2} dz \quad (8.3)$$

$$= \sqrt{\pi} \times \sqrt{\pi} \times \sqrt{\pi} = \pi^{\frac{3}{2}} \quad (8.4)$$

Now a choice must be made in terms of evaluating this 3-D integral with respect to the number of Monte Carlo points. If we want to maintain the initial conditions from the 1-D integral that means the 3-D integral could be evaluated with 3.0×10^6 Monte Carlo points. This choice in evaluation will result in great accuracy of the integral value, but the cost of the calculation is high, $N_{M.C.}^3$, a couple of hours. The other choice to be made in terms of evaluating the integral would be to maintain a million points between all three dimensions. The computational cost is now $(\frac{N_{M.C.}}{3})^3$ which is now a few minutes. But the accuracy of the integral evaluation will be on the order of 1.0×10^0 . As this simple example demonstrates dimensionality of the integral evaluation can be computationally burdensome, even for 3-D. But what if someone is interested in two particle or four particle complex integrals that are 6-D or 12-D as is the nature of the work discussed in

[Chapter 5](#)

Let us consider an generic 12-dimensional integral,

$$I = \int_D d\mathbf{r}_1 d\mathbf{r}_2 d\mathbf{r}_3 d\mathbf{r}_4 \rho(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \mathbf{r}_4) \frac{\Lambda(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \mathbf{r}_4)}{\rho(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \mathbf{r}_4)} \quad (8.5)$$

where $\Lambda(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \mathbf{r}_4)$ is a 4-particle function which is evaluated through sampling from $\rho(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \mathbf{r}_4)$, where $\rho(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \mathbf{r}_4)$ is a valid probability distribution function that is defined as,

$$\int_D d\mathbf{r}_1 d\mathbf{r}_2 d\mathbf{r}_3 d\mathbf{r}_4 \rho(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \mathbf{r}_4) = 1 \quad (8.6)$$

$$\rho(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \mathbf{r}_4) \geq 0 \quad (8.7)$$

Permutation sampling Monte Carlo begins by decoupling the dimensionality of the N-dimensional point for evaluation by choosing each dimension of the N dimensions based on the probability distribution within each N dimension. In essence, instead of sampling each Monte Carlo point from a N-dimensional probability distribution, the N-dimensional point is constructed from uncoupled N probability distributions. The decoupling starts with a coordinate transformation where $\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \mathbf{r}_4$ corresponds to q values, such that $q \in [0, 1]$.

$$I = \int_{-\infty}^{\infty} d\mathbf{r}_1 d\mathbf{r}_2 d\mathbf{r}_3 d\mathbf{r}_4 \Lambda(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \mathbf{r}_4) \quad (8.8)$$

$$= \int_1^0 dq_1 dq_2 dq_3 \dots dq_{12} \Lambda(q_1 q_2 q_3 \dots q_{12}) J(q_1 q_2 q_3 \dots q_{12}) \quad (8.9)$$

where J is the Jacobian associated with the coordinate transformation. This allows for the integration to occur in intervals of $[0, 1]$ instead of infinite bounds. This coordinate transformation also allows for the decoupling of the $\rho(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \mathbf{r}_4)$ distribution that will be sampled from in [Equation 8.5](#) by making ρ to be a product of 12 one-dimensional probability distribution functions in q -space. In essence, instead of sampling each Monte Carlo point from a N-dimensional probability distribution, the N-dimensional point is constructed from uncoupled N probability distributions,

$$\rho(q) = \rho_1(q_1) \times \rho_2(q_2) \times \rho_3(q_3) \times \dots \times \rho_{12}(q_{12}) \quad (8.10)$$

The next key component to permutation sampling Monte Carlo is how these individual distributions, generically labeled as $\rho_d(q_d)$ are evaluated to sample, $\rho(q)$ in Equation 8.8. Imagine that each distribution, $\rho_d(q_d)$ is a deck of cards, and a hand ($\rho(q)$) is dealt by drawing the top card of each unique deck. This can be demonstrated as,

$$\begin{array}{cccccc}
 \rho_1 & \rho_2 & \rho_3 & \cdots & \rho_{12} \\
 \downarrow & \downarrow & \downarrow & & \downarrow \\
 q_1^A & q_2^A & q_3^A & \cdots & q_{12}^A \\
 q_1^B & q_2^B & q_3^B & \cdots & q_{12}^B \\
 \vdots & \vdots & \vdots & & \vdots \\
 q_1^Z & q_2^Z & q_3^Z & \cdots & q_{12}^Z
 \end{array} \tag{8.11}$$

where the superscripts A, B, \dots, Z are the number of hands dealt. In this situation a hand would then be the $\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \mathbf{r}_4$ point to be evaluated during Monte Carlo integration. The next Monte Carlo point will then be the next hand dealt from the 12 one-dimensional probability distribution functions. To improve the accuracy of the integral value each deck could then be shuffled continuing to evaluate Monte Carlo points as described, thereby allowing for redistribution of the probability distribution function.

$$\begin{array}{cccccc}
 \rho_1 & \rho_2 & \rho_3 & \cdots & \rho_{12} \\
 \downarrow & \downarrow & \downarrow & & \downarrow \\
 q_1^G & q_2^F & q_3^T & \cdots & q_{12}^W \\
 q_1^D & q_2^I & q_3^M & \cdots & q_{12}^V \\
 \vdots & \vdots & \vdots & & \vdots \\
 q_1^P & q_2^L & q_3^X & \cdots & q_{12}^A
 \end{array} \tag{8.12}$$

Permutation sampling Monte Carlo then allows for evaluation of complex multi-dimensional integrals as a one-dimensional integral in q -space. The derivation of permutation sampling Monte Carlo was demonstrated for a 12-dimensional generic integral with an undefined Λ function. In

practice permutation sampling Monte Carlo is N-dimensional and the choice of function is independent to the sampling. Permutation sampling Monte Carlo is a generic integration technique that can be applied to any choice of integral evaluation.

8.3 Object-Oriented Programming

As stated, the theory of permutation sampling Monte Carlo is generic in terms of the number of dimensions for integration and the function of choice. Therefore it was a great coding project to practice the programming paradigm, object-oriented programming (OOP). OOP is a programming paradigm based on creating "objects" that contains both data and the functions for the data. [145] In general objects are instances of classes, which are definitions of the data format and available procedures within the class. Objects and classes are readily seen within the real world and not simply in programming. There are major principles to discuss with regards to OOP, they are polymorphism, composition and inheritance, abstraction, and encapsulation.

8.3.1 Polymorphism

Polymorphism is one of many forms. For example, think of a hydrogen, helium and sodium atom, each of these are objects. They all belong to a element class, which contains the information on their name, symbol, atomic number, atomic weight, etc. The individual response each atom has to electromagnetic radiation is an example of a procedure as the electromagnetic radiation is information going to the atom, the atom then has its own procedure on what to do with that information. Polymorphism allows for construction of multiple objects from the same class.

