Abstract

The Rattray Volcanics Member, at the triple junction of the North Sea rift, is here subdivided into two informal sub-members based on analysis of core, wireline and seismic data. The Lower and Upper Rattray Volcanics were emplaced during two distinct phases of volcanism separated by a sustained volcanic hiatus. The presence of hyaloclastite and abundant freshwater algae at the base of the Lower Rattray indicates large lakes were present in the area prior to the volcanism, possibly indicating that collapse of the regional Jurassic Central North Sea dome began prior to volcanism. Pulsed subsidence likely

occurred through the duration of the volcanism with lacustrine conditions becoming re-established during the mid-volcanic hiatus. Sediments were deposited across the Rattray Volcanic Province in fluvial systems and floodplain coal swamps after the final cessation of volcanism, with later marine transgression leading to drowning of the area in the Callovian to Oxfordian. In terms of hydrocarbon prospectivity, no evidence is currently found to confirm the presence of an intra-basaltic play analogous to the Rosebank Field in the Faroe-Shetland Basin, although post-volcanic Pentland Formation sedimentary sequences in the Fisher Bank Basin area indicates the possibility of supra-basaltic prospectivity in the triple junction.

Introduction

The Rattray Volcanic Province is an area of basaltic rocks at the triple junction of the North Sea rift system covering ~7400 km² and reaching a maximum thickness of ~1.5 km (Quirie *et al.* 2019). The volcanics were erupted and emplaced during the Mid-Jurassic, c. 170-163.5 Ma (Howitt *et al.* 1975; Underhill 1998; Husmo *et al.* 2002), prior to the main phase of extension (Late Jurassic) responsible for the formation of the Viking Graben, Central Graben and Moray Firth rift basins (Fraser *et al.* 2002). The volcanic rocks are unconformably overlain by reservoir sandstones of Upper Jurassic age in the Outer Moray Firth (e.g. the Piper Formation) and by marine source rocks of the Kimmeridge Clay Formation in the Witch Ground Graben. The position of the volcanic succession beneath these important petroleum system intervals has resulted in them being encountered by >200 hydrocarbon exploration and appraisal wells, with an abundance of well data available through the volcanic sequence, including petrophysical logs, core and cuttings material. The volcanic rocks were first encountered by the Forties field discovery well (21/10-1) in 1970. Recent re-evaluation using 3D seismic data has established the Rattray Volcanics were likely

erupted in a series of fissure eruptions from linear fissure systems and small associated volcanic edifices, including the major Buchan-Glenn Fissure System in the centre of the Rattray Volcanic Province (Quirie *et al.* 2019).

While recent work has clarified the likely eruption mechanism for the Mid-Jurassic volcanism, the precise tectonic and stratigraphic evolution of the North Sea triple junction area before, during and after the Mid-Jurassic volcanism is not well constrained. Regional uplift is suggested to have occurred during the latest Early Jurassic – early Mid-Jurassic (Underhill & Partington 1993) followed by volcanism and later rifting during the Late Jurassic (Fraser *et al.* 2002). However, the precise timing of emplacement of the volcanics and their relationship to the background sedimentation is poorly understood. Very little detail has been published about the c. 8 million years between apparent domal uplift of the area in the Late Toarcian (c. 174.1 Ma (Gradstein *et al.* 2012)) and the cessation of volcanism which likely occurred during the late Bathonian (c. 166.1 Ma (Gradstein *et al.* 2012)) in the Rattray Volcanic Province.

The large and disparate datasets (including seismic, petrophysical logs and palynology data) available in the Rattray Volcanics provide a rare and important opportunity to evaluate the evolution of a volcanic province at a triple junction. Outcrop studies in onshore triple junction volcanic provinces, e.g. the Afar Depression in East Africa (Barberi *et al.* 1972), allow detailed evaluation of the volcanic rocks in situ but is limited by exposure. In contrast, the abundance of seismic and well data through the Rattray Volcanics allows examination of the volcanic province at a gross scale, in three dimensions.

A detailed petrographic and geochemical understanding of cored lavas in individual boreholes has previously been established and possible implications discussed (Howitt *et al.* 1975; Gibb & Kanaris-Sotiriou 1976; Woodhall & Knox 1979; Dixon *et al.* 1981; Fall *et al.* 1982; Ritchie *et al.* 1988; Latin *et al.* 1990; Latin & Waters 1992). However, no regional scale

well correlation of volcanic lithologies has been constructed across the Rattray Volcanic Province and there exists no stratigraphic framework that systematically describes the lateral and vertical volcanic lithology distribution through the Rattray succession.

In this paper we present an integrated analysis of the Rattray Volcanic Province using core, petrophysical logs and 3D seismic reflection data to establish a lithostratigraphic framework for the volcanic sequence. We show that the Rattray Volcanics Member can be subdivided into two sub-members that were emplaced during two main phases of volcanism separated by an eruptive hiatus, during which the area underwent subsidence. The extrusive units that comprise the two main phases of volcanism are here named the Lower Rattray Volcanics and Upper Rattray Volcanics Members. Combining volcanic lithological analysis with palynological data from sedimentary interbeds we present a series of palaeogeographic diagrams representing the evolution of the Rattray Volcanic Province, providing fresh insight into the geological history of the triple junction area during the Mid-Jurassic.

Geological Setting

The North Sea is a continental rift basin with the main phase of extension occurring during the Late Jurassic (Fraser *et al.* 2002). The Rattray Volcanic Province is located across UK offshore Quads 15, 16, 21 and 22 at the rift triple junction where the Viking Graben, Central Graben and Outer Moray Firth Basin intersect (Fig. 1). The triple junction area is comprised of a series of fault-bounded sub-basins and intra-basinal highs with the pre-rift volcanic rocks downthrown by ~3 km in basinal areas by later faulting (Quirie *et al.* 2019).

The Rattray Volcanics Member (RVM) is part of the Mid-Jurassic Pentland Formation (Richards *et al.* 1993) with the volcanic rocks interbedded with mudstones, coals and sandstones around the fringes of the lava field (Fig. 2; Richards *et al.* 1993) indicating eruption in a fluvio-deltaic environment. The RVM was likely sourced in a series of effusive

eruptions from fissures including the major Buchan-Glenn Fissure System, which is thought to have exploited the Highland Boundary Fault which developed during the Caledonian Orogeny in the Devonian Period, c. 220 million years prior to the Rattray eruptions (Quirie *et al.* 2019). The RVM is broadly coeval with the Ron Volcanics Member (Richards *et al.* 1993), located ~150 km south in the West Central Graben, which is not considered further in this study.

Data & Methodology

The main dataset used in this study is publicly released hydrocarbon exploration and appraisal well data from the UK Oil and Gas Database (CDA), now the National Data Repository (NDR). A variety of well data was used including cuttings, core, palynological data and petrophysical logs. 3D seismic reflection data were used to investigate the basin-scale architecture of the volcanic province, and to indicate potential volcanic facies in areas with limited well control. We subdivide the Rattray Volcanic Province into five main areas, based on structural elements established during Late Jurassic rifting, to enable systematic interpretation of the volcanic facies in each region (Table 1; Fig. 3).

There are 235 wells which encounter the RVM with 148 (63%) drilled in the *NW Area* of the volcanic province (Tab. 2). The wells in the *NW Area* predominantly targeted Upper Jurassic Piper Formation sandstone reservoirs which unconformably overlie the volcanic succession. The RVM is also relatively thin (~200-400 m thick) in the *NW Area*, meaning that 41 wells (~28% of *NW Area* wells) penetrate the base of the volcanic succession. In contrast, wells in the *SW Area* and *SE Areas* of the volcanic province targeted younger reservoirs, e.g. Paleocene sandstones of the Forties Field. As such, only 16 wells (~10% of total Rattray well penetrations) are located in the *SW* and *SE Areas* of the volcanic province. Additionally, most wells that encountered the volcanic rocks in the *SE* and *SW Areas* ceased drilling

within the volcanic succession and so do not penetrate the base of the Rattray sequence (only three base-Rattray well penetrations occurred). Consequently, uncertainty remains with regards to the palaeoenvironments and volcanic facies associated with the initiation of volcanism in the southern areas of the Rattray Volcanic Province.

Core & Cuttings

Core and cuttings of the RVM were viewed at the British Geological Survey (BGS) core store in Keyworth with samples taken for preparation of thin sections. The cuttings available for the RVM are often closer to dust or coarse powder in consistency, rather than the typical small pieces of rock. As such, features such as the proportion of vesicles in the lava package (used to indicate whether lavas are tabular or a compound series of flows (Millett *et al.* 2014)) are not discernible from the cuttings examined in this study. The variability of colour of the cuttings was used as an indicator of the type of subaerial volcanic material present in the RVM: tabular lavas generally produce cuttings which are dark grey and dull, with very little colour variation. Compound lavas produce cuttings with more colour variation (Millett *et al.* 2014) due to the high proportion of crust in compound flows, which is generally more weathered and has a higher proportion of amygdales than dense flow cores. However, given the lack of discernible features in cuttings, subaerial lava facies were interpreted primarily using wireline signature.

