LATE QUATERNARY SEDIMENTATION IN THE EASTERN ANGOLA BASIN

Brian D. Bornhold

Submitted to the Massachusetts Institute of Technology - Woods Hole Oceanographic Institution Joint Program in Oceanography on August 7, 1973 in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

ABSTRACT

Recent sedimentation in the eastern Angola Basin includes calcareous oozes in the north and south (Guinea Rise and Walvis Ridge) and hemipelagic lutites and terrigenous turbidites on the Congo Cone and on the Angola rise and abyssal plain. Slumped and ponded sediments are dominant within the Angola diapir field. Illite and montmorillonite are abundant in the southern part of the basin, reflecting the source in soils of South West Africa and northward transport in the Benguela Current system. Kaolinite dominates the clay-mineral assemblage in the north-central part of the basin, reflecting a source in the tropical-humid Congo Basin and transport to the deep-sea through the Congo River and canyon systems.

Piston cores from the continental rise revealed major fluctuations in the surface oceanographic conditions, primary productivity, and near-bottom depositional environment during the late Quaternary. Sediments deposited during glacial intervals contain markedly lower carbonate, higher levels of organic carbon, and more abundant siliceous biogenic components, fecal pellets, and pyrite. Sedimentation rates during the past 200-300 x 10³ years remained relatively constant on the rise, averaging 3-5 cm/10³ years.

Oceanographic changes from interglacial to glacial periods, based on sediment composition and geochemistry, include:

- (1) northward extension and intensification of the Benguela Current and associated high primary productivity off southern Angola;
- (2) onset of upwelling and high surface productivity off northern Angola, Congo, and Gabon; and
- (3) major influx of bottom water into the Angola and Guinea Basins.

These conditions resulted in higher benthic productivity, a shallower lysocline, and a more reducing near-bottom environment, as bottom water in the Angola Basin, produced during glacial maxima, became isolated. This "climax" bottom water was eventually mixed with the overlying water by geothermal heating.

Thesis Supervisor: Dr. John D. Milliman

Title: Associate Scientist

ACKNOWLEDGEMENTS

I wish to express my thanks to Dr. John D. Milliman for his excellent guidance and encouragement throughout this research project. I should also like to thank Dr. K. O. Emery for enabling me to participate in the WALDA expedition of the N/O "Jean Charcot" in 1971 and in the Eastern Atlantic Continental Margin study of R/V "Atlantis II" in 1972, and for permitting me to use samples and data collected from these cruises.

I also wish to thank Messrs. Guy Pautot, Daniel Reyss, and Vincent Renard of the Centre Oceanologique de Bretagne for their excellent cooperation and assistance during the WALDA cruise and M. Léo Pastouret for his help in describing the piston cores in Brest, France.

I am very grateful, as well, to the following individuals who supplied samples which were used in this study: Dr. George Keller (NOAA), Dr. Howard Sanders (WHOI), M. P. Giresse (Laboratoire de Géologie du Centre d'Enseignement Supérieur de Brazzaville), M. André Capart (Institut Royal des Sciences Naturelles de Belgique), and Mr. Roy Capo (Lamont-Doherty Geological Observatory). Cores were made available by the Lamont-Doherty Geological Observatory through NSF grants GA29460 and GA35454 and ONR grant N00014-67-A-0108-0004.

Mrs. Lois Toner provided invaluable advice and instruction in various laboratory methods and Mr. Jack Hathaway provided helpful advice on the X-ray diffraction methods.

The following people critically read the manuscripts and offered many helpful suggestions: Dr. K. O. Emery, Dr. Colin Summerhayes, Dr. John Southard, and Dr. John D. Milliman.

Finally, I should like to thank my wife, Penelope, for her patience and

encouragement throughout this study and for typing various parts of the manuscript.

LATE QUATERNARY SEDIMENTATION IN THE
EASTERN ANGOLA BASIN

INTRODUCTION

The purpose of this investigation is to study the modern conditions of sedimentation in the Angola Basin and the changes brought about by variations in the climate of western Africa and in the oceanographic regime during the late Quaternary. Present sedimentation was studied by attempting to relate the composition and dispersal of suspended matter in the surface and deep water and the composition of surface sediments to the prevailing oceanographic and climatic conditions. Variations in sedimentary conditions and paleoenvironments during the late Quaternary were investigated by studying the composition of sediments in piston cores from the Angola Basin.

The interacting influences of climate and oceanographic conditions can have profound effects on sediment sources and volumes, on sedimentary processes, and on the environment of deposition. Until recently, studies of Quaternary marine sedimentation have been concerned primarily with establishing the details of paleoclimatology on the basis of planktonic assemblages, oxygen isotopic composition of foraminiferal tests, or calcium carbonate contents. Only within the past few years has attention turned to the influence of changing surface and deep-sea circulation patterns on the nature of marine sedimentation (e.g., McIntyre and Ruddiman, 1972; Kennett and Brunner, 1973; Watkins and Kennett, 1972; Broecker, 1971).

The Angola Basin is well suited for a study of both paleoclimatological and paleoceanographic effects on sedimentation. The climate of tropical west Africa underwent major changes during the Quaternary, from tropical-humid during the interglacial periods to arid-semiarid during glacials. The circulation pattern of surface waters includes two contrasting current systems,

the cold, productive, northward-flowing Benguela Current in the south and the warm, eastward-flowing South Equatorial Countercurrent farther north; models of Quaternary climatic variation based on studies of the adjacent areas of Africa, postulated important changes in this scheme. In addition, the nearly complete restriction of bottom waters of the basin at the present time offered the opportunity to study the effects of major changes in deep circulation on the nature of sedimentation during the late Quaternary.