8.3.2 Composition and Inheritance

Let us now consider dimers of the atoms, creating structure of two atoms. The structure can be stored in a class molecule, which contains information on the number of atoms, the position of the atoms and which atoms are bonded to each other. In the example I have created a new class

that that contains two instances of class atoms. But the way the molecule class interacts with these atom classes has two different forms, composition or inheritance.

First is composition, where the molecule class is composed of two simple atoms classes. Composition is a useful tool when developing in that the top level object can be constructed through a complex network of other objects. When information is asked to the molecule class about the properties contained in the atom class, molecule will ask the atom class for that information. Second is inheritance where the molecule class has inherited two atom classes and their separate functionality. The key difference comes with how the molecule class uses the information from each atom class. In inheritance the information and functionality that is unique of an atom class can be utilized by molecule class. Therefore molecule class can take responsibility for passing information of atomic number or weight without have to ask the atom class. The doctrine of composition over inheritance was implemented within permutation sampling Monte Carlo. This doctrine means objects were responsible for their own functionality and their information.

8.3.3 Abstraction

Abstraction is the idea that the complexity associated with a function or information within a object is obscured by the requester of the information. For example in the theory of permutation sampling Monte Carlo, there was a discussion between integrating a Gaussian or a complex quantum chemistry problem. The user defined function is the example of the top level object, as this is the information that is needed when sampling the integral, *i.e.* what is the value of the integral at this position. In the case of a Gaussian it is simply, $f(\mathbf{r}) = e^{-\mathbf{r}^2}$, but for a complex quantum chemistry problem the value at position r needs information on molecular orbitals at $\chi(r)$. This is beneficial because it allows classes to be dynamic in their use as long as they contain the matching procedures at the top-level. But in terms of the implementation of permutation sampling Monte Carlo, it has no preference to how the value is being calculated, it just needs to know what value to update within the calculation. Abstraction is hiding internal implementation details to other objects when information is requested.

8.3.4 Encapsulation

Encapsulation is how the data within the object is made private to other objects. The principle of encapsulation is about which objects can obtain or modify data that is owned by another class. The information within an object can be public or private data. Where public data can just be utilized by outside objects, but private data can not be easily accessed. That does not mean private data is never recoverable, but has to be requested and it is up to owner of the data if that information can be passed along. Encapsulation is in the same light as abstraction but is further restrictive towards the access to information.

8.4 C++ Language Features

With this programming paradigm framework set, the natural programming language of choice was C++, a language that was built by Bjarne Stroustrup as "C with Classes". As it easily allows many of the principles of OOP in quick and easily implementation as seen in [Figure 8.1](#). In addition C++ allows much more creative and beneficial features such as references, encapsulation of copy constructor and portability to CUDA C. References are denoted with "&" and used as an alias to an already existing variable. References are important within coding in that references reduce the memory footprint of a code. Notice in Line 7 ([Figure 8.1](#)) the declaration and assignment of memory of two double variables (*atm1_weight* and *atm2_weight*). These variables are then passed by reference (Line 23) to the function *get_weight()*, which allows the function to directly effect the data stored in memory for *get_weight()*. If these variables were passed by value, a copy of the values would be sent to *get_weight()* where any modifications would not be reflected in Line 7 as these values are copies of the original data, *atm1_weight* and *atm2_weight*. Utilizing references within permutation sampling Monte Carlo allows for dramatic memory reduction as duplication of information is not performed. The next benefit within C++ is the encapsulation of the copy constructor for classes. This is demonstrated in Line 26 where the copy constructor is put into private information contained within atom class. This therefore enforces that any instance of the atom class must be passed by reference. Therefore any large object that is created will not be

Figure 8.1: Generic C++ class that demonstrates OOP principles.

```
1 class Molecule {
2     public: //Public access for information
3         //Functions that provide private information
4         void get_number_atoms( int &natm) { natm = natm_ ; } ;
5         void get_molecular_weight(double &weight) =
6         {
7             double atm1_weight, atm2_weight ;
8             // Request for information from Atom class [Composition and
9                 Abstraction]
10            atm1_get_weight(atm1_weight) ;
11            atm2_get_weight(atm2_weight) ;
12            weight = atm1_weight + atm2_weight;
13        } ;
14        [...]
15    private: //Private information denoted with '_' at end [Encapsulation]
16        int natm_ ;
17        // [Polymorphism]
18        Atom atm1_ ;
19        Atom atm2_ ;
20        [...]
21};
22class Atom {
23    public:
24        void get_weight(double &weight) { weight = weight_ ;} ;
25        [...]
26    private:
27        double weight_ ;
28        Atom(const Atom& rhs) ; //Copy Constructor
29        [...]
30};
```

copied as it is passed to other objects and functions. The final reason for using C++ in development of permutation sampling Monte Carlo was for the portability to graphics processing units (GPU) using Compute Unified Device Architecture [CUDA] C. Which is a parallel computing platform in the C language created by NVIDIA as a tool for parallel programming on GPU's. The end goal of this project is to utilize GPU acceleration, allowing for massive parallization in a integral calculations resulting in fast sampling and compute time.

8.5 Conclusions

The coding project resulted in approximately 6,000 lines of code, the biggest coding project within the presented research, which is completely object-oriented for the groups future integral needs. Included in [Figure 8.2](#) is the full source code for the main code for permutation sampling Monte Carlo. Which shows the techniques discussed in the previous sections within this chapter. It is important to deconstruct this source code to truly understand some of the complexity, first from Lines 16-22 is just preparation of how data will be printed and starting a timer to be used for calculation of run time. Next from Lines 32-36 there is declaration of all the classes that are needed for the code. The Lines 44-52 build each of these classes, then once building is complete a check is performed to ensure continuity within the code. [For example that number of dimensions is equal throughout each object] Next is Line 53 which is the run of the permutation sampling code. It isn't until this line that the calculation begins. Then there is the print results in Line 54, all the steps needed in run are abstracted, for once the run is complete results are ready to be printed. Finally are the lines 64-73 which calculate run time internally and proceed to normal termination of the code.

In addition I have included a graphical hierarchy of the class structure within the permutation sampling Monte Carlo code, [Figure 8.3](#). This graphically depicts how classes are related within the code. The way information and data flows is designated by pointed arrows. As seen in the figure all the arrows flow downwards, this exemplifies composition over inheritance and encapsulation as no arrows are bi-directional.

Included in [Appendix A](#) is the manual for permutation sampling Monte Carlo.

Chapter 9

Collaborative Projects

9.1 Introduction

This chapter will introduce collaborative projects that I was apart of during my time at Syracuse University. I had the great opportunity to work on projects with the Dr. Pranav Soman group at the Syracuse Biomaterials Institute and the Dr. Weiwei Zhang group within the Department of Chemistry. I will provide brief introduction into the collaborative work and the results that I was able to contribute to the projects.