Petrophysical logs

Mafic igneous lithologies produce characteristic wireline log signatures which can be used to indicate rock types in wells without core data (Planke 1994; Archer *et al.* 2005; Nelson *et al.* 2009; Watton *et al.* 2014; Millett *et al.* 2016; Watson *et al.* 2017, 2019; Hardman *et al.* 2018, 2019). Figure 4 shows examples of typical igneous wireline facies drilled in the Rattray

Volcanic Province. Logs used for lithological interpretation of igneous rocks in this study include gamma ray, deep and micro-resistivity, density, neutron porosity, acoustic travel time, caliper and photoelectric factor, though in some wells only a partial log suite is available.

Basaltic material produces typically low gamma values (15-60 API) due to the low abundances of U, Th and K in early crystallising minerals from mafic melts. Tabular lavas (individual flows comprised of singular cooling units) are characterised by blocky log motifs – often with asymmetrical bell-shaped profiles (Planke 1994; Fig. 4(i)) – with high resistivity (20-200 ohm.m), high density ($2.7-3.1 \text{ g.cm}^{-3}$) and fast acoustic travel times ($40-60 \mu\text{s.ft}^{-1}$ or $5.1-7.6 \text{ km.s}^{-1}$) (Fig. 4(i)). Compound lavas (multiple stacked thin lavas with a high proportion of crust) produce serrated log profiles with slightly lower average densities and acoustic travel times than tabular lavas due to the increased proportion of flow crust and alteration of thinner flow cores (Nelson *et al.* 2009; Millet *et al.* 2016; Fig. 4(ii)).

Hyaloclastite (Fig. 4(iii)) produces log profiles with lower density ($2.2-2.6 \text{ g.cm}^{-3}$) and resistivity (1-10 ohm.m) and slower acoustic travel time ($80-100 \mu\text{s.ft}^{-1}$ ($3.0-3.8 \text{ km.s}^{-1}$)) than subaerial lavas, and high neutron porosity values (40-60 pu) due to clay-bound water in the diagenetic alteration products of volcanic glass (Planke 1994; Bartetzko *et al.* 2005; Watton *et al.* 2014). Hyaloclastites can exhibit variable log character due to the inherent heterogeneity associated with rapid quenching of hot magma during interaction with water (Watton *et al.* 2013; Greenfield *et al.* 2019). Volcaniclastic sedimentary rocks (Fig. 4(iv)) have lower densities ($2.3-2.5 \text{ g.cm}^{-3}$), resistivities (1-10 ohm.m) and acoustic travel times ($60-80 \mu\text{s.ft}^{-1}$ ($5.1-3.8 \text{ km.s}^{-1}$)) than subaerial lavas, exhibiting high neutron porosity due to the presence of clay-bound water, and display a wide density-neutron separation similar to that of shale (Watson *et al.* 2017). Hyaloclastite and volcaniclastic sedimentary rocks display significant overlap in rock properties such as density and acoustic travel time and as such

distinguishing between these facies on wireline alone can be problematic. For the purposes of this study we have identified uniform units with thickness in the order of >50m as hyaloclastite given that large interbedded thicknesses of epiclastic volcanic sediment would take much longer to accumulate than hyaloclastite, and would likely undergo significantly more compaction during burial. It is therefore likely that the proportion of hyaloclastite in the Rattray Volcanic Province has been underestimated, with thinner hyaloclastite units included as generic volcanoclastic facies. Increased gamma ray signature can indicate increased sediment content (clay minerals) and non-mafic constituents, which can be helpful in identifying siliciclastic sedimentary units, although again, defining these units based on petrophysical characteristics alone without cuttings is challenging (Andersen *et al.* 2009).

Intrusions typically exhibit blocky log profiles with little variation through thin intrusions due to the relatively consistent distribution of minerals through the intrusive body (Nelson *et al.* 2009; Mark *et al.* 2018). Basaltic intrusions exhibit low gamma ray values and are very dense and acoustically fast ($5.5\text{-}5.6 \text{ km}\cdot\text{s}^{-1}$) due to the crystalline groundmass and lack of porosity (Planke *et al.* 1999; Nelson *et al.* 2009). No large-scale intrusive sill complexes are observed on seismic data associated with the Rattray Volcanic Province (Quirie *et al.* 2019) and so while intrusions are present within the RVM (Fall *et al.* 1982; Richie *et al.* 1988; Quirie *et al.* 2019) the majority are sub-seismic scale. However, late-stage basaltic melt likely intruded into the existing basaltic lava pile (Quirie *et al.* 2019), with relatively thin basaltic intrusions likely indistinguishable from basaltic lava on seismic and wireline data. As such the proportion of intrusive material in the RVM is therefore likely underestimated.

Subsurface basaltic melts undergo crystalline fractionation with time, commonly resulting in later intrusions of more evolved mineralogical compositions (Bailey & Schairer 1966; Kushiro 1979). The Rattray Volcanics are alkaline (Howitt *et al.* 1975; Woodhall &

Knox 1979; Gibb & Kanaris-Sotiriou 1976; Dixon *et al.* 1981; Fall *et al.* 1982); as such fractionation of the same melt would produce trachytic and phonolitic late-stage melt compositions (Bailey & Schairer 1966; Kushiro 1979; Fall *et al.* 1982). Evolved alkaline melts have higher proportions of K-bearing minerals such as potassium feldspar and hornblende compared to non-alkaline melts due to the low silica content and resulting low proportion of quartz (Pechnig *et al.* 2005). The presence of evolved alkaline intrusions within the basaltic volcanic succession would likely result in significant increase in baseline gamma ray values (Delpino & Bermúdez 2009) – this is observed in the centre of the Rattray Volcanic Province in well 21/03b-3 (see Rattray Igneous Lithologies section). Evolved alkaline intrusions have lower proportions of dense mafic minerals (e.g. olivine and pyroxene) compared to their basaltic counterparts and exhibit correspondingly lower density values and can even display density-neutron overlap similar to a limestone (Mark *et al.* 2018).

Palynological data

Palynological data was collated from well documents including palynological reports, charts, logs and end of well reports from wells drilled throughout the 1970s to 1990s. No new samples were processed. The vintage of the palynological data meant that only limited quantitative data was available for the Pentland Formation in the triple junction area, with the majority of the data set compiled being in the form of presence/absence matrices. Most of these data were recorded from cuttings samples and, rarely, side wall cores. Cavings from overlying strata are therefore potentially present in the data set; where obviously caved species were noted in reports, the species were disregarded. Because these well data sets were prepared over several decades by different analysts, a degree of taxonomic variability is present. To resolve this issue with the metadata set, individual species were collated into higher taxonomic groups: ferns, bryophytes, lycopsids, xerophytic

gymnosperms, gymnosperms, cycads, conifers, acritarchs, dinocysts and other algae. In addition, some ostracods and foraminifera were recorded. The palynological data was subjected to principle component analysis, correspondence analysis and detrended correspondence analysis (for an overview of these methods see Hammer & Harper 2007), however, because of the nature of the data set, no statistically significant results were obtained. An alternative approach using broad palynomorph ecogroups after Abbink *et al.* (2004) and Olivera *et al.* (2015) was used, in conjunction with the definition of petrophysical and seismic facies, to indicate broad palaeoenvironmental conditions during the development of the Rattray Volcanic Province. The absence of quantitative data meant that the grouping of different species into different palynomorph ecogroups is subjective and should be considered as a preliminary environmental model for the area.

Seismic Data

Two 3D seismic surveys were used in this study: the PGS 3D Central North Sea MegaSurveyPlus (MSP) and the PGS 3D North Sea MegaSurvey (MS) (Fig. 3), which cover the majority of the Rattray Volcanic Province. The previously defined western *Central Area* is not covered by either survey and thus the interpretation of the stratigraphy in this area is solely based on well control. The MSP and MS are displayed in the time domain and extend to ~6-7 s two-way travel time (TWT), with the heavily faulted Top Rattray surface mapped at depths ranging from 2-2.4 s TWT (c. 2.3-2.8 km) on fault block footwalls to 4.4-4.9 s TWT (c. 5.6-6.2 km) in downthrown grabens (Quirie *et al.* 2019). A downwards increase in acoustic impedance corresponds to a negative amplitude seismic reflection (displayed in blue) and a downwards decrease in acoustic impedance corresponds to a positive amplitude seismic reflection (displayed in red).

RESULTS

Palynology of the Pentland Formation in the triple junction area

The palynological record of the Middle Jurassic Pentland Formation is dominated by terrestrial palynomorphs, with an abundance of fern spores, gymnosperm pollen (e.g. Conifers, *Ginkgo*-types and Cycads) and freshwater algae. The Pentland Formation in the Rattray area can be divided into two broad palynomorph ecogroups: Aquatic and Lowland Terrestrial. Examples of marginal marine palynomorphs are present in supra-basaltic Pentland Formation sedimentary units in the north of the Rattray Volcanic Province but are very rare within the volcanic succession. Table 3 shows a condensed summary of the taxa recorded in twenty-five wells; five in each defined area of the Rattray Volcanic Province. A full table containing the recorded Pentland Formation palynology in each of the 62 examined wells can be found in the supplementary material.

Aquatic Environments

The Aquatic palynomorph ecogroup is comprised of species representative of freshwater environments. Well 15/12-1 in the far north of the NW Area of the Rattray Volcanic Province records the occurrence of the fresh to brackish water ostracods *Darwinula incurve* and *Belekocytheridea punctate* within the RVM. Numerous other wells in the NW Area contain abundant *Botryococcus*, a chlorophycean algae, in the volcanic succession (e.g. 15/06-1, 15/17-10, 15/18-2, 15/18b-3, 15/21-4; Tab. 3). Chlorophycean algae such as *Botryococcus* occur in freshwater environments (Tappan 1980) in eutrophic standing water (e.g. Jolley *et al.* 2008). Chlorophycean algal blooms have been associated with episodes of volcanism due to the increase in available nutrients associated with volcanic ash deposits (Jolley *et al.* 2008). Occurrences of *Botryococcus* in the RVM are recorded within hyaloclastite deposits (see

Ratray Igneous Lithologies section below), indicating lava progradation into a freshwater lacustrine environment rather than a fully marine embayment.