Sediment samples used in this study include both piston cores and bottom samples and were acquired from several sources. Piston cores were obtained from the Lamont-Doherty Geological Observatory, the Centre Oceanologique de Bretagne, and the Woods Hole Oceanographic Institution; grab samples were from the Centre Océanologique de Bretagne, Dr. Howard Sanders (WHOI), Woods Hole Oceanographic Institution, Bureau of Commercial Fisheries (courtesy of Dr. G. Keller), Institut Royal des Sciences Naturelles de Belgique, and M. P. Giresse (Congo Republic). The locations of these samples are included in Appendix I and are shown in Figure 1. The suspended-matter samples were taken from the N/O "Jean Charcot" during the WALDA expedition of 1971 and from the R/V "Atlantis II" during the Eastern Atlantic Continental Margin study of 1972.

Figure 1. Location of bottom samples and core descriptions used in the investigation.

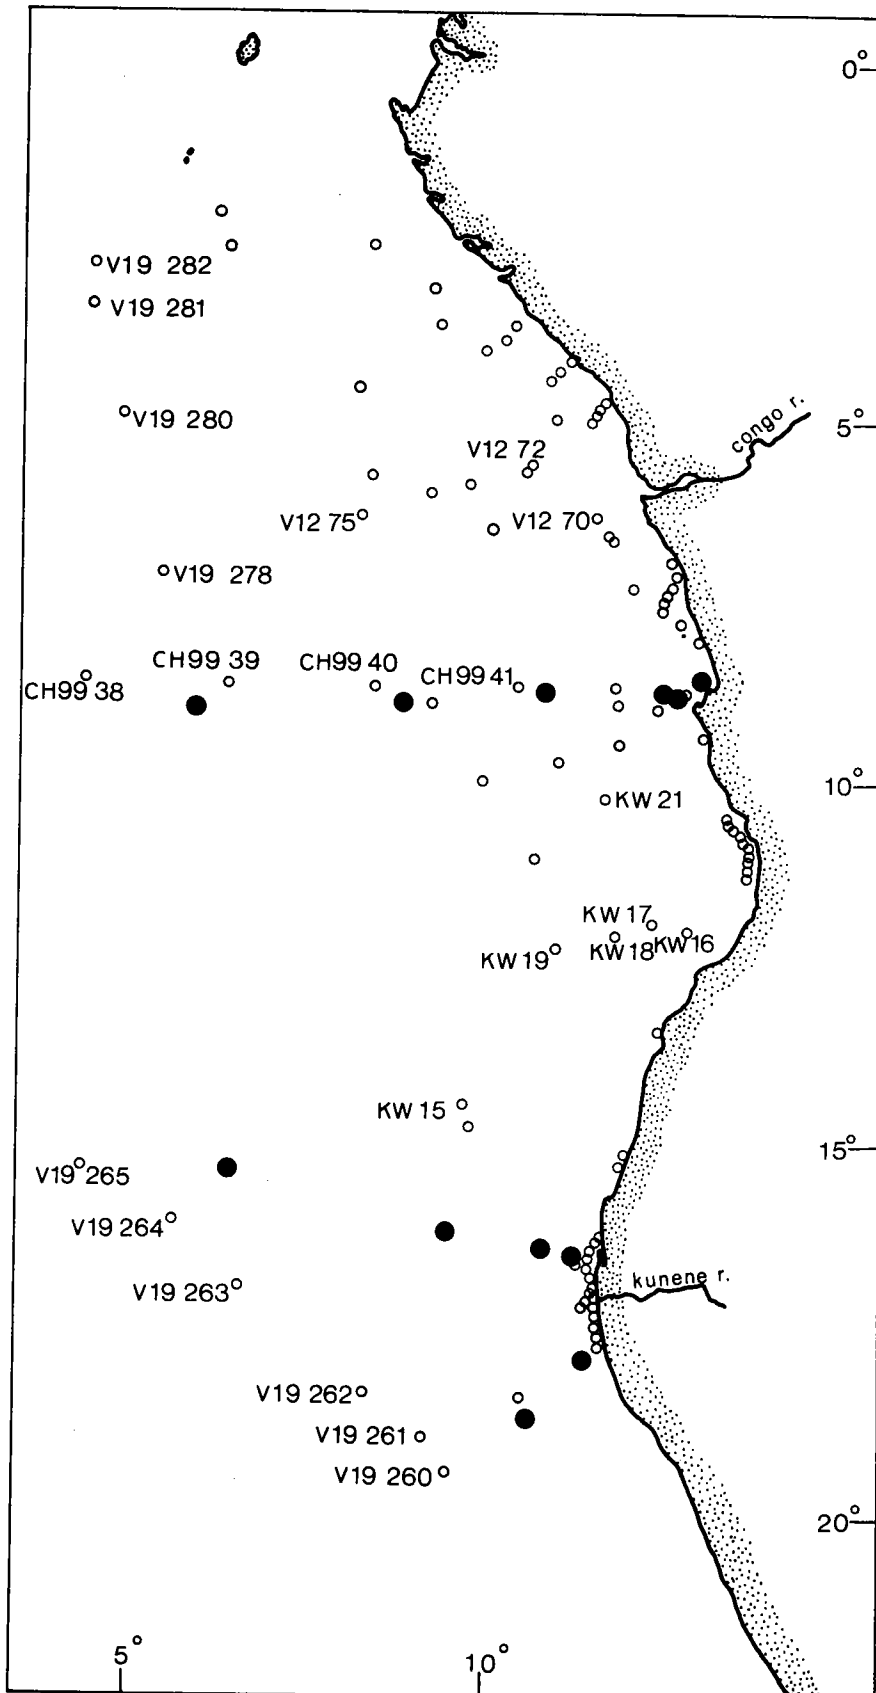

Figure 1

PHYSIOGRAPHIC SETTING

The coastal areas of Angola, Congo, and Gabon are characterized by a narrow zone of Cretaceous to late Cenozoic sedimentary rocks (10-100 km wide) to the east of which rises a long high plateau of Precambrian age. This plateau has its highest elevations in the south, averaging 1500 to 2000 m, with the highest point (2620 m) being east of Lobito, Angola. The plateau descends towards the north, where it lies at 500 to 1000 m above sea level. The coastal plain is broadest in areas of major Tertiary embayments such as the Moçamedes, Cuanza, Cabinda, and Gabon Basins that have received considerable geological attention in view of their petroleum potential. The Congo River and its tributaries drain a large interior basin of Tertiary to Recent continental sediments.

The continental shelf in the study area is generally very narrow (Figure 2), particularly off southern Angola and immediately south of Luanda (< 5 km). It is wider off the Kunene River, South West Africa, and in the large reentrant of the coastline between Lat. 13° S and Luanda, Angola where it is 40 to 50 km wide. The shelf broadens steadily northward towards the mouth of the Congo River where it reaches a maximum width of about 80 km. The shelf remains 40 to 60 km wide off Gabon and the Congo Republic.

The offshore area can be subdivided into six major physiographic regions; (1) the Guinea Rise; (2) the Congo Cone; (3) the Angola diapir field; (4) the Angola continental rise; (5) the northern Walvis Ridge; and, (6) the Angola abyssal plain.

Guinea Rise

The Guinea Rise is a broad swell separating the Angola Basin from the

Figure 2. Bathymetry of the Angola Basin and adjacent continental margin. Depths are in corrected meters with a 400-meter contour interval (after Uchupi, 1972).