9.2 Investigation of Optical Properties of Silver Nanoclusters

9.2.1 Introduction

Recently a synthetic method was developed by Kunwar *et. al.*[146, 147] which demonstrated the creation of silver nanoclusters in a polymer film by direct-laser writing. Their method was able to create highly photostable Ag nanoclusters of various sizes entrapped in the polymer film. This synthetic procedure allows for size-controlled Ag nanocluster formation that is dependent on irradiation time. Since the Ag nanoclusters are trapped in a polymer matrix aggregation of the nanoclusters is prevented. Thereby allowing for the novel examination of the optical properties as a function of time and size, see Figure 9.1. They observe a sharp increase in fluorescent intensity to

a maximum, followed by a gradual decay in intensity during Ag nanocluster formation. Currently, their experimental studies are limited in definitely providing information of the Ag nanocluster structure. Hence, they are unable to prove the transition of these Ag nanocluster to nanoparticles to bulk material.

Figure 9.1: (a) Fluorescence intensity of Ag polymer matrix during irradiation. The inset demonstrates the effect of fluorescent intensity with various irradiation intensities. (b) Fluorescence microscopy images at time points 1-8 from (a). (Figure 1)[146]

9.2.2 Results

The intent of the presented work will be to provide collaborative theoretical support for their experimental claims. The theoretical investigation will primarily focus on understanding excited state properties like oscillator strength and excitation energy as a function of increasing number of atoms. This will hopefully gain insight into the experimental claims that the an increased fluorescent intensity can be observed within a series of silver clusters.

Since the theoretical investigation is trying to understand the fluorescent quenching from experiment, the Hartree-Fock calculations will need to account for Ag clusters ranging from <1 nm

to 5 nm (16 ~ 14000 atoms). This equates to a range of 752 to 658,000 total electrons, which is computationally expensive and impractical. The use of CRENBs basis and effective core potential (ECP) will assist with the theoretical choke by limiting the number of active electrons from 47 per atom to 11 per atom.[148] The use of ECP will allow for a significant reduction in the number of basis functions by approximating the core electrons as a pseudopotential as compared to a full electron basis like 3-21G, Table 9.1. Utilizing CRENBs basis and ECP also significantly reduces the number of basis functions to just the valence shell. Even though we are using a very minimal basis set, we are limited by the SCF procedure to (>2 nm) Ag clusters in size.

Table 9.1: **The number of basis functions for 2nm Ag cluster**

Basis set	N_b	N_{elec}
3-21G	17280	11280
CRENBs ECP	4320	2640

The presented work will focus on a range of Ag clusters under <2 nm in diameter, Table 9.2. The initial geometries for the clusters were generated by cutting dots of the desired size from metallic Ag structure.[149] The SCF procedure was performed using the Q-CHEM package[150] with CRENBs basis and ECP. Instead of performing geometry optimization calculations that would likely fail or be too computationally expensive, a systematic approach was taken to obtain the lowest energy structure.

Table 9.2: **Computational impact of Ag clusters.**

N_{atm}	N_b	N_{elec}
2	36	22
16	288	176
44	792	484
68	1224	748
80	1440	880
92	1656	1012
104	1872	1144
116	2088	1276
128	2304	1408

In order to keep the cost of the SCF procedure at a minimum it was decided that we would like

to preserve as much symmetry of the cluster as possible. Since the geometry was cut from a pristine bulk structure it was expected that the average distance of the silver atoms should increase to relax the structure. Therefore it was decided that scaling the distance of the atoms from the origin would be the grounds for the geometry optimization. Where the inner shell is defined as the atoms that had a distance $\leq \frac{r}{2}$, where r is the radius of the cluster and the outer shell where distances $> \frac{r}{2}$. The inner shell will be scaled by α and the outer shell by β to allow the cluster to be dynamically scaled. The various permutations of α and β from the initial structure were then run to obtain their total SCF energy to find the lowest energy structure. This was then used to construct an energy surface for Ag_{80} in, **Figure 9.2**, where the blue dot was the lowest energy geometry from the systematic geometry search. This geometry search was performed for all the structures. This

Figure 9.2: A plot of the total SCF energy for Ag_{80} at various geometries that were systematically searched for by a scalar radial approach.

radial scaling consisted of two components, which were separated by the inner shell and outer shell of the cluster.

A key excited state property that will aid in understanding the experimental observations is the oscillator strength. The oscillator strength is the probability of an excitation between an occupied and unoccupied orbital. If we can understand the oscillator strength as a function of increasing atom size, then the theoretical work can help understand the experimental observations. The oscillator strength was calculated for all single excitation permutations for the 10 highest energy

occupied and 10 lowest energy unoccupied Hartree-Fock orbitals. These results were then histogrammed according the calculated oscillator strength to better interpret the results, [Figure 9.3](#). The width of the bins are related to the energy of the excitation, therefore a narrow bin is the lowest excitation. These results show that as the number of silver atoms increase there is a point, Ag₆₈, for which there is a sharp increase in oscillator strength. Which is the exact observation seen from Kunwar *et. al.* [[146](#), [147](#)].

Figure 9.3: A plot which shows a histogram of oscillator strengths for the 10 highest occupied and 10 lowest unoccupied orbitals of silver nanoclusters.

9.2.3 Conclusion

The challenge within the presented Ag nanoclusters was in regards to the next interest in obtaining electron-correlated excitation energies. It was at this junction that development began on the previously reported work in [Chapter 5](#) to assist within this collaborative project. The true advancement towards this project lies in the dressed molecular orbitals method presented in [??](#). With these two methods developed the understanding of the excited states for the various Ag nanoclusters could continue.

9.3 Understanding Mn²⁺ Dopant Migration in CdS/ZnS Quantum Dots

9.3.1 Introduction

They were interested in gathering a computational understanding of dopant migration versus dopant ejection in incorporated dopants in core/shell quantum dots for a manuscript in preparation. This thermodynamic study expands on their previously reported work.[151] The goal of the computational work was to determine if Mn²⁺ dopant ion in a CdS/ZnS core/shell quantum dot was migrating or ejecting from the dot to provide further conclusions to the experimental work. The difference is subtle but is all dependent on the thermodynamics of the interaction of the dopant ion to the core/shell lattice. Dopant migration is an activated processes where energy is needed for the dopant to move over energy barriers. Dopant ejection is not an activated process and requires no energy for the dopant to traverse the quantum dot. Below I am providing the theoretical details and results for these studies that are being prepared for publication.