Lowland Terrestrial Environments

The Lowland palynomorph ecogroup comprises spores and pollen from a variety of fern, bryophyte (e.g. mosses), and lycopsid (e.g. clubmosses) spores, xerophytic gymnosperms, and gymnosperm families. Fern, bryophytes and lycopsid spores are indicative of plants which likely grew in relatively wet lowland environments (Abbink *et al.* 2004; Olivera *et al.* 2015), e.g. fluvial floodplains or lake-side vegetation. Gymnosperm pollen are indicative of larger plants such as cycads, pines and araucarian conifers and were likely derived from upland areas or drier floodplain environments (Abbink *et al.* 2004). Gymnosperm pollen are easily transported by wind and water – when coupled with the variety of lowland spores found in the Pentland Formation their occurrence is probably indicative of transported pollen rather than in situ gymnosperm forests.

Lowland terrestrial palynomorphs are found in wells throughout the Ratray Volcanic Province (Tab. 3) indicating that the volcanics were erupted across a relatively wet lowland environment consisting of fluvial channels, associated floodplains and lakes. Drier upland areas were likely the site of larger forests, sourcing wind-transported gymnosperm pollen to be preserved in floodplain environments with lowland group palynomorphs.

Marine Palynomorphs: isolated incursions and post-volcanic transgression

Towards the northern fringes of the Ratray Volcanic Province in the NW Area and NE Area there are rare occurrences of marine palynomorphs within the Pentland Formation against a background of terrestrial sedimentation (Tab. 3). These marine palynomorphs (predominantly dinocysts e.g. *Gonyaulacysta* and *Dichadogonyaulax*) are restricted to thin

horizons (e.g. a thin clay unit in 16/23-3 in the *NE Area*; sample 1402) and may represent short-lived marine incursions during instances of high relative sea level; marine conditions reached the Buchan area in the Callovian, likely from the Viking and Central Grabens (Davies *et al.* 1996), and a Late Bathonian transgression in the South Viking Graben is identified by Cockings *et al.* (1992). However, the paucity of marine palynomorphs sampled in the majority of the RVM indicates that during the deposition of the Pentland Formation (~Bajocian-Bathonian in this area) the depositional environment remained broadly terrestrial (Cockings *et al.* 1992; Richards *et al.* 1993).

Marine palynomorphs in association with Lowland Terrestrial palynomorphs are recorded in supra-volcanic siliciclastic Pentland Formation units in wells in the far north of the *NW Area* of the Rattray Volcanic Province (e.g. well 15/12-1 sample 201; Tab. 3), likely indicating the initiation of transgression at the fringes of the lava field following the cessation of volcanism. However, supra-volcanic Pentland Formation palynomorphs in the majority of the volcanic province (e.g. 22/05b-4; 16/23-4) are assigned to the Lowland Terrestrial group with no marine palynomorphs recorded.

The few well penetrations in the southern areas of the Rattray Volcanic Province (Tab. 2) result in very limited palynological data for the Pentland Formation in this area. However, the supra-volcanic Pentland Formation in the *SE Area* is dominated by Lowland Terrestrial palynomorphs, which are interpreted to be indicative of post-volcanic drainage systems being established on the exposed volcanic landscape. The lack of marine taxa in available palynomorph data in the Pentland Formation in the south of the volcanic province compared to the northern areas indicates that the post-volcanic marine transgression may have progressed from north to south, although well data bias may be a factor.

Ratray Igneous Lithologies

Using wireline and core data we identify three major igneous lithological associations within the RVM: subaerial volcanic rocks, subaqueous volcanic rocks and a minor intrusive suite. The subaerial group is composed of subaerial lavas, including tabular and compound lavas, and volcanoclastic sedimentary interbeds. The subaqueous group is comprised of basaltic hyaloclastite and reworked subaqueous volcanic material. The minor intrusive suite intrudes into the lava pile and underlying strata. Figure 5 shows the proportions of different igneous and sedimentary lithologies present in drilled Pentland Formation sequences across the Ratray Volcanic Province.

Subaerial volcanic rocks: lavas and volcanoclastic sedimentary interbeds

Subaerial basaltic lavas with interbedded volcanoclastic sedimentary rocks are found across the majority of the areal extent of the Ratray Volcanic Province (Fig. 5). Volcanoclastic rocks include both primary deposits (thin hyaloclastite units from interaction of lava with surface water, e.g. streams and ponds) and epiclastic deposits which have been reworked by surface processes (Fisher 1966). Tabular lavas are formed by high volume eruptions with fast effusion rates (Walker 1971). When erupted into areas of increased accommodation space, lava ponds in topographic lows and inflates with continued eruption, resulting in the formation of thick individual lava flows. Individual flows with thicknesses >30 m are observed in the NW Area (well 15/24b-3; Fig. 4). Compound lavas are composed of multiple thin stacked flows (individual flow units ~5cm-5m thick) and form when the effusion rate is lower (Walker 1971). The proportion of compound to tabular lavas increases distally to the source of volcanic eruptions (Nelson *et al.* 2009). The proportion of compound flows increases in the east of the Ratray Volcanic Province (Fig. 5).

A core through the RVM in well 15/22-13 contains examples of the different subaerial volcanic lithologies (Fig. 6). Examples of both aphyric and porphyritic lavas are drilled in close succession (Fig. 6(i) and (ii)). Both have a groundmass of pyroxene and plagioclase feldspar (the latter showing some degree of flow alignment (ii)), and contain abundant opaque minerals, likely magnetite as reported by Howitt *et al.* (1975) and Fall *et al.* (1982). The porphyritic basalt in well 15/22-13 has large phenocrysts (~2 mm across) of heavily altered olivine; the olivines are entirely replaced by secondary minerals. There are also large pyroxene phenocrysts (~2 mm), which in the pictured sample are relatively fresh, but in other flows have also undergone pervasive secondary alteration. The presence of pyroxene and olivine phenocrysts without plagioclase phenocrysts indicates these porphyritic basalts may represent the ankaramites previously reported by Fall *et al.* (1982).

The 15/22-13 core also contains a series of basaltic clastic packages situated between subaerial lavas (Fig. 6). The basal ~7 m of the core contains repeated fining-upwards reworked volcanoclastic (i.e. epiclastic (Fisher 1966; Millet *et al.* 2014)) packages. These include conglomerate with large (up to 10 cm across) rounded cobbles of different volcanic lithologies, including porphyritic and aphyric basalt with variably grey-green to purple-black groundmass, fining upwards into sandstone and siltstone. The two main fining-upwards packages are ~2-3 m thick separated by a thin fining-upwards sequence ~50 cm thick.

These repeated volcanoclastic fining-upwards sedimentary units are interpreted as being deposited in a fluvial system (e.g. Bridge & Tye 2000) within the volcanic province during a hiatus in eruption (or at least during a time when lava did not reach this part of the province). The variety and rounded nature of the volcanic cobbles in the conglomerate indicates that the clasts are not always derived from the immediately adjacent volcanic strata, with prolonged transport in the fluvial system likely. The stacked channel system indicates these deposits represent a hiatus of sufficient time for a sustained fluvial system to

be established, which can take several thousand years, compared to equivalent lava thicknesses which accumulate in decades (Hole *et al.* 2013). The individual fining upwards packages comprise stories that record minimum channel depths of 2-3 m, with channel belts likely in the order of <1-2 km in width (e.g. Gibling 2006).

The stacked fluvial channels are overlain by a ~3 m thick unit of primary volcanoclastic rock (Fig. 6(iii)) which differs markedly from the fluvial conglomerates and sandstones. It has a dark red-brown fine-grained clay matrix with clasts of dark grey-black fine-grained basalt. The clasts vary in size from ~1-30 mm and are either angular to sub-angular or have uneven clast edges, with the latter likely representing juvenile basalt clasts (primary magma clasts that solidify in situ, rather than being redeposited following reworking of existing volcanic rocks (Fisher & Schmincke 2012)). There is a high proportion of a white pore-filling mineral, identified as calcite in thin section, infilling vesicles in basalt clasts and large areas of the matrix.

The presence of juvenile and fragmented basalt clasts, volcanic clay matrix and a high proportion of secondary pore-filling calcite leads to interpretation of this unit as a thin bed of hyaloclastite formed by lava being quenched and fragmented during contact with surface water. The volcanic clay matrix likely replaced primary volcanic glass that formed from rapid cooling of magma upon contact with water; volcanic glass alters very readily to clay minerals (Cerling *et al.* 1985). The pervasive pore-filling calcite indicates that the rock initially had relatively high porosity, likely due to fragmentation during interaction with the water. This cored sequence of fluvial sediment-hyaloclastite-subaerial lava (Fig. 6) is interpreted as having formed by lava flowing into a topographic low occupied by a fluvial system.