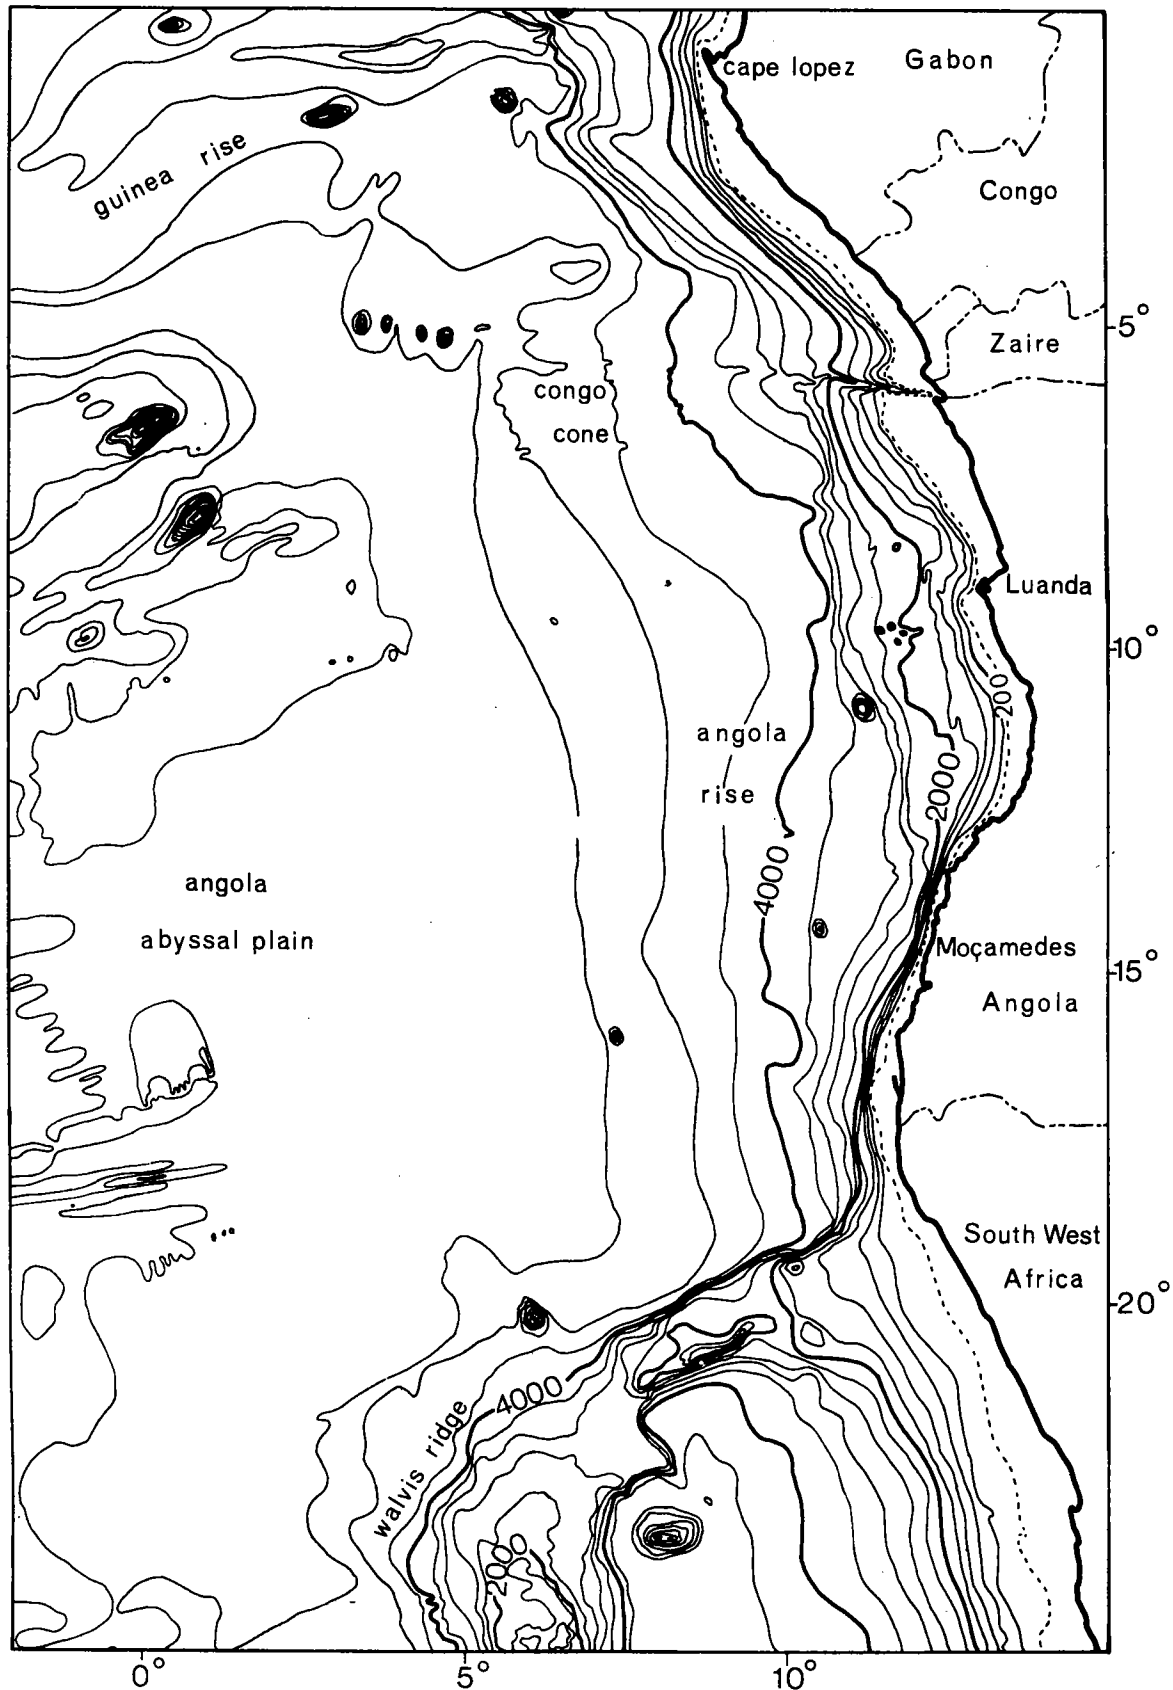

Figure 2

Guinea Basin, thereby marking the northern boundary of the study area. It rises to approximately 4400 m depth from the Angola abyssal plain (> 5200 m) on the south and is characterized by numerous seamounts and volcanic islands of the Cameroon Line (Annabon, Principe, Sao Tome, and Fernando Poo). Continuous seismic profiling data show that the Guinea Rise has a highly irregular sub-bottom topography of very high relief, covered by a thick blanket of sediments (Heezen *et al.*, 1964; Emery *et al.*, in prep). This topographic feature is believed to have been built primarily during the Cenozoic as a fracture zone-ridge system (LePichon and Hayes, 1971).

Congo Cone

The Congo Cone occupies an area in excess of $250,000 \text{ km}^2$ to the northeast of the Angola abyssal plain (Figure 2). The cone and in particular the associated canyon system have been the subject of a detailed investigation by Heezen *et al.* (1964).

The cone is characterized by the undulating topography typical of an abyssal cone, being dissected by several canyon distributaries, especially west of 9°E . The overall shape of the continental rise and slope is convex seaward in this region, in contrast to the slope and rise farther south which are concave seaward. A positive free-air gravity anomaly (> 40 mgal) is associated with the area west-southwest of the Congo River (Rabinowitz, 1972).

The following are the important aspects of the Congo canyon system and its deep-sea fan:

- (1) the canyon extends 30 km into the mouth of the river and thus diverts virtually all of the river's bedload into the deep sea;
- (2) the total length of the canyon system is 800 km and is made up in

- its lower parts of 8 to 10 branches (below 3500 m);
- (3) the canyon is V-shaped to a depth of about 3500 m, with the floor between 200 and 700 m below the level of the adjacent sea floor;
 - (4) below a depth of 3500 m, the channel is defined primarily by natural levees.

Angola Diapir Field

The Angola diapir field has been the focus of several recent studies (Baumgartner and van Andel, 1971; von Herzen *et al.*, 1972; Leyden *et al.*, 1972; Rabinowitz, 1972; Emery, 1973) in the light of the area's possible economic significance and of its position in the reconstruction of the South Atlantic. The evaporitic nature of these diapirs is supported by gravity, magnetics, heat flow, seismic refraction, and similarity to known salt diapirs.