9.3.2 Theory

The thermodynamics of the dopant migration was investigated computationally by evaluating the relative effective radial Helmholtz free energy, $\Delta A_{\text{eff}}(r)$ experienced by the dopant ion. The $\Delta A_{\text{eff}}(r)$ provided key thermodynamic insight into effect of dopant ion at the core/shell interface and the experimentally observed temperature dependence of the migration. To calculate $\Delta A_{\text{eff}}(r)$, we define the radial configuration integral $Z(r, T)$ which is mathematically expressed as [Equation 9.1](#)

$$Z(r, T) = \int_{-\infty}^{+\infty} \partial \mathbf{r}' \exp \left[\frac{-U_{\text{dopant-lattice}}(\mathbf{r}')}{k_B T} \right] \partial (|\mathbf{r}'| - r) \quad (9.1)$$

where, T is temperature, k_B is Boltzmann constant. The relationship between the Helmholtz free energy and the configuration integral is well-known [152] and the free energy is proportional to

the logarithm of the configuration integral

$$A(r, T) \propto -RT \ln [Z(r, T)] \quad (9.2)$$

Using $Z(r, T)$, we define the change in the radial Helmholtz free energy $\Delta A(r)$ as

$$\Delta A_{\text{eff}}(r) = A(r) - A(r_0) = -RT \ln \left[\frac{Z(r, T)}{Z(r_0, T)} \right] \quad (9.3)$$

where r_0 is some reference point. The free energy barrier associate with the migration of the dopant was used to calculate the rate constant of the transition using transition state theory as shown below,

$$k(T) = \frac{k_B T}{h} e^{-\frac{\Delta A^\ddagger}{k_B T}} \quad (9.4)$$

where $k(T)$ is the rate constant, ΔA^\ddagger is the free energy barrier along the transition path and h is the Planck's constant.

9.3.3 Computational Details

Computational investigation of the Mn^{2+} migration in the CdS/ZnS host lattice was performed at quantum mechanical level using density functional theory (DFT). The Q-CHEM electronic structure package [60] was used and the DFT calculation were performed using the B3LYP functional with LANL2DZ effective-core potential and basis set. The core/shell QD with the stoichiometric formula of $\text{Cd}_{288}\text{S}_{288}/\text{Zn}_{2488}\text{S}_{2488}$, having a core radius of 1.5 nm and a dot radius of 3.0 nm was constructed from the bulk crystal structures. Analysis of the quantum mechanics data revealed that the interaction of the Mn^{2+} with the host lattice can be predominantly described by a pairwise ion-dipole interaction potential as shown in [Equation 9.5](#),

$$U_{\text{dopant-lattice}} = \sum_i \frac{C}{|\mathbf{r}_{\text{dopant}} - \mathbf{R}_i^{\text{lattice}}|^2} \quad (9.5)$$

where $\mathbf{R}^{\text{lattice}}$ is the center of the dipole, \mathbf{r} is the position of the dopant, and C is an adjustable parameter optimized to fit the DFT data. The integrals needed for calculating $\Delta A_{\text{eff}}(r)$ were evaluated numerically using Monte Carlo sampling. Specifically,

$$\left[\frac{Z(r, T)}{Z(r_0, T)} \right] \approx \frac{\sum_{i=1}^{N_{\text{sample}}} \left[\frac{-U_{\text{dopant-lattice}}(\mathbf{r}\hat{\eta}_i)}{k_B T} \right]}{\sum_{i=1}^{N_{\text{sample}}} \left[\frac{-U_{\text{dopant-lattice}}(\mathbf{r}_0\hat{\eta}_i)}{k_B T} \right]} \quad (9.6)$$

where, $\{\hat{\eta}_i\}$ is a set of unit vectors distributed randomly on a unit sphere. The vectors $\{r\hat{\eta}_i\}$ uniformly sampled points that are distance r from the center of the dot. For each value of the r , a million randomly generated points were used for performing Monte Carlo sampling, this procedure was repeated for 10 additional runs to provide data to obtain averages for each temperature. The for the Helmholtz free energy, was selected at the local minima in the core region of the QD. The calculated values of the relative Helmholtz free energy is presented in Figure S16 and S17 as a function of the dopant distance r from the center of the QD.

9.3.4 Results and Discussion

The calculated radial free energy for the movement of Mn dopants in CdS/ZnS QDs exhibits a local minimum at the core/shell interface of -0.111 eV at 573 K ($r = 1.5$ nm, [Figure 9.4](#), [Figure 9.5](#)). Therefore, the dopant migration from the interior of the core towards the interface is due to decrease in the overall free energy. However, this decrease in the free energy is not monotonic and the minima at the core/shell interface is preceded by a free energy barrier within the CdS core, with a barrier height of 4.25E-3 eV at $r = 0.8$ nm at 573 K. The presence of this barrier indicates that dopant migration requires thermal activation to overcome the barrier within the core ([Figure 9.5](#)). The plot of the relative radial free energy also shows the presence of a high energy barrier with

Figure 9.4: Density function theory calculation of Mn:CdS core QDs dispersed in hexane. (a) The average relative potential the Mn(II) ion experiences at various radial positions in the CdS core and solution and (b) The average relative free energy of the Mn(II) ion, CdS core, and solvent system as the Mn(II) ion moves radial through the system at the lowest (393 K) and highest temperature (573 K) from the experimental study.

the height of $1.59\text{E-}2$ eV in the ZnS shell region ($r = 1.5 - 3$ nm, 573 K) for the ejection of the dopants from the core/shell minimum to solvent minimum. The barrier for dopant ejection was broader and higher than the migration to the core/shell interface, by $1.16\text{E-}2$ eV, which is consistent with fact that higher temperature required for dopant ejection than dopant migration observed in our experiments. The rate constants of reactions for CdS/ZnS show that the rate limiting step is the interface to solvent reaction ($k_{Interface}$) step, [Figure 9.5](#). The ratio of the rate of reactions for the CdS/ZnS QD show that the rate for Mn dopant migration from k_{Core} , is 1.7 times higher than migration from interface to solvent ($k_{Interface}$) at lower temperatures, demonstrating that dopant migration to interface is faster than Mn dopant ejection to solvent.

The dopant migration was also computationally evaluated for core-only CdS QDs in solvent without ZnS shell and core/shell interface, [Figure 9.6](#). The plot of the radial free energy (Figure S17b) shows a free energy barrier in the CdS QD with the highest free energy barrier of $2.69\text{E-}3$ eV at $r = 0.8$ nm. This demonstrates that dopant ejection in the simple doped CdS QDs still require high thermal activation. The difference between CdS and CdS/ZnS is the presence of the core/shell minimum and shell to solvent barrier in the CdS/ZnS QDs (Figure 6a). The rate constant of for the migration of the dopant (k_{Core}) in the CdS QDs from the core region was found to be slower