Subaqueous volcanic rocks: hyaloclastite

Hyaloclastite forms when magma is quenched during interaction with water (Honnorez & Kirst 1975; Watton *et al.* 2014). Rattray hyaloclastite generally displays higher density, acoustic velocity and resistivity, and more homogeneous wireline log profiles than the volcanoclastic sedimentary packages. The presence of hyaloclastite in the Rattray Volcanics is inferred from wireline and seismic character. Although the subaerial volcanic rocks group (discussed above) has thin (~3 m) individual hyaloclastite units interbedded with subaerial lavas (Fig. 6(iii)), the subaqueous group comprises thick units of hyaloclastite (> 50-100 m thick) forming correlatable units across the Rattray Volcanic Province. This thickness of the hyaloclastite indicates that substantial volumes of lava flowed into a long-lived standing body of water. Basaltic hyaloclastite packages have been drilled in the NW and *Central Areas* (Fig. 5). In the *SW Area* few wells penetrate to any great depth within the RVM, and so the total extent of hyaloclastite is uncertain. In wells penetrating the base of the RVM succession (e.g. 15/21-3 and 15/23-1Z) hyaloclastite forms the lowest extrusive volcanic lithology of the RVM, i.e. implying the presence of a standing water body pre-dating the onset of volcanism.

Seismic line A-A' from north to south across the Buchan-Glenn Horst at the western end of the Buchan Glenn Fissure System shows a distinct lateral seismic character change within the Rattray Volcanics (Fig. 7). The seismic reflections in the centre of the horst near the fissure are laterally continuous and horizontal, and change laterally into thick packages (~0.6 s TWT thickness; ~1.6 km) of inclined seismic reflections dipping northwards and southwards. The bright, laterally continuous reflections in the centre of the horst are interpreted as subaerial tabular lavas (drilled nearby in well 21/03b-3). The inclined reflections are interpreted as foresets of hyaloclastite deltas from lava that prograded northwards and southwards from the subaerial fissure system into two adjacent bodies of water, forcing the lakes backwards. Inclined seismic reflections are traceable across ~200

km² of the SW Area. Hyaloclastite is drilled in multiple wells across the NW Area covering ~1800 km².

Intrusions

This group represents a minor suite of evolved igneous intrusions that were emplaced into both the existing lava succession and underlying strata. Quirie *et al.* (2019) investigated the volcanic province on seismic data and found no evidence of large-scale intrusive complexes on seismic data. The intrusions, described here from core data from well 21/03b-3, cross-cut pre-existing Rattray lavas. The intrusions generally range from < 10 cm to ~5 m thick and have undergone extensive alteration. As the majority are centimetre-scale they are typically not thick enough to be identifiable on either seismic data or petrophysical logs (Schofield *et al.* 2017; Mark *et al.* 2018). The intrusions are composed of alkali feldspar, mica and nepheline (Fig. 8). The thickest evolved intrusion drilled in the Rattray Volcanic Province (well 15/23a-8) is ~50 m thick (Fig. 4). It produces extremely high gamma ray values (190-220 API) likely due to the high proportion of potassium in the alkali feldspar, and the high uranium and thorium content in nepheline. The intrusion is less dense than the surrounding basaltic material (~2.5-2.6 g.cm⁻³), which, combined with the low neutron values associated with crystalline material due to the lack of porosity, produces a density-neutron wireline overlap similar to that of limestone.

The alkali feldspar, mica and nepheline mineralogy is indicative of nepheline syenites, which form by fractional crystallisation of silica-undersaturated alkali basalts (Delpino & Bermúdez 2009). The mineralogy and the cross-cutting relationship of the intrusions compared to the basalts indicates that this intrusive phase was likely a minor late-stage event that was not associated with the main phase of lava eruption. The intrusions are therefore interpreted to represent the emplacement of the residual melt during the latter

stages of magmatism (e.g. similar to the syenites associated with the alkali dolerite boss from Cnoc Rhaonastil in Islay (Hole & Morrison 1992)).

Lithostratigraphic framework of the Rattray Volcanic Province

Using the volcanic lithology scheme described above, the RVM is subdivided into two main lithostratigraphic sequences representing two distinct phases of eruption: the Lower RVM ('Lower Rattray') and Upper RVM ('Upper Rattray') (Fig. 2), separated by a mid-volcanic hiatus in eruption which is represented by the accumulation of volcanoclastic sedimentary rocks, tentatively identified in wells across the width of the Rattray Volcanic Province. Figure 9 shows a correlation panel of the wells containing the two distinct eruptive sequences in the Rattray Volcanic Province. The differentiation between the Lower Rattray and Upper Rattray is typified in well 15/21-3 in the NW Area (Fig. 9).

The base of the Pentland Formation in 15/21-3 is composed of shales, siltstones and volcanoclastic sedimentary rocks ~21 m thick, representing the immediate pre-volcanic environment. Above this basal sedimentary unit is a ~70 m thick hyaloclastite sequence, overlain by subaerial lavas and interbeds. This hyaloclastite to subaerial lava sequence is interpreted as having been emplaced during the first phase of volcanism forming the Lower Rattray. The hyaloclastite is interpreted to have formed by lava erupting into a lake (indicated by the presence of freshwater algae *Botryococcus* in nearby hyaloclastite e.g. 15/21-4), with subaerial lavas eventually prograding over the hyaloclastite as the lake was in-filled by volcanic material.

A ~17 m thick volcanoclastic sedimentary unit overlies the subaerial lavas of the Lower Rattray in 15/21-3. This volcanoclastic unit is interpreted as having formed from the erosion and redeposition of Lower Rattray volcanic rocks during a hiatus in eruption. Mid-Rattray volcanoclastic units are drilled, and can be correlated, across the Rattray Volcanic

Province (Fig. 9) indicating this unit likely represents a prolonged hiatus in magmatism across the volcanic province rather than being localised to the area of well 15/21-3.

The volcanoclastic sedimentary unit representing the mid-volcanic hiatus in eruption in 15/21-3 is overlain by a ~65 m thick hyaloclastite succession, which is in turn capped by subaerial lavas. This second hyaloclastite to subaerial sequence is interpreted as having been emplaced during a separate, second phase of volcanism, forming the Upper Rattray. The presence of hyaloclastite at the base of the Upper Rattray sequence indicates that lacustrine conditions were re-established on the volcanic landscape during the mid-volcanic hiatus, likely indicative of continued basin subsidence between the first and second eruptive phases.

The Lower Rattray and Upper Rattray are also tentatively interpreted in wells without hyaloclastite (e.g. 21/03b-3 and 22/05b-4), based on the presence of mid-volcanic sedimentary units and the proportion of compound and tabular lavas. A volcanoclastic sedimentary bed is interpreted as being representative of the mid-volcanic hiatus in 21/03b-3 (Fig. 9). Immediately beneath the mid-volcanic hiatus is a package of compound lavas. Compound lava flows are associated with a slower flow rate than tabular flows (Walker 1971). The presence of a thick series of compound lavas overlying tabular lavas may indicate changes in volumetric flow rate associated with the end of the first phase of volcanism at the top of the Lower Rattray. A ~20 m thick volcanoclastic sedimentary unit is interpreted as representing the mid-volcanic hiatus in well 22/05b-4 (Fig. 9). The presence of tabular lavas overlying the mid-volcanic hiatus in wells 21/03b-3 and 22/05b-4 is interpreted as possibly representative of the renewed pulse of magmatism associated with the initiation of the second phase of volcanism emplacing the Upper Rattray Volcanics.

Discussion

Duration of Mid-Jurassic volcanism

The precise age and duration of the Rattray volcanic eruptions is unknown, with K-Ar and Ar-Ar radiometric dating (e.g. Howitt *et al.* 1975; Ritchie *et al.* 1988) having produced ages which contradicts biostratigraphic ages of sedimentary interbeds on the current stratigraphic timescale (Gradstein *et al.* 2012), e.g. approximate magmatic ages of 153 ± 4 Ma - 148 ± 2 Ma (well 21/03b-3, Ritchie *et al.* 1988). Recent studies have shown that K-Ar (and increasingly Ar-Ar) dating of basaltic rocks is considered as relatively unreliable compared to other stratigraphic age evidence (Jolley 2009; Schofield *et al.* 2017; Wilkinson *et al.* 2017). The stratigraphic position of the Rattray Volcanics indicates eruption during the Mid-Jurassic, likely at some point during the Bajocian-Bathonian based on the palynology of the interbedded sedimentary rocks, or possibly into the Callovian (c. 170-163.5 Ma; Howitt *et al.* 1975; Underhill 1998; Husmo *et al.* 2002). However, we suggest the lack of volcanic strata in preserved Callovian sequences around the fringes of the Rattray Volcanic Province indicates the volcanics were likely erupted within the Bajocian-Bathonian (170.3-166.1 Ma; Gradstein *et al.* 2012)).

Based on the eruptive durations of other continental flood basalt provinces, it is extremely unlikely that the volcanism lasted the entire duration of this 4.2-million-year window. In the Deccan Traps, $\sim 10,000,000$ km³ of volcanic rocks were erupted in only c. 4 million years (2,500 km³ per 1000 years) (Jerram & Widdowson 2005) and the main phase of the Columbia River Flood Basalt Province erupted $\sim 220,000$ km³ of basalt in 1.6 million years (140 km³ per 1000 years) (Hooper *et al.* 2007). The Grande Ronde Basalt lavas form $\sim 66\%$ of the total volume of the Columbia River Basalt Group, with 150,000 km³ erupted in c. 420,000 years (360 km³ per 1000 years) (Barry *et al.* 2010).