The diapir field, which extends from about Lat. 13.5°S to at least as far north as Cape Lopez, lies at depths between approximately 1000 and 3500 m and is characterized by relief of up to several hundred meters. The field terminates abruptly on the seaward side as a steep scarp up to 1200 m in height. Articles by Leyden *et al.* (1972) and Mascle *et al.* (in press) suggest that this zone of diapirs may extend into the northern Gulf of Guinea, possibly as far as the Niger delta. This latter view is also supported by more recent geophysical data (Emery, personal communication).

On the basis of sediment ponding observed in seismic reflection profiling (Figure 3), detailed surveys of individual features, and gravity determinations, it has been concluded that many of these individual diapirs must form linear ridges up to 15 km long and roughly parallel to the bathymetric contours.

Figure 3. 3.5 kHz echo-sounding record showing ponded sediments within the Angola diapir field.

Figure 3

Angola Continental Rise

The Angola continental rise includes the region bounded by the Congo cone to the north, the Angola diapir field to the east, the Walvis Ridge to the south, and the Angola abyssal plain to the west. It has smooth topography, broken only by occasional canyons, seamounts, and small, poorly developed continental rise hills (Figure 4). The last are most apparent at depths of about 4000 to 4500 m in the southeastern part of the area. The largest appear to be approximately 1500 m long and 30 m high and are thought to be the products of deep currents. For reasons to be presented in a later section, these features are believed to be relict, dating from before the last major transgression.

Walvis Ridge

The Walvis Ridge, a major topographic and structural feature exhibiting rugged volcanic relief of several hundred meters, trends approximately NNE-SSW from the Mid-Atlantic Ridge to the African continent, and separates the Cape Basin from the Angola Basin. Its northern sector is a more or less continuous unit with an average minimum depth of approximately 2500 m. West of the study area (at about Long. 2°E), the ridge is cut by a deep valley which reaches a depth of 4000 m. The ridge is a less continuous feature west of this gap.

The steep north flank merges abruptly with the sea floor of the Angola Basin (Figure 2). Slump structures and the continental rise hills continue at least along the northeastern part of the Walvis Ridge.

Figure 4. 3.5 kHz echo-sounding record showing continental rise swells off southern Angola.

Figure 4

Angola Abyssal Plain

The abyssal plain occupies an area of approximately 15×10^5 sq km and lies at a depth of 5200-5600 m. It is essentially flat and featureless in its central portions. On the west it merges with the abyssal hill province of the Mid-Atlantic Ridge, on the north with the Congo cone, and elsewhere with the Angola continental rise or the similar topographic feature on the north flank of the Walvis Ridge.

CLIMATE

The coastal region adjacent to the Angola Basin belongs primarily within the Class V or Tropical Climatic Zone of Landsberg *et al.* (1963) and embraces four of their five subdivisions within this zone, from "tropical humid-summer climate" to "tropical semi-desert and desert." These zones are arranged with the most humid in the north and the driest in the south (Figure 5); the southernmost sector of the area lies within Class IV or the Warm Temperate Subtropical Zone and in the "semi-desert and desert" subdivision of this zone.

Inland, the climatic zones penetrate far south of their coastal positions due to the presence of the nearby Precambrian plateau, located less than 100 kilometers inland (see page 17). The major effect of this plateau is to increase rainfall in the interior; in southern Angola four major climatic zones occur within 400 kilometers of the coast. In the northern interior much of the Congo's drainage basin lies within a tropical-rainy climatic zone. This distribution of climatic zones has a profound influence upon the hydrologic regimes of the rivers in this area and on their contribution of sediment to the adjacent continental margin.

The climate and hydrographic conditions of this area are controlled principally by the presence of a major high-pressure area, the center of which is located at about Lat. 28°S and Long. 9°W in January and at about Lat. 24°S and Long. 13°W in July (Figures 6 & 7). In January, a major low-pressure area is centered over central equatorial Africa but moves far to the northeast by July.

Offshore, the anticyclonic circulation associated with this configuration gives rise to dominantly southeast trade winds in the entire area. These

Figure 5. Climatic zonation of Africa (after Landsberg et al., 1963). Details for eastern Africa are not shown.