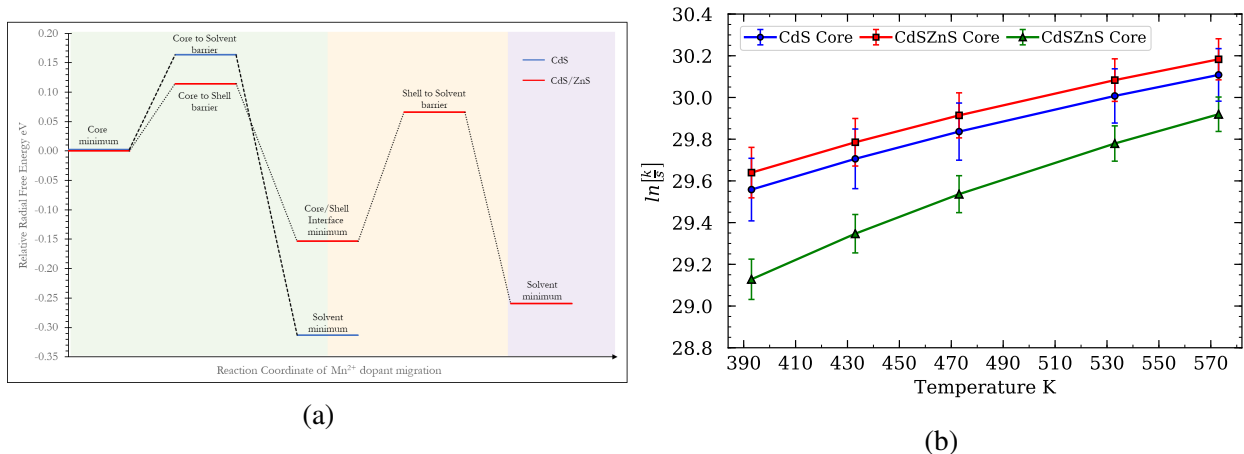

Figure 9.5: (a) The free energy profile along the reaction coordinate for Mn(II) ion migration in the CdS/ZnS and CdS host lattice at 573 K. The green, yellow, and purple regions indicate the core, shell, and solvent regions, respectively for the CdS/ZnS QDs. Two distinct barriers are observed in the CdS/ZnS QDs, first from the core to core/shell interface and second from the core/shell interface to solvent. In contrast, only one barrier from core to solvent, is observed for CdS QDs. (b) Rate constants of reactions for Mn(II) ion in both CdS/ZnS and CdS host lattice systems as a function of temperature.

than the corresponding (k_{Core}) in CdS/ZnS QDs (Figure 9.5). This observation indicates that the presence of the core/shell interface has a positive impact of increasing the rate constant of the migration of the dopant from the core region.

Figure 9.6: Density function theory calculation of Mn:CdS/ZnS core/shell QDs dispersed in hexane. (a) The average relative potential the Mn(II) ion experiences at various radial positions in the quantum dot and solution and (b) The average relative free energy of the Mn(II) ion, quantum dot, and solvent system as the Mn(II) ion moves radial through the system at the lowest and highest temperature from the experimental study.

9.3.5 Conclusion

In summary, the presented work shows that dopant migration is the primary reaction within these quantum dot systems. That dopant ejection is not present since thermal energy barriers exist within the Helmholtz free energy of the system. The presented theoretical work on Mn^{2+} dopant migration was added as part of the larger experimental work from the Zheng group that was recently accepted for publication. The theoretical method that was introduced has its own merit for further theoretical investigations into other dopant migration models. It provides a simplistic Monte Carlo method that can be used for large many-atom systems for understanding thermodynamic properties.

Chapter 10

Conclusions and Future Work

In this work, 5 methods were presented. In [Chapter 5](#), the frequency-dependent geminal-screened electron-hole interaction kernel (FD-GSIK) method was presented. Within this work the FD-GSIK method was able to demonstrate new development towards efficient implementation of electron-hole interaction kernel. The method provided a frequency-dependent kernel which greatly reduced the computational effort in excited state calculations, demonstrated by large many-electron semiconductor quantum dots. In [Chapter 6](#), the dressed molecular orbital basis was introduced. This method was an advancement of the FD-GSIK method by providing a basis to be used to understand the multi-reference nature of highly degenerate systems. The dressed molecular orbital basis provided a compression of the configuration space to reduce computational effort in the excited state calculations. This method was demonstrated with silver nanowires, which demonstrate highly degenerate orbitals, particularly near the HOMO-LUMO gap. With this approach I was able to demonstrate a blue shift in excitation energy for long silver nanowires. In [Chapter 7](#), the derivation of moment generated molecular orbital basis was presented. This approach provides a method for obtaining electron-correlation through moments of a reference particle/hole state without the use of the projector operator $\Lambda(\omega, r_{eh})$. In [Chapter 8](#), the permutation sampling Monte Carlo integration method was presented. The permutation sampling Monte Carlo method provides a sampling technique that decouples dimensionality within integrals. The presented work focuses on the design and implementation of the algorithm towards developing a integration tool that is

computationally efficient. This was demonstrated through a graphical hierarchy that depicts the use of object-oriented programming paradigm. The final method was presented within [Chapter 9](#) which contained the theoretical investigations within collaborative efforts. The method presented was a Monte Carlo sampling technique that allowed for modeling the thermodynamic interactions between Mn^{2+} and CdS/ZnS quantum dot. This approach allowed for determining that free energy barriers exist within the system which demonstrated that dopant migration was the dominate process. Rather than the expected dopant ejection which requires no energy.

Efficient implementations, particularly in the excited state calculations are of key focus within the presented work. Understanding the challenges in modern excited state theories are essential to the motivation of all the presented work. [Chapter 4](#) provided a brief introduction to the theory and implementations of popular methods. Second quantization in [Chapter 3](#) provides an understanding of the notation used throughout the thesis. Finally [Chapter 2](#) provided background information to the main challenge within quantum chemistry obtaining a ground state wave function and electron correlation energy.

The future of the presented methods include utilizing FD-GSIK to investigate chemically interesting systems, that are computationally prohibited by existing excited state methods. Much of the work presented with FD-GSIK was towards validation of the theory and implementation. An example of a future investigation with FD-GSIK is to use it towards understanding the effect of distance between asphaltene dimers. The FD-GSIK can also advance with trying to understand thermal broadening due to Boltzmann distribution of structures. Since FD-GSIK is a computationally cheap excited state method, investigations into understanding an ensemble of structure can provide insight into experimental comparisons. In addition, dressed molecular orbital basis can be used to understand the energy transfer between two quantum dots. The dressed molecular orbital basis provides an approach to deal with high degeneracy that can be present in separated quantum dots interacting with each other. With the implementation of dressed molecular orbitals and FD-GSIK investigation into silver nanoclusters could continue. These two presented methods provide essential theory that was not developed during the collaborative work but could prove useful for understanding the experimental observations in the optical properties. The future of moment gener-

ate basis is to implement the theory to validate the approach towards obtaining electron-correlated excitation energies. The approach used for understanding dopant migration in quantum dots can also be used for other systems. The method was not derived specifically for the collaborative work, and has its own merit towards understanding thermodynamic properties in molecular systems. The future of permutation sampling Monte Carlo method is to integrate to a GPU platform through CUDA. The development was focused on providing GPU acceleration towards providing a fast and efficient integration package. Development will also include providing more functionality to the sampling techniques used within permutation sampling Monte Carlo, to provide a more accurate integration but maintain computational efficiency.