An approximate eruption volume of $\sim 3000 \text{ km}^3$ is calculated for the Rattray Volcanic Province from the areas of the thickness contours in Fig. 1(b). By comparison with the eruption rates during the main phase of the Columbia River Flood Basalts, 3000 km^3 of lava could be erupted in c. 8,000-22,000 years. Since the Rattray Volcanic Province is orders of magnitude smaller than large continental flood basalt provinces such as Columbia River, extrapolation of flood volcanism duration from larger provinces to the Rattray Volcanic Province must be treated with caution. However, it is likely that discrete pulses of the Lower Rattray and Upper Rattray lava sequences were erupted over timescales of 10,000s-100,000s of years during the Bajocian-Bathonian in the Mid-Jurassic, rather than millions of years as previously suggested in the Central North Sea (e.g. Richards *et al.* 1993). However, the length of the major mid-volcanic hiatus – and any other unidentified intra-volcanic hiatuses – and therefore the total duration of the volcanism is unknown. This uncertainty highlights the need for detailed re-assessment of the Middle Jurassic stratigraphy of the Central North Sea.

Palaeogeographic evolution of the Rattray Volcanic Province

Based on the palynological data from the Pentland Formation, in conjunction with wireline and seismic facies analysis, we present an interpretation of the palaeogeographic evolution of the Rattray Volcanic Province in a series of gross depositional environment cartoons.

Pre-Mid Jurassic

Investigation of the Mid-Jurassic subcrop lithologies in wells which contain Pentland Formation strata shows that the Fladen Ground Spur and Buchan-Glenn Horst areas had the oldest exposed subcrop preserved before the eruption of the RVM, with Permian, Carboniferous and Devonian rocks exposed (Fig. 10, 21/03b-3). The lack of Triassic strata

on these current intra-basinal highs, either through non-deposition or complete erosion of Triassic sediments, indicates the structures were relative high points prior to the eruption of the RVM. The Fladen Ground Spur likely formed a positive structure throughout the Jurassic (Boldy & Brealey 1990). The *NW, Central, SE Areas* have Triassic sedimentary rocks present beneath the Middle Jurassic (Fig. 10). Triassic strata in the west of the Rattray Volcanic Province predominantly comprise red claystone of the Lower Triassic Smith Bank Formation, whereas the Triassic subcrop in the east of the Rattray area is dominated by sandstones of the Middle and Upper Triassic Skagerrak Formation. Several wells in the far east of the Rattray area have thin Liassic (Lower Jurassic-uppermost Triassic) sedimentary units beneath the Middle Jurassic (Fig. 10, 16/23-2).

The eastwards-younging progression of pre-Rattray strata from Lower Triassic in the west to Middle and Upper Triassic to Lower Jurassic in the far east of the Rattray area indicates that the uplift and erosion of the crust was not centred on the Rattray Volcanic Province as has previously been inferred (Underhill & Partington 1993), but rather that the west side of the area underwent greater uplift and erosion than the eastern side.

Early Mid-Jurassic: palaeotopography

The variety and proportion of spores and pollen species found in the Pentland Formation can be used in conjunction with sedimentary facies to indicate the possible presence of upland and lowland areas during volcanism. For example, the RVM in Blocks 15/17 and 15/18 rarely has more than one species of gymnosperm pollen recorded but contains multiple species of fern spores in addition to freshwater *Botryococcus*, which indicates that this area was distal to the upland source of gymnosperm pollen. In contrast, the RVM in Blocks 15/24 and 15/30 (close to the Fladen Ground Spur) contain numerous species of gymnosperm pollen and fewer species of fern spores (e.g. well 15/30-1 contains 6 species of

gymnosperms and 3 species of ferns). This may indicate that this area was more proximal to the upland area sourcing the gymnosperm pollen. The combination of older pre-Rattray subcrop on the Fladen Ground Spur and the inferred proximity to upland flora leads us to interpret that the Fladen Ground Spur was likely a low-relief topographic spur with flora dominated by gymnosperm (e.g. conifer forests) during the eruption of the RVM.

A second low-relief intra-basinal high – the proto-Buchan-Glenn Horst – is proposed to have been present trending WSW-ENE in the Central area (Fig. 11). The presence of Carboniferous-Permian subcrop to the Middle Jurassic strata indicates that erosion (or non-deposition) of Triassic strata occurred on the Buchan-Glenn Horst prior to the Middle Jurassic; it is therefore interpreted as being subaerially exposed during the early Middle Jurassic. Additionally, the presence of subaerial basaltic tabular lavas at the base of the RVM in nearby well 15/26a-2 and the subaerial lava seismic facies present across the horst (Fig. 7) indicates subaerial exposure of the Buchan-Glenn Horst during volcanism.

Early Middle Jurassic: sedimentation (T=0)

Mapping of sedimentary facies in the basal ~30 m section of the Middle Jurassic Pentland Formation allows the construction of the early Middle Jurassic pre-volcanic palaeoenvironment in this area of the Rattray Volcanic Province (Fig. 11, T=0). Pentland Formation siliciclastic sedimentary rocks including mudstones and coal have been drilled beneath the RVM in the NW Area (Fig. 10), with the pre-Rattray Pentland Formation containing terrestrial palynomorphs including gymnosperm pollen and fern spores. Prior to the onset of volcanism, the presence of a large lake (with a surface area of ~1,800 km²) is interpreted in the NW Area (Fig. 11, T=0) from the areal extent of wells which contain hyaloclastite at the base of the Lower Rattray. A second smaller lake is interpreted in the SW Area just to the south of the Buchan-Glenn Horst intra-basinal high (Fig. 11, T=0); the

surface area of this lake (~200 km²) is constrained from the extent of hyaloclastite foresets in the RVM observed in seismic data.

The *NE Area* was likely the site of a fluvial system, with sandstones and mudstones drilled at the base of the Pentland Formation containing terrestrial lowland group palynomorphs (e.g. I6/23-4). The fluvial system in the *NE Area* likely flowed northwards up the proto-South Viking Graben from the lake towards the coast; the younger sections of the Pentland Formation and the overlying Callovian age Hugin Formation in the *NE Area* contain marine palynomorphs indicating a southward-progressing marine incursion in the ?Late Bathonian-Callovian as the Brent delta was transgressed.

The lowermost Pentland Formation facies in the south of the *SE Area* comprises volcanoclastic deposits. We suggest this area was relatively flat and at a slightly higher elevation than the *NW* and *SW Areas* and therefore underwent limited deposition during the earliest Middle Jurassic. The Pentland Formation in this area contains lowland ecogroup palynomorphs including fern spores and gymnosperm pollen. We speculate the *SE Area* could have been the site of a fluvial system feeding northwest-wards into the two lake bodies. The *SW Area* of the Rattray Volcanic Province has no wells that penetrate through to the base of the volcanic succession and as such the nature of the Early Middle Jurassic palaeoenvironment in this area is unknown.

Eruption of Lower Rattray Volcanics (T=1)

The first phase of volcanism (Fig. 11, T=1) emplaced the rocks of the Lower Rattray. The onset of volcanism is marked by the appearance of volcanoclastic sediments in the lacustrine deposits in the *NW Area* (e.g. I5/21-3), with blooms of *Botryococcus* algae in nearby wells likely exploiting the increase of nutrients in the water (Jolley *et al.* 2008). The volcanism was presumably sourced from the Buchan-Glenn Fissure System (BGFS) (Quirie *et al.* 2019) in

the southern *Central Area* of the volcanic province (Fig. 11, T=1). The fissure likely opened during the earliest onset of extension in the Rattray area (Quirie *et al.* 2019). Lava effused primarily from the BGFS but other source areas are probable, e.g. the Renee Ridge (Stewart 1999) and the Forties Montrose High (Quirie *et al.* 2019). The lava flowed away from the BGFS northwards and southwards into the low areas occupied by lakes, forming thick prograding hyaloclastite to eventually subaerial sequences (Fig. 11, T=1).

The northwards-prograding lava reached the southern parts of the *NE Area* (e.g. 16/23-2). However, the vast majority of the Pentland Formation in this area during T=1 comprises volcanoclastic deposits; it is likely that erosion and re-working of primary volcanic material and possible primary ash-fall deposits from the eruptions dominated deposition in the *NE Area*. The *SE Area* was distal to the fissure system; the first phase of volcanism emplacing the Lower Rattray in this part of the study area is dominated by compound lavas and volcanoclastic sedimentary units with rare thin tabular lavas (Fig. 9, 22/05b-4). While the RVM comprises interbedded volcanoclastic and siliciclastic sedimentary units in the *NE Area* (discussed in Mid-Rattray hiatus below), we have not identified clear evidence of transport of 'clean' siliciclastic sediments into the lava field during eruption. Based on our lithological interpretations, the majority of intra-volcanic sedimentation was likely the result of erosion and reworking of volcanic sequences. In terms of hydrocarbon prospectivity, we have not yet identified an obvious analogue to the intra-basaltic Colsay play of the Rosebank Field (Schofield & Jolley 2013; Hardman *et al.* 2018) in the Rattray Volcanic Province.