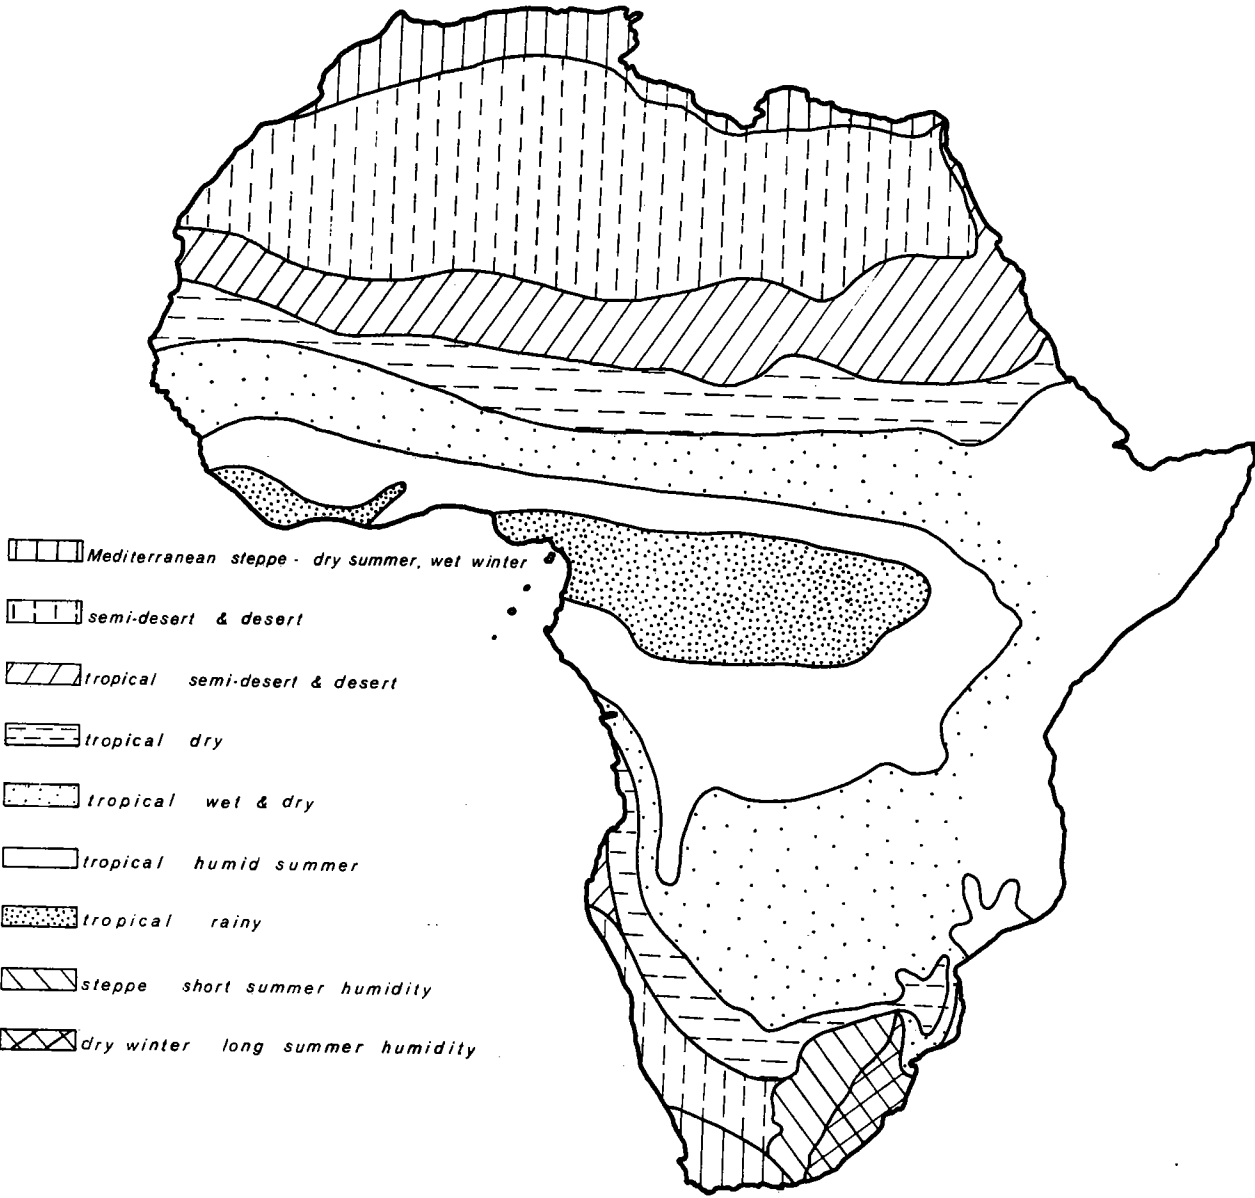

Figure 5

Figure 6. Schematic interpretation of the important climatic features during an interglacial southern summer in western Africa (after van Zinderen Bakker, 1967). Horizontal hatching indicates pluvial conditions; diagonal hatching indicates upwelling.