Appendix A

Monte Carlo Variance Reduction

Monte Carlo integration was an key component of many methods presented. It is relevant to take note of several key variance reduction techniques used throughout the works that improve on the quality of the Monte Carlo method. Within Monte Carlo integration, error variance has the form σ^2/n , where σ^2 is the variance within a sample and n is the number of samples. The final error variance and thereby the quality of the method can be improved in two ways, first by a larger value of n which comes at the cost of computational time, or by reducing σ . The variance reduction techniques that will be presented are antithetic sampling, stratification, control variate and importance sampling.

A.0.1 Antithetic Sampling

Suppose that the goal of the Monte Carlo integration is to evaluate the following integral,

$$\int_{-\pi}^{\pi} \sin(x) dx = 0 \tag{A.1}$$

The exact solution of 0 is due to the symmetry of the function at $x = 0$, which means that, $f(x_i) = -f(-x_i)$. If we were to evaluate this integral using Monte Carlo, cancellation of sample x_i of would not occur until $-x_i$ is sampled, which isn't guaranteed unless $n \rightarrow \infty$. Antithetic sampling is based on improving cancellation of error within the Monte Carlo method by increasing the number of sampling points. This done by enforcing that for every sample, the equally probably opposite

sample is also evaluated. So from the example, for every sample of x_i , $-x_i$ will also be evaluated, thereby ensuring cancellation within the integral evaluation since $f(x_1) + f(x_1) = -f(-x_1) = 0$. In antithetic sampling the overall number of sampling points is increased exponentially based on the dimensionality of the sampling point, $n * (2)^{N_{dim}}$. Therefore even though antithetic sampling is useful for variance reduction, the dimensionality of the Monte Carlo integration could prove burdensome and computationally costly for evaluating all antithetic points.

A.0.2 Stratification

Stratified sampling is the idea of splitting up the sampling region into separate regions to create a fair distribution. Imagine that a Gaussian function, $g(x)$ is going to be evaluated through Monte Carlo sampling of random points, [Figure A.1](#). Notice that the region where $g(x)$ would provide

Figure A.1: A graph of a normalized Gaussian function.

any significant contribution to the calculation is from $-2 \leq x \leq 2$, since $g(x) \approx 0$ when $|x| > 2$. Stratification takes advantage of this by creating strata, or regions in which sampling would occur. In the case of [Figure A.1](#), strata could be constructed that are from the regions of $x < -2$, $-2 \leq x \leq 2$, and $x > 2$. From these strata the Monte Carlo sampling will be restricted to these regions, whether the sampling will be uniform or weighted. Since the function is known, we could therefore sample the 2nd strata significantly more than the other two strata. This way our sampling is improving σ of the overall calculation by directly improving the evaluate within each strata since the σ of strata 1 and 2 would not significantly change since $g(x) \approx 0$. In the long run stratification

will also improve the cost of the Monte Carlo sampling by ensuring that efficient sampling is taking place in strata that are significant.

A.0.3 Control Variate

The next variance reduction technique of interest is control variate. The purpose of a control variate is to improve the error in our desired calculation by understanding the error obtained from a known quantity. Say we want to know $\langle f(x) \rangle$ of function, $f(x)$ and we have a second function, $h(x)$ for which we know $\langle h(x) \rangle$, exactly. As we sample $f(x)$ we are going to subtract $h(x)$ and add $\langle h(x) \rangle$ to the end of the Monte Carlo integration,

$$\langle f(x) \rangle = \frac{1}{n} \sum_{i=1}^n [f(x_i) - h(x_i)] + \langle h(x) \rangle \quad (\text{A.2})$$

What this does is that the error obtained at $h(x_i)$ is removed from $f(x_i)$, thereby leading to cancellation of errors from the whole integration because in the end of the evaluation we should have,

$$\langle f(x) \rangle = \frac{1}{n} \sum_{i=1}^n [f(x_i) - h(x_i)] + \langle h(x) \rangle \quad (\text{A.3})$$

$$\langle f(x) \rangle = \langle f(x) \rangle - \langle h(x) \rangle_{MC} + \langle h(x) \rangle_{exact} \quad \text{if} \quad \langle h(x) \rangle_{MC} = \langle h(x) \rangle_{exact} \quad (\text{A.4})$$

$$\langle f(x) \rangle = \langle f(x) \rangle \quad (\text{A.5})$$

Note the distinction of $\langle h(x) \rangle_{MC} = \langle h(x) \rangle_{exact}$, for evaluation of $h(x)$ through Monte Carlo sampling and exactly. The use of control variate allows for cancellation in the error obtained in $\langle h(x) \rangle_{MC}$ from the Monte Carlo procedure by correcting with the exact result, $\langle h(x) \rangle_{exact}$. This in turn improves the error obtained for our desired calculation of $\langle f(x) \rangle$ by simply evaluating another function during each Monte Carlo step. The use of control variate also allows for easily evaluation of the quality of the Monte Carlo procedure as $\langle h(x) \rangle_{MC}$ can quantify if sampling was sufficient.

A.0.4 Importance Sampling

The final variance reduction technique that is of note is importance sampling. Importance sampling is simply taking a distribution, ρ with a known expectation value and creating a biased use of ρ that provides a different expectation value. Imagine that we have a "fair" 6-sided die, which is a die that has a fair probability of $1/6$ for rolling any value and therefore an expectation value of 3.5. Now think of a probability, ρ' for which is a distribution of a "biased" die, that has an expectation value lower than 3.5. This distribution is created when the rolls of the die are unfair and more heavily weighted toward lower values on the die, resulting in a lower expectation value. The key to importance sampling is creating an expectation value of the "biased" die using ρ from the "fair" die, by weighting the importance of a die roll or by sampling the "important" values more frequently. If the important values are sampled more frequently then the variance in the expectation value will be lower.

3.5.1 Detailed Description

Definition at line 17 of file 100_MCRunDriver.h.

3.5.2 Constructor & Destructor Documentation

3.5.2.1 `MCRunDriver::MCRunDriver ()`

Definition at line 20 of file 100_MCRunDriver.cpp.

3.5.2.2 `MCRunDriver::~MCRunDriver ()`

Definition at line 25 of file 100_MCRunDriver.cpp.

3.5.2.3 `MCRunDriver::MCRunDriver (const MCRunDriver & rhs)` [private]

3.5.3 Member Function Documentation

3.5.3.1 void `MCRunDriver::build ()`

Definition at line 30 of file 100_MCRunDriver.cpp.