Mid-Rattray hiatus in eruption (T=2)

The energy of the first phase of eruption dissipated, with the decrease in volume and rate of magma effusion recorded by a change from tabular to compound lavas at the top of the Lower Rattray in well 21/03b-3, situated close to the BGFS (Fig. 9). Lacustrine conditions

were re-established in the *NW Area* due to continued subsidence in the basin (Fig. 11, T=2). The limited well data in the *SW Area* means identifying the different phases of volcanism in the south is challenging, however well 21/02-2 drilled hyaloclastite towards the top of the RVM, i.e. likely in the Upper Rattray, close to the southward-prograding hyaloclastite foresets (Fig. 5). We therefore suggest that subsidence also re-established the lacustrine conditions in the *SW Area*. The locations of the renewed lakes likely suggests that the *NW*, *Central* and *SW Areas* saw greater subsidence than the *NE* and *SE Areas* of the volcanic province. During the hiatus in eruption the fluvial system in the *NE Area* was dominated by siliciclastic sedimentation, resulting in the deposition of Pentland Formation sandstones over the earlier volcanoclastic sedimentary rocks (e.g. 16/23-4). The *SE Area* has limited well control and the subdivision into the two phases of volcanism is uncertain, but we suggest that the hiatus is likely represented by a thick volcanoclastic sedimentary unit in well 22/05b-4 (Fig. 9), as the overlying tabular lavas may indicate the renewed volcanism of the second phase.

Eruption of Upper Rattray Volcanics (T=3)

Renewed magmatism resulted in the second phase of volcanism which emplaced the Upper Rattray, consisting of another hyaloclastite to subaerial lava flow sequence in the *NW Area* (Fig. 11, T=3). The lavas in the *NW Area* comprise thick, inflated tabular flows (>30 m thick), indicating ponding and inflation of flows in regions of increased accommodation space (Lyle 2000). Conversely, the whole Upper Rattray sequence in the *SE Area* is relatively thin (~70 m) and is composed of sparse tabular and compound lavas with a high proportion of volcanoclastic sedimentary rocks. Wells in the far south of the *SW Area* penetrate stacked sequences of compound and tabular lavas and volcanoclastic sediments in the Upper Rattray succession, however the individual tabular lavas are relatively thin (~3-7 m in 21/10-1). The

lava thicknesses and morphologies suggest the far south of the SW and SE Areas of the volcanic province likely formed within a relatively flat subaerial environment with limited accommodation space, hindering inflation of lava flows, in comparison to those in the NW Area. In the NE Area a fining-upwards volcanoclastic package above the mid-volcanic siliciclastic units in well 16/23-4 is interpreted as re-working of volcanic material in a fluvial system rather than primary volcanoclastic deposits from explosive eruptions. The distribution and thicknesses of lavas in the Upper Rattray indicates the majority of lava emplacement in the second phase of volcanism was focussed towards the NW, Central and SW Areas of the volcanic province. Well 21/03b-3 is close to the source of the magmatism and contains nepheline syenite intruding the Lower Rattray sequence as seen in Fig. 8, and given the erratic and higher gamma values, possibly also in the Upper Rattray, although this is not confirmed by core. These intrusions likely occurred during the later stages of the second phase of volcanism as the evolved residual melts intruded into the volcanic sequence.

Post-volcanic drainage systems (T=4)

Following cessation of volcanism in the Late Middle Jurassic, drainage systems were established on the volcanic landscape (Fig. 11, T=4). Thick packages of sandstone, coal, siltstone and shale (~100-290 m) are present above the RVM in the SE Area (e.g. 22/05b-4 and 22/02-2). Thin Pentland Formation siliciclastic deposits are also present above the volcanic rocks in the NW and SW Areas (e.g. 21/15b-4). The presence of Pentland Formation siliciclastic sedimentary rocks above the volcanic rocks in well 21/02-1 indicates that post-volcanic fluvial sedimentation also occurred in the Central Area. However, the upper boundary of the Rattray Volcanics is unconformable across most of the volcanic province (Fig. 10; Boldy & Brealey 1990). Erosion of Upper Jurassic and uppermost Middle Jurassic

rocks, likely associated with the Late Jurassic rifting event e.g. in the *Central Area*, resulted in the volcanic stratigraphy being unconformably overlain by Upper Jurassic and Cretaceous sedimentary rocks (Fig. 10). While it is possible that the *Central Area* may have remained upstanding for longer after volcanism had ceased, we suggest that the post-volcanic fluvial systems likely formed across the majority of the Rattray Volcanic Province, with subsequent footwall uplift during Late Jurassic rifting causing erosion of post-volcanic fluvial deposits.

The North Sea Dome: Implications for tectonic development of the triple junction

The tectonic evolution of the North Sea rift triple junction area through the Jurassic is complex. Marine sediments were deposited in a shallow sea during the Early Jurassic (Husmo *et al.* 2002). During the late Early Jurassic to earliest Mid-Jurassic (Toarcian to Aalenian, c. 182-170 Ma) the whole of the Central North Sea area is thought to have undergone regional domal uplift (Hallam & Sellwood 1976; Eynon 1981; Ziegler 1990; Underhill & Partington 1993, 1994) driven by a short-lived thermal anomaly centred on the area of the Rattray Volcanic Province at the present-day triple junction, preceding the eruption of the RVM (Fig. 12) (Underhill & Partington 1993). The uplift is thought to have caused emergence and erosion of the Lower Jurassic and uppermost Triassic sedimentary rocks in the area (Underhill & Partington 1993, 1994).

The dome is proposed to have affected an area of ~1000 km in diameter (Underhill & Partington 1993) based on the age of the subcrop to the Intra-Aalenian unconformity, with the area of greatest uplift in a circular to elliptical region centred on what subsequently became the triple junction during the Late Jurassic (Underhill & Partington 1993). This area, which extends from the Ross Field in the west (Moray Firth) to east of the Rattray Volcanic Province in the Norwegian Sector, was likely a low-lying paralic region with erosion keeping pace with uplift (Underhill & Partington 1993).

Discounting the palaeo-highs of the Fladen Ground Spur and Buchan-Glenn Horst during the Mid-Jurassic, the eastwards-younging of the Intra-Aalenian unconformity subcrop in the Rattray Volcanic Province from early Triassic to lowermost Jurassic (Fig. 10) may indicate that the volcanics were erupted on the eastern flank of the dome. It is possible that peak uplift occurred to the west of the Rattray Volcanic Province in the Halibut/Ross granite area of the Moray Firth, which has been suggested as a high point between the Inner and Outer Moray Firth Basins during coeval Pentland Formation and Brora Coal Formation sedimentation (Davies *et al.* 1996).

The regional uplift reached its maximum lateral extent during the Aalenian, with deflation of the dome margins beginning in the Late Aalenian-Early Bajocian (c. 170 Ma (Gradstein *et al.* 2012)) as recorded by progressive marine onlap in the proto-rift arms such as the Viking Graben and Inner Moray Firth (Underhill & Partington 1993, 1994). While pre-volcanic subsidence in the centre of the dome was considered possible (Underhill & Partington 1993, 1994), a lack of evidence for subsidence in the centre of the dome implied that the Rattray Volcanics were erupted during continued (contemporaneous) uplift of the dome centre (in the Bathonian to Early Callovian; Underhill & Partington 1993). The dome margins – several hundreds of kilometres away – were suggested to be undergoing subsidence during this time (Underhill & Partington 1993) (Fig. 12). The deflation of the dome centre was hypothesised to have begun in the late Callovian following the eruption of the Rattray Volcanics (Underhill & Partington 1993).

However, our analysis of the sub-volcanic Pentland Formation facies indicates the area of the Rattray Volcanic Province (around Quads 15, 16, 21 and 22) was undergoing sediment deposition in large lakes during the Mid-Jurassic prior to, and indeed throughout, the eruption of the Rattray Volcanics. Lakes can form at high elevation (e.g. Lake Victoria in East Africa), however we suggest that the re-establishment of lacustrine conditions during

the eruptive hiatus indicates the area undergoing either pulsed or continuous subsidence during the volcanic episode. The observed hyaloclastite to subaerial successions of both the Lower Rattray and Upper Rattray sequences indicate similar depositional settings for each. We therefore suggest that the subsidence of the proto-Rattray area likely began before the onset of volcanism (Fig. 12) with the initiation of extension. The presence of lacustrine sediments beneath the volcanic rocks, the occurrence of hyaloclastite at the base of the volcanic sequence, and the re-establishment of lacustrine conditions during the mid-volcanic hiatus indicates the area of the Rattray Volcanic Province was likely undergoing subsidence prior to and during the volcanic eruptions, although we cannot say with certainty whether the subsidence was continuous or pulsed during the volcanism (Fig. 12).

It is important to consider the scale of regional uplift compared to localised tectonic subsidence when discussing pre-volcanic uplift (Jerram & Widdowson 2005), as localised subsidence in regionally uplifted areas can result in volcanism occurring across a variety of environments including subaqueous settings (Jerram & Widdowson 2005). However, as deflation of the dome margins is proposed to have begun during the Late Aalenian-Early Bajocian (Underhill & Partington 1993), c. 170 Ma (Gradstein *et al.* 2012), we suggest that the presence of a large lacustrine environment in the Rattray area prior to volcanism indicates that subsidence was also occurring at this stage in this area.

The onset of subsidence of the uplifted crust prior to volcanism in this case study of the Rattray Volcanics may have implications for the geodynamic relationships between uplift, subsidence, volcanism and extension in other modern-day volcanic rift settings, where examination of pre-volcanic subsidence is not necessarily possible.