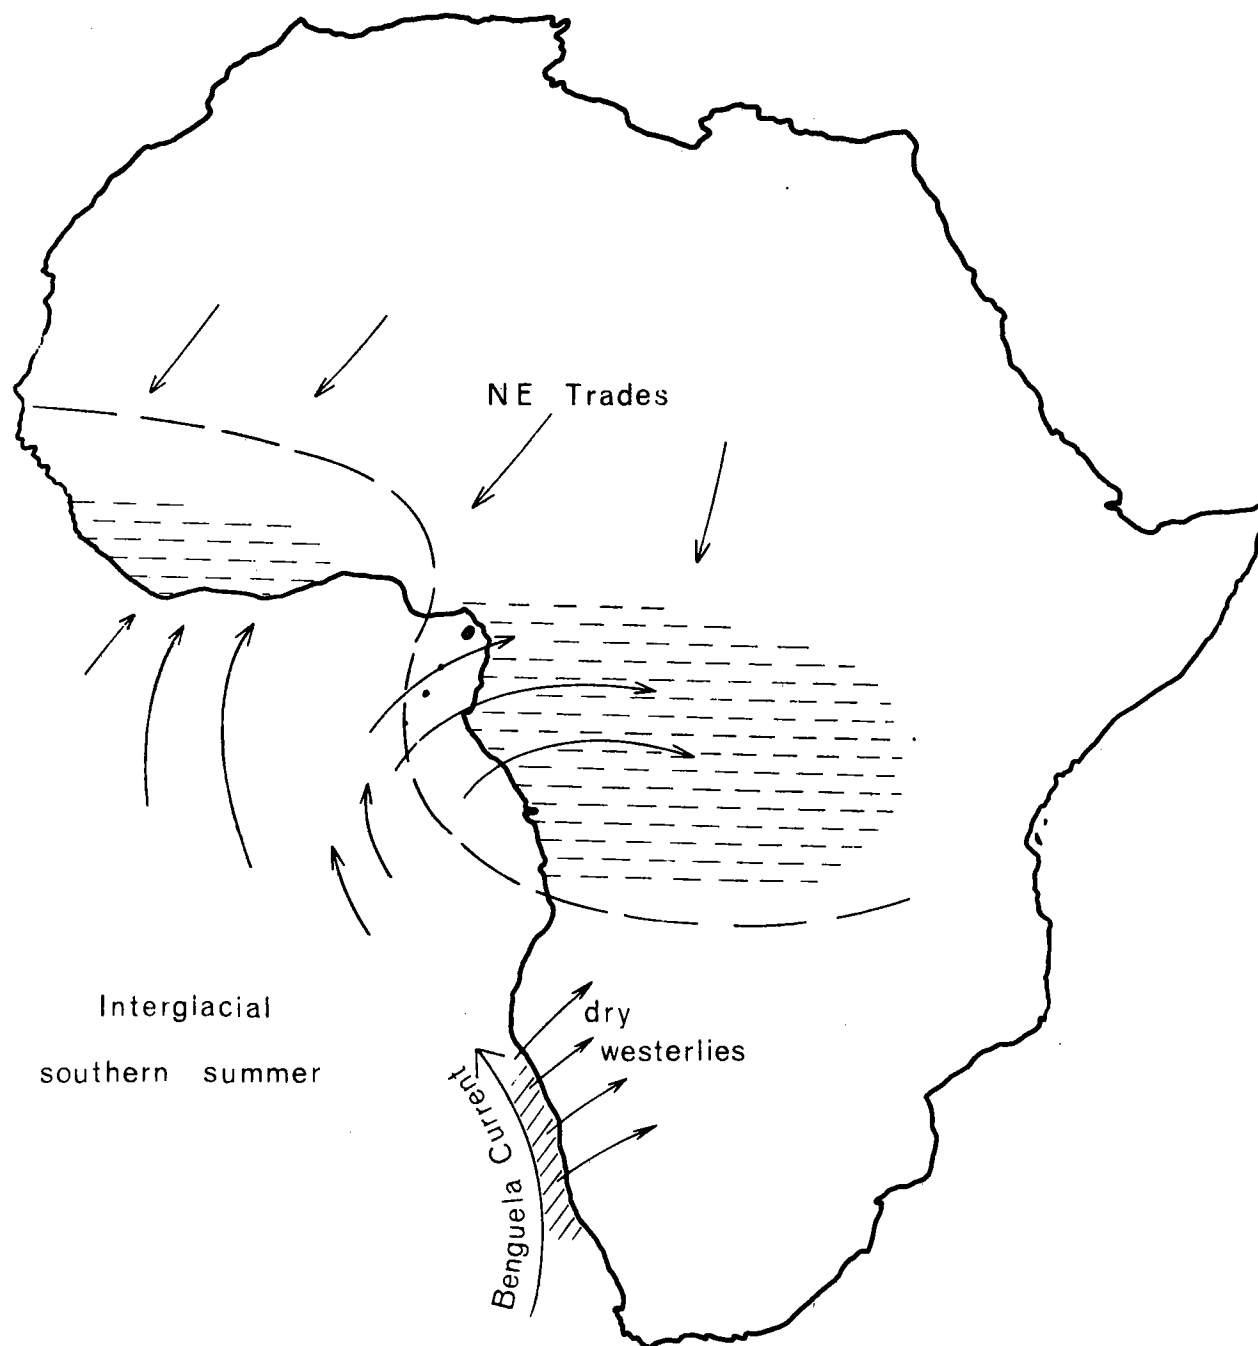

Figure 6

Figure 7. Schematic interpretation of the important climatic features during an interglacial northern summer in western Africa (after van Zinderen Bakker, 1967).