Here is the caller graph for this function:

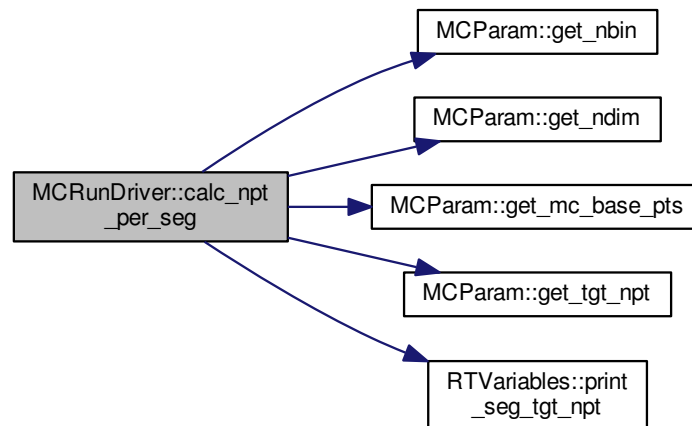

3.5.3.2 void `MCRunDriver::calc_npt_per_seg (RTVariables & myRTV, const MCPParam & myMCPParam)` [private]

Calculates the number of points per segment of ρ

Definition at line 64 of file 100_MCRunDriver.cpp.

Here is the call graph for this function:

3.5.3.3 `void MCRunDriver::calc_npt_using_wt_1d (RTVariables & myRTV, const int & ndim, const int & nbin, const int & mc_base_pts, const int & mc_tgt_npt, const int & idim) [private]`

Determines the number of points to assign to a segment of ρ based on the weights

Definition at line 83 of file 100_MCRunDriver.cpp.

Here is the call graph for this function:

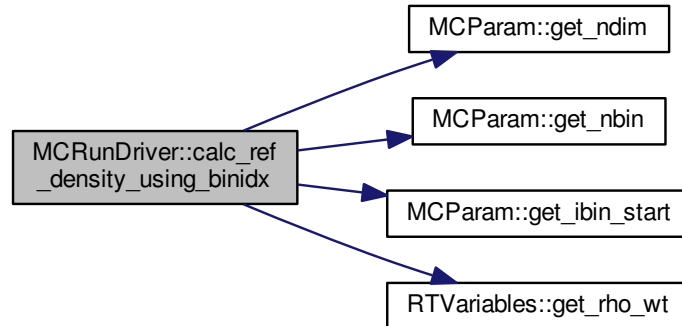

3.5.3.4 `void MCRunDriver::calc_ref_density_using_binidx (const MCPParam & myMCPParam, const RTVariables & myRTV, const vector< int > & idx, double & rho) [private]`

Calculate the N-dimensional density for a point in space from ρ of each dimension.

Definition at line 237 of file 100_MCRunDriver.cpp.

Here is the call graph for this function:

3.5.3.5 void MCRunDriver::check_all () const

Assertions of the [MCRunDriver](#) object.

Definition at line 274 of file 100_MCRunDriver.cpp.

3.5.3.6 void MCRunDriver::check_for_underflow (double & val) [private]

Check for underflow of a value

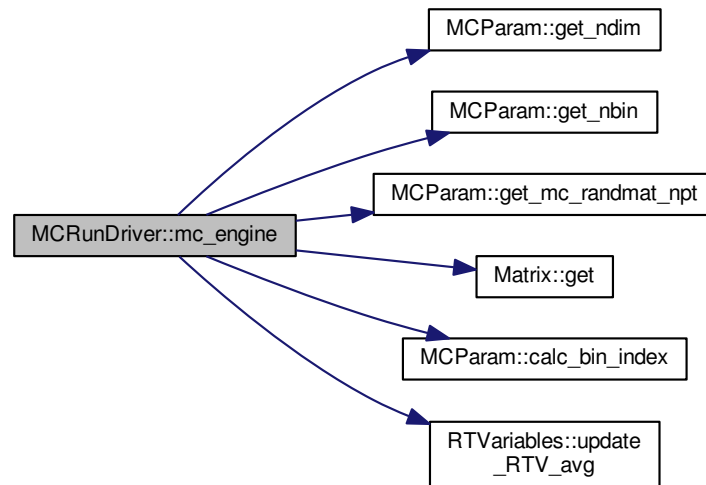

Definition at line 263 of file 100_MCRunDriver.cpp.

3.5.3.7 void MCRunDriver::mc_engine (const UserParam & myUser, const MCPParam & myMCPParam, RTVariables & myRTV, Matrix< double > & randmat) [private]

Main Monte Carlo engine where the random matrix is now used to generate N-Dimensional points in space that will be evaluated within User defined function. The value of the function at each position is then updated in the evaluation of the integral.

Definition at line 180 of file 100_MCRunDriver.cpp.

Here is the call graph for this function:

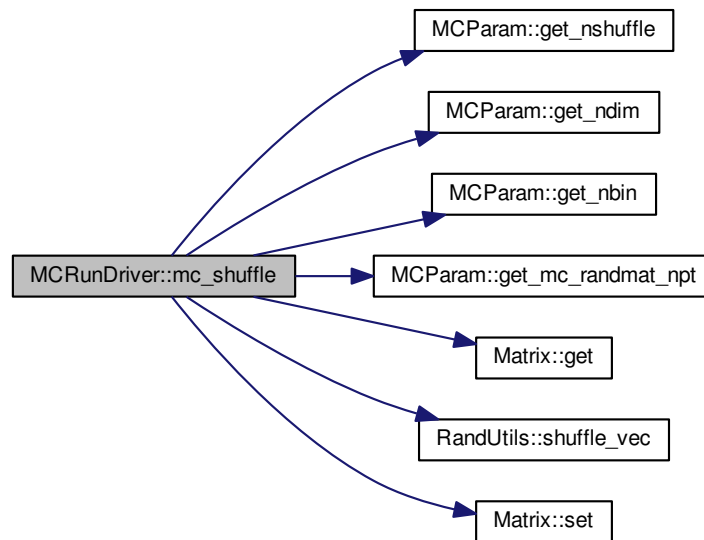

```
3.5.3.8 void MCRunDriver::mc_shuffle ( const UserParam & myUser, const MCPParam & myMCPParam, RTVariables & myRTV, const RandUtils & myRNG, Matrix< double > & randmat ) [private]
```

Take the random matrix and shuffle the ρ along the dimension in each shuffle loop.

Definition at line 145 of file 100_MCRunDriver.cpp.

Here is the call graph for this function:

3.5.3.9 `void MCRunDriver::mc_with_fixed_dist (const UserParam & myUser, const MCPParam & myMCPParam, RTVariables & myRTV, RandUtils & myRNG) [private]`

Using the ρ constructed, evaluate a random matrix that contains position values with the same distribution of ρ within each loop. During each loop pass the random matrix to be used for evaluation of the integral. Updating the integral value and error until the max number of Monte Carlo points has been achieved.

Definition at line 104 of file `100_MCRunDriver.cpp`.