Implications for prospectivity in the triple junction area

The inferred presence of non-intruded sedimentary sequences beneath the Rattray Volcanic Province and the implications for hydrocarbon prospectivity was highlighted by Quirie *et al.* (2019). While the potential existence of sub-basaltic hydrocarbon plays is not discussed further in this paper, our re-evaluation of the stratigraphy of the Rattray Volcanic Province has implications for both intra- and supra-basaltic prospectivity in the triple junction area.

The Rosebank Field in the Faroe-Shetland Basin comprises reservoir-seal pairs of Paleocene-Eocene fluvial-marginal marine sandstones interbedded with basaltic lavas (Duncan *et al.* 2009; Schofield & Jolley 2013; Hardman *et al.* 2018). The success of the Rosebank play is in part due to the fluvial deposits comprising clean clastic sediments sourced from outside the lava field. Volcanic activity associated with the opening of the North Atlantic (Naylor *et al.* 1999; Passey & Jolley 2009) to the west resulted in lavas flowing south-eastwards towards the Faroe-Shetland Basin. The interfingering sandstones were deposited during extended periods of volcanic quiescence in large fluvial systems flowing from the south-west across the volcanic landscape (Schofield & Jolley 2013; Hardman *et al.* 2018). The oblique interface of the lavas and the fluvial systems created the successful intra-volcanic play fairway.

Our re-evaluation of the Rattray Volcanic Province has not identified clear evidence of an extensive analogous intra-basaltic play in the triple junction area. The interfingering sedimentary units in the wells analysed are predominantly volcanoclastic silts and clays derived from erosion and redeposition of the Lower Rattray Volcanics during the mid-volcanic hiatus – rather than siliciclastic sandstones brought into the volcanic province in external drainage systems – likely resulting in poor intra-volcanic reservoir potential. Volcanoclastic units derived from erosion of in situ lavas have previously been highlighted as a risk to prospectivity in the Rosebank area (Schofield & Jolley 2013).

Based on our study the most likely area for any intra-volcanic reservoir sandstones in the Rattray Volcanic Province is in the South Viking Graben. The ~Bajocian-Bathonian sequence in well 16/23-4 comprises a volcanoclastic Lower Rattray Volcanics sequence, overlain by siliciclastic sandstones deposited in the mid-volcanic hiatus, capped by further volcanoclastic sedimentary rocks forming the Upper Rattray Volcanics. However, while the transgressive Callovian-aged sandstones in the same well are oil-bearing, the underlying Bajocian-Bathonian Rattray Volcanics contain no oil shows, and only minor gas shows. While several wells in the South Viking Graben contain oil and gas shows in non-volcanic Bajocian-Bathonian sedimentary successions, including small hydrocarbon accumulations (e.g. ~5m net pay column in 16/23-3 Bajocian-Bathonian sandstones), we find no evidence suggestive of a large-scale intra-volcanic hydrocarbon play in this area.

The juxtaposition of the Rattray Volcanics with Kimmeridge Clay source rock occurs in the *Central Area* where the Kimmeridge Clay Fm is downthrown in the Witch Ground Graben adjacent to the uplifted volcanic succession on the Renee Ridge. The RVM on the Renee Ridge contains oil and gas shows (e.g. 15/29-1), and – given the identification of a mid-volcanic hiatus with the potential for fluvial systems being re-established during this time – the Renee Ridge area may be worthy of further study should an appetite for exploration of an intra-basaltic play arise in future.

The Pentland Formation is a proven reservoir in the Central Graben, although less prolific than overlying transgressive sequences such as the Oxfordian Fulmar Formation (Jeremiah & Nicholson 1999; Wilkinson *et al.* 2014). Given the reservoir potential of the Pentland Formation elsewhere in the Central North Sea, and the small hydrocarbon accumulations in the Bajocian-Bathonian and overlying Callovian sedimentary successions in the South Viking Graben, the post-volcanic Pentland Formation in the Rattray Volcanic Province may be worth investigating for untapped hydrocarbon prospectivity. The presence

of substantial post-volcanic Bajocian-Bathonian Pentland Formation deposits on the terraces surrounding the Fisher Bank Basin (e.g. wells 22/05b-4 and 22/02-2) indicates the possibility of a supra-basaltic hydrocarbon play in the Fisher Bank Basin, and perhaps elsewhere in the triple junction area.

Conclusions

We have constructed a lithostratigraphic scheme for the Rattray Volcanics and illustrated the lateral variation in the proportions of volcanic lithologies across the Rattray Volcanic Province. The Rattray Volcanics Member of the Pentland Formation is dominated by basaltic lavas, interbedded volcanoclastic sedimentary units and basaltic hyaloclastite. A minor intrusive suite intrudes the base of the lava sequence.

The Rattray Volcanics were erupted in a broadly terrestrial environment with subaqueous hyaloclastites formed from lava flowing into large lakes. Volcanism resulted in hyaloclastite deltas prograding and eventually infilling the lakes.

The lavas were erupted in two phases of volcanism resulting in emplacement of the Lower and Upper Rattray Volcanics Members, separated by a hiatus between volcanic episodes during which the area underwent subsidence. Subsidence likely continued throughout the eruption of the Rattray Volcanics, re-establishing lacustrine conditions during the mid-volcanic hiatus. After the cessation of the second phase of volcanism fluvial systems were established across the volcanic landscape.

The presence of lacustrine deposits and hyaloclastite at the base of the Rattray Volcanics indicates the area was a sedimentary depocentre prior to the volcanic eruptions, rather than undergoing continued doming and uplift during volcanism. Subsidence of the North Sea dome in the area of the triple junction likely began before the eruption of the Rattray Volcanics, rather than post-volcanism.

In terms of hydrocarbon prospectivity, the intra-volcanic sedimentary rocks are predominantly volcanoclastic sediments derived from erosion and redeposition of the in situ lavas, and would likely be of poor reservoir quality. The identification of a mid-volcanic hiatus indicates potential for intra-volcanic fluvial systems to have deposited reservoir sandstones, but no clear evidence is found of an existing intra-basaltic play based on the well penetrations examined in this study. However, a supra-basaltic Pentland reservoir play in the Fisher Bank Basin may be worthy of further investigation.

Acknowledgements

PGS are thanked for the donation of MegaSurveyPlus and MegaSurvey 3D seismic datasets to this PhD project. The British Geological Survey are thanked for the visit to the Keyworth core store and the loan of cuttings and core samples. John Millett and an anonymous reviewer are thanked for their detailed and helpful reviews which greatly improved the manuscript.

Funding

This work forms part of AQ's PhD research, which is funded by a scholarship from the Carnegie Trust for the Universities of Scotland. AQ thanks the Carnegie Trust for their support.

Fig. 1. (a) Location of Central North Sea in NW Europe, Google Earth. (b) Position of the Rattray Volcanic Province at the triple junction of the North Sea rift system where the Viking Graben, Central Graben and Outer Moray Firth Basin intersect. After Fraser *et al.* 2002. (c) Present day thickness map of the Rattray Volcanics Member (RVM) of the Pentland Formation with the position of the Buchan-Glenn Fissure System highlighted; after Quirie *et al.* 2019, structures after Fraser *et al.* 2002. (d) Inset of Buchan-Glenn Fissure System identified on spectral decomposition of the top-Rattray seismic surface, after Quirie *et al.* 2019.

Fig. 2. Stratigraphic column for the triple junction area of the Central North Sea (after Quirie *et al.* 2019). In this paper the RVM of the Middle Jurassic Pentland Formation is subdivided into two informal sub-members, the Lower Rattray Volcanics and the Upper Rattray Volcanics, based on wireline interpretation of the drilled volcanic lithologies.

Fig. 3. (a) Map of the Rattray Volcanic Province split into five areas in this study: *NW Area*, *NE Area*, *Central Area*, *SW Area*, and *SE Area* based on structures formed during post-volcanic rifting (see Table 1). Also highlighted are the seismic surveys used in this study: MS, PGS 3D North Sea MegaSurvey; MSP, PGS 3D Central North Sea MegaSurveyPlus. After Quirie *et al.* 2019. Position of seismic line shown in Figure 7 highlighted in yellow. Also shown are the positions of key wells mentioned in this study. (b) Polarity of seismic line shown in Figure 7 (after Quirie *et al.* 2019). A downwards increase in acoustic impedance coincides with a negative amplitude reflection, shown in blue.

Fig. 4. Composite log of drilled Rattray lithologies in wells 16/27a-3, 15/23a-8 and 15/24b-3 showing typical examples of the igneous lithologies present in the RVM.

Fig. 5. Proportion of Pentland Formation facies in drilled sequences across the Rattray Volcanic Province, calculated from wireline data. N.B. Intrusive rocks are not included as a separate proportion as they are very minor; intrusions in 21/03b-3 are included in the tabular lava component which they intrude.

Fig. 6. Examples of volcanic rocks found in the RVM from core samples in well 15/22-13. (i) Thin sections of porphyritic basalt with phenocrysts of olivine and pyroxene. (ii) Thin sections of aphyric basalt. (iii) Thin unit (~3 m thick) of hyaloclastite beneath basaltic lava flow. (iv) Volcaniclastic siltstone, grading downwards into (v) volcaniclastic conglomerate. Fining upwards sedimentary units capped by thin hyaloclastite then subaerial lavas indicates this sequence likely represents lava flowing into an active fluvial system.

Fig. 7. Seismic facies of the RVM across the Buchan-Glenn Fissure System on the Buchan-Glenn Horst. (1) Laterally continuous seismic reflections indicative of subaerial lavas. (2) Inclined seismic reflections on either side of the subaerial flows are probably representative of two hyaloclastite deltas created by lava foresets prograding into standing water bodies from the subaerial fissure system between them.

Fig. 8. (a) Core and (b) thin section of intrusive nepheline syenite from well 21/03b-3. The intrusions cross-cut lavas in the centre of the volcanic province near the Buchan-Glenn Fissure System. This cross-cutting relationship, in addition to the composition of the

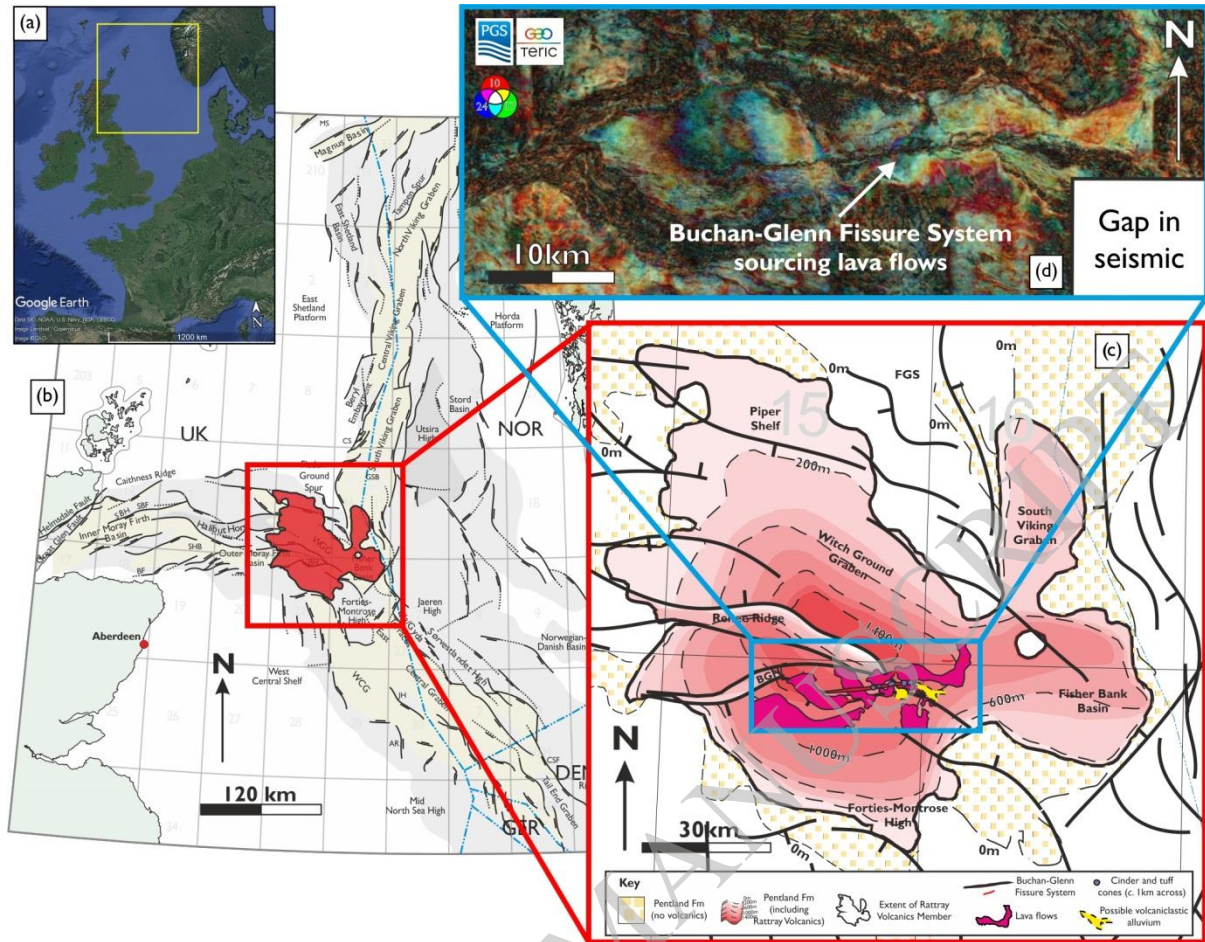

intrusions (see text), indicates they likely formed during a minor intrusive event of residual melt during the final stages of magmatism.

Fig. 9. Well correlation, flattened on the base of the Upper Rattray, highlighting the two lithostratigraphic units of the RVM across the volcanic province. The Mid-Rattray volcanic hiatus is represented by a volcanoclastic sediment-dominated Pentland Formation layer interpreted between the Lower and Upper Rattray units in wells across the width of the province.

Fig. 10. Typical stratigraphic sequences drilled across the different areas of the Rattray Volcanic Province. Subaerial lavas and interbedded volcanoclastic sedimentary rocks are found throughout the majority of the volcanic province. Hyaloclastite appears to be confined to the *NW* and *Central Areas*. The RVM is typically unconformably overlain by Upper Jurassic or Cretaceous rocks due to footwall uplift and erosion during Late Jurassic rifting.

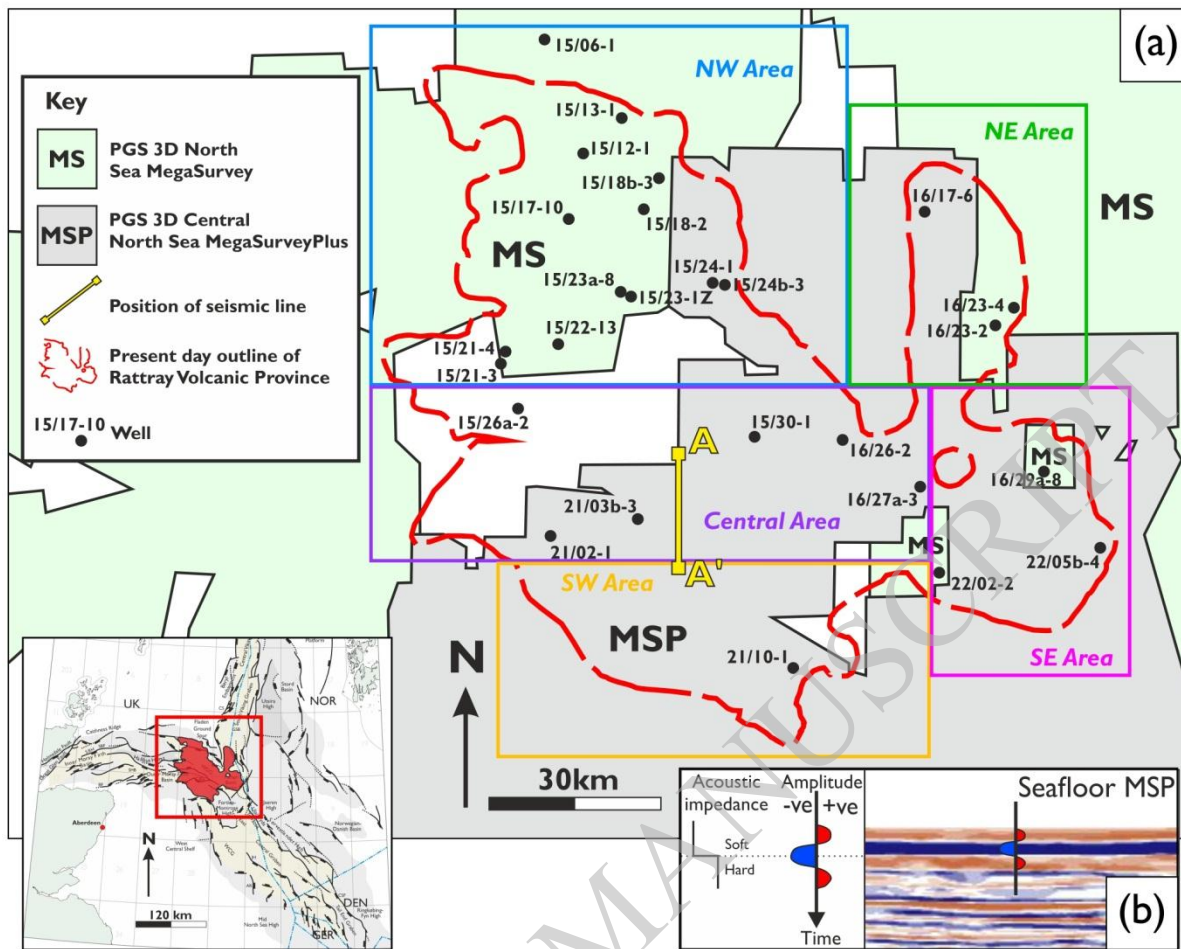

Fig. 11. Palaeogeographic evolution of the Rattray Volcanic Province. The timing of the different stages are relative; possible ages are suggested but the quality of the palynology data present in the Pentland Formation only indicate a broad Bajocian-Bathonian age to the whole sequence. Positions of some of the wells used to interpret each stage are highlighted as yellow dots.

Fig. 12. Uplift and subsidence curve for the area of the Rattray Volcanic Province through the Jurassic Period. N.B. this is an approximation based on stratigraphic observations, not a numerical model. The presence of the lacustrine hyaloclastite at the base of the RVM indicates subsidence of the Rattray area of the North Sea dome began prior to volcanism, likely at a similar time as subsidence of the dome margins (Late Aalenian-Early Bajocian (Underhill & Partington 1993)).