Here is the call graph for this function:

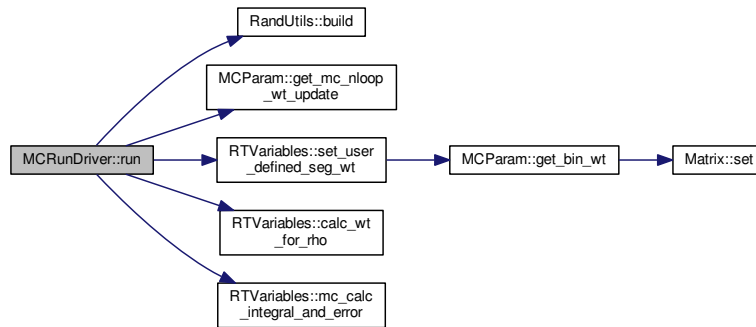

3.5.3.10 `MCRunDriver& MCRunDriver::operator=(const MCRunDriver & rhs)` [private]

3.5.3.11 `void MCRunDriver::run (const FileParam & myFile, const UserParam & myUser, const MCPParam & myMCPParam, RTVariables & myRTV)`

Main run driver that calculates a probability distribution, p from weights for each Monte Carlo cycles to perform
Definition at line 35 of file 100_MCRunDriver.cpp.

Here is the call graph for this function:

#include "100_MCRunDriver.h"
Include dependency graph for 001_main.cpp:
```

Functions

- int main ()

4.1.1 Function Documentation

4.1.1.1 int main ()

Step1: Declaring all objects—// file param contains list of all files used user param wraps user defined functions mc-param has all run-time param for performing mc calc intermediate and final results are stored in run-time-variables (RTV) driver is the global object for running the entire mc calc declare as empty objects... we will build them in the next step.

Step2: build all objects—// first get file names, then get data from those files always use check_all to verify consistency information flow: file -> user_param -> mcrun_param -> RunTimeVariable -> driver

Step3: DO MC calculations—//

Step4: print results

Step5: print time info and do normal termination

Definition at line 14 of file 001_main.cpp.

Curriculum Vitae

PETER F. MCLAUGHLIN

@ E-mail: mclaughlin.peterf@gmail.com in [linkedin.com/in/peterfmclaughlin](https://www.linkedin.com/in/peterfmclaughlin)

RESEARCH EXPERIENCE

Doctoral Research

Research Advisor: Prof Arindam Chakraborty

📍 Department of Chemistry, Syracuse University, Syracuse, NY

📅 Oct 2018 – Present

- Developed a frequency-dependent explicitly-correlated ansatz for excited state calculations in order to investigate many-electron systems
- Programmed Monte Carlo integration methods with the goal of achieving computationally efficient algorithms
- Investigated thermodynamic properties of dopant migration/ejection within modeled system
- Utilized real-space representation to perform excited state calculations for many-electron systems
- Programmed and developed software for large coding projects
- Experience of using electron-structure packages: Q-CHEM, NWCHEM, TERACHEM, GAUSSIAN

Masters Research

📍 Department of Chemistry, Syracuse University, Syracuse, NY

📅 Aug 2013 – Oct 2018

- Examined the solid state photopolymerization of host-guest inclusion crystals to create isolated long chain polyenes
- Investigated solid state structure and chemical composition utilizing Raman and IR spectroscopy for analysis of newly synthesized polyenes
- Studied electronic absorption of polyenes towards understanding triplet states

Immersive Seminar

Research Advisor: Prof Jason Ribblett

📍 Virginia B. Ball Center for Creative Inquiry, Ball State University, Muncie, IN

📅 Aug 2012 – Dec 2012

- Guided the creation of interactive multimedia textbook for application for the fifth-grade physical science classroom following the Indiana state standards
- *Chemistry Matters*, 1.0.1; Frog Baby Apps LLC: Apple iTunes Store, 2014.
- Regulated the scientific content including text and laboratory experiments

Undergraduate Summer Research

Research Advisor: Prof E. Michael Perdue

📍 Department of Chemistry, Ball State University, Muncie, IN

📅 May 2012 – Aug 2012

- Analyzed the pH dependence for the removal of boric acid using electrodialysis in fresh and saltwater conditions

WORK EXPERIENCE

Laboratory Prep 📍 Ball State University, Muncie, IN 📅 Aug 2011 – Dec 2012

- Prepared laboratory experiments to be used for chemistry labs for department

Quality Control 📍 Quaker Chemical, Crawfordsville, IN 📅 May 2010 – Jul 2010

- Performed quality control experiments on liquids and oils used in the industrial process of steel

ACADEMIC HISTORY

PhD in Chemistry

Syracuse University 📍 Syracuse, NY

📅 Oct 2018 – Aug 2020

Supervisor: Prof Arindam Chakraborty

- Specialization: Computational Quantum Chemistry

MPhil in Chemistry

Syracuse University 📍 Syracuse, NY

📅 Aug 2013 – Apr 2015

- Specialization: Experimental Physical Chemistry

BS in Chemistry

Ball State University 📍 Muncie, IN

📅 Aug 2009 – Dec 2012

- ACS Certified

PROGRAMMING SKILLS

Python

Fortran

Numpy, Scipy

Linux

C++

Latex

BitBucket

Git

TECHNICAL SKILLS

Object-Oriented Programming

Test-Driven Development

Monte Carlo Integration

Algorithm Development

Quantum and Classical Mechanics

High-Performance Computing

Differential Equations

Linear Algebra

ACHIEVEMENTS

- Eagle Scout
- Science Student of the Month (Ball State University, April 2012)

AFFILIATIONS & MEMBERSHIPS

- American Chemical Society
- American Physical Society
- Phi Mu Alpha Fraternity

TEACHING EXPERIENCE

Syracuse University 📅 Aug 2012 – Aug 2018

Guest Lecturer

Physical Chemistry Lecture I Thermodynamics

- Taught one lecture review of elementary chemical kinetics and complex reaction mechanisms for exam preparation for students

Teaching Assistant

Physical Chemistry Lecture I Thermodynamics

- Held office hours for students, graded assignments and exams, reviewed and proctored exams

Physical Chemistry Lecture II Quantum Mechanics

- Generated answer keys for homework assignments for students, held office hours for students, graded assignments and exams, reviewed and proctored exams

Physical Chemistry Laboratory I Thermodynamics

- Designed laboratory experiments including pre-lab assignments, procedures and post-lab work due to acquisition of new laboratory equipment. Taught laboratory section, held office hours for students and graded reports. Instructed students how to use laboratory instruments including UV-VIS, fluorescence, and solution and bomb calorimeters.

Physical Chemistry Laboratory II Quantum Mechanics

- Constructed laboratory experiments including lecture, pre-lab assignments, procedures and post-lab work. Taught laboratory section, held office hours for students and graded reports. Instructed students how to use laboratory instruments including UV-VIS, fluorescence, liquid and solid Raman, FT-IR for gases and ATR-IR for liquids, and NMR. Introduced students to Gaussian09 for computational studies that supplemented their laboratory experiments.

General Chemistry

- Held office hours for students

Ball State University 📅 Aug 2011 – Dec 2012

Teaching Assistant

General Chemistry for Pre-Nursing

- Taught laboratory section, held office hours for students and graded reports

Analytical Chemistry

- Aided students during laboratory experiments including supervising and answering questions