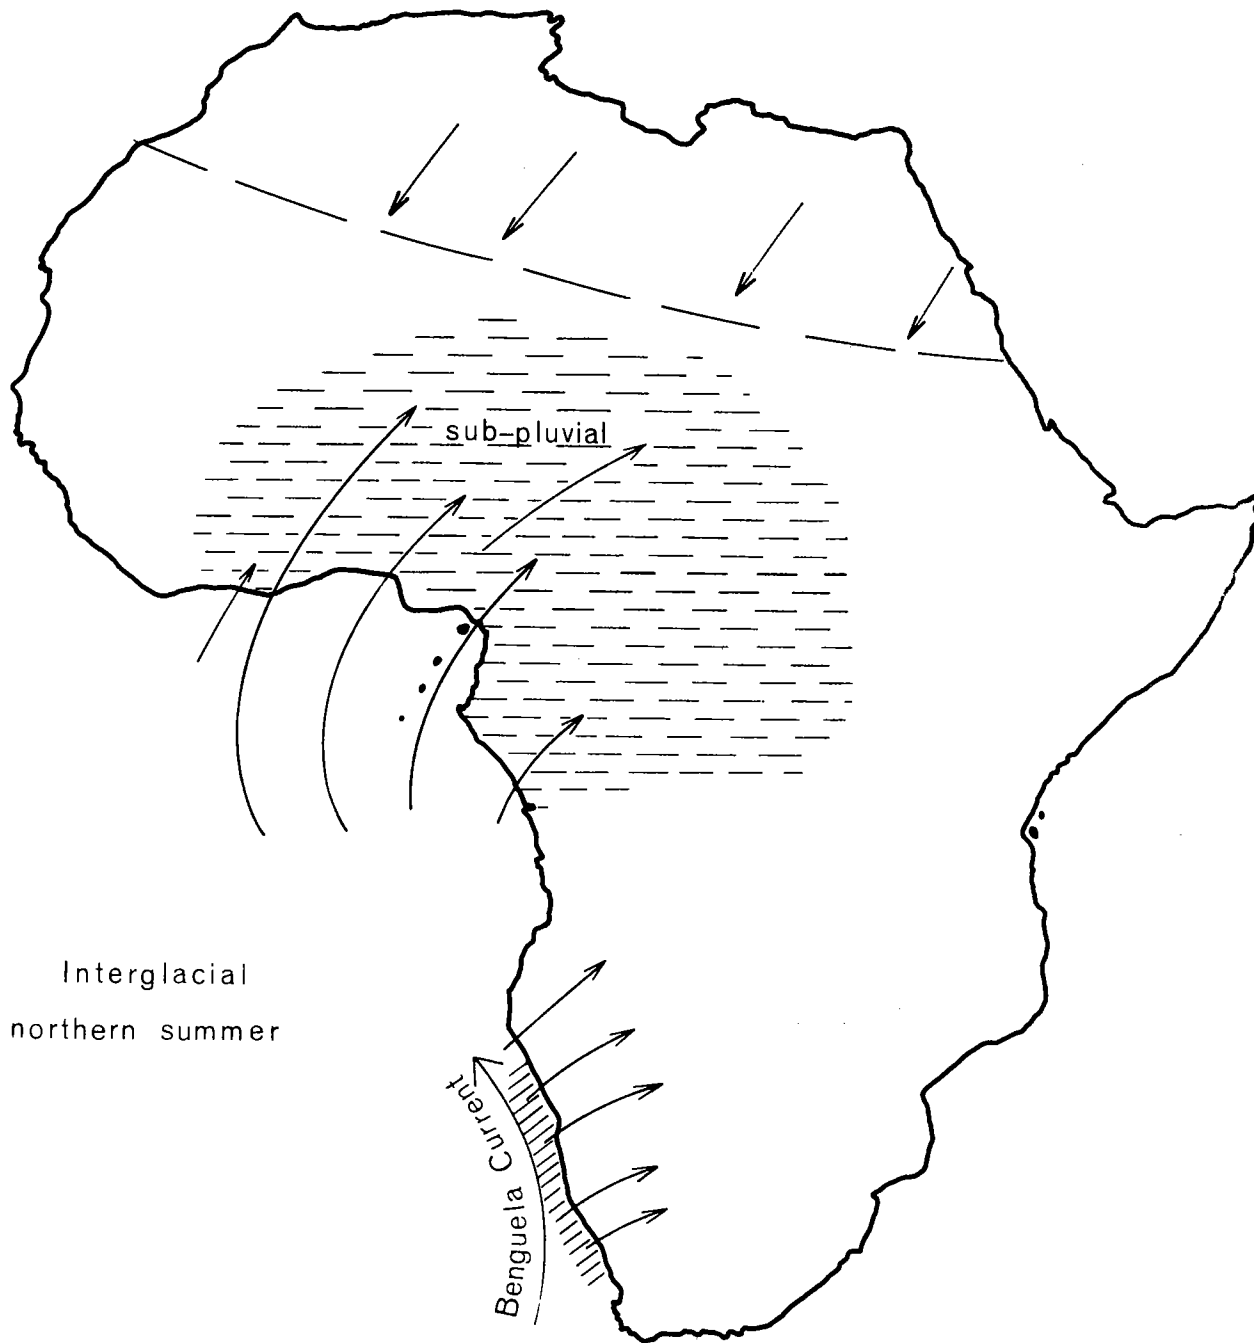

Figure 7

southeast trade winds are particularly important in driving the Benguela Current (see below). As a result of the presence of a major cold water mass adjacent to shore, convectional winds very near the coast tend to be relatively dry.

The prevailing ocean winds are from the south or southeast. Winds average between Beaufort force 4 and 5 but are slightly stronger during the winter. North of 15°S the winds are more southerly and weaker.

In the interior of Angola and South West Africa easterly and southeasterly winds predominate with the strongest coming from a more southerly direction. Of particular interest with respect to potential offshore eolian transport of sediment off southern Angola and South West Africa are the Berg winds. These hot, dry, east winds blow from the plateau and generally are strong, gusty, and laden with dust and sand. These winds occur commonly in winter, lasting from several hours to several days, and have velocities of over forty miles per hour (20 m/sec).

Most of the coastal region receives very little rainfall diminishing from north to south. Typical annual precipitation is shown in Figure 8. Important rains in Angola come in summer (October-April) and are chiefly convectional. In the south, rain comes as occasional showers in late summer. The isohyets in the study area closely parallel the coast (Figure 8) owing to the rapid rise in elevation. East of Mocamedes, Angola, on the plateau, the rainfall is more than 100 cm/yr resulting in the almost annual flooding of the rivers of Angola, particularly the Cuanza, Cubal, Catumbela, Cuvo, Quicombo, and Corpolo.

Figure 8. Pattern of average rainfall in Gabon, Congo Republic, Angola, and South West Africa (after Flint, 1959).

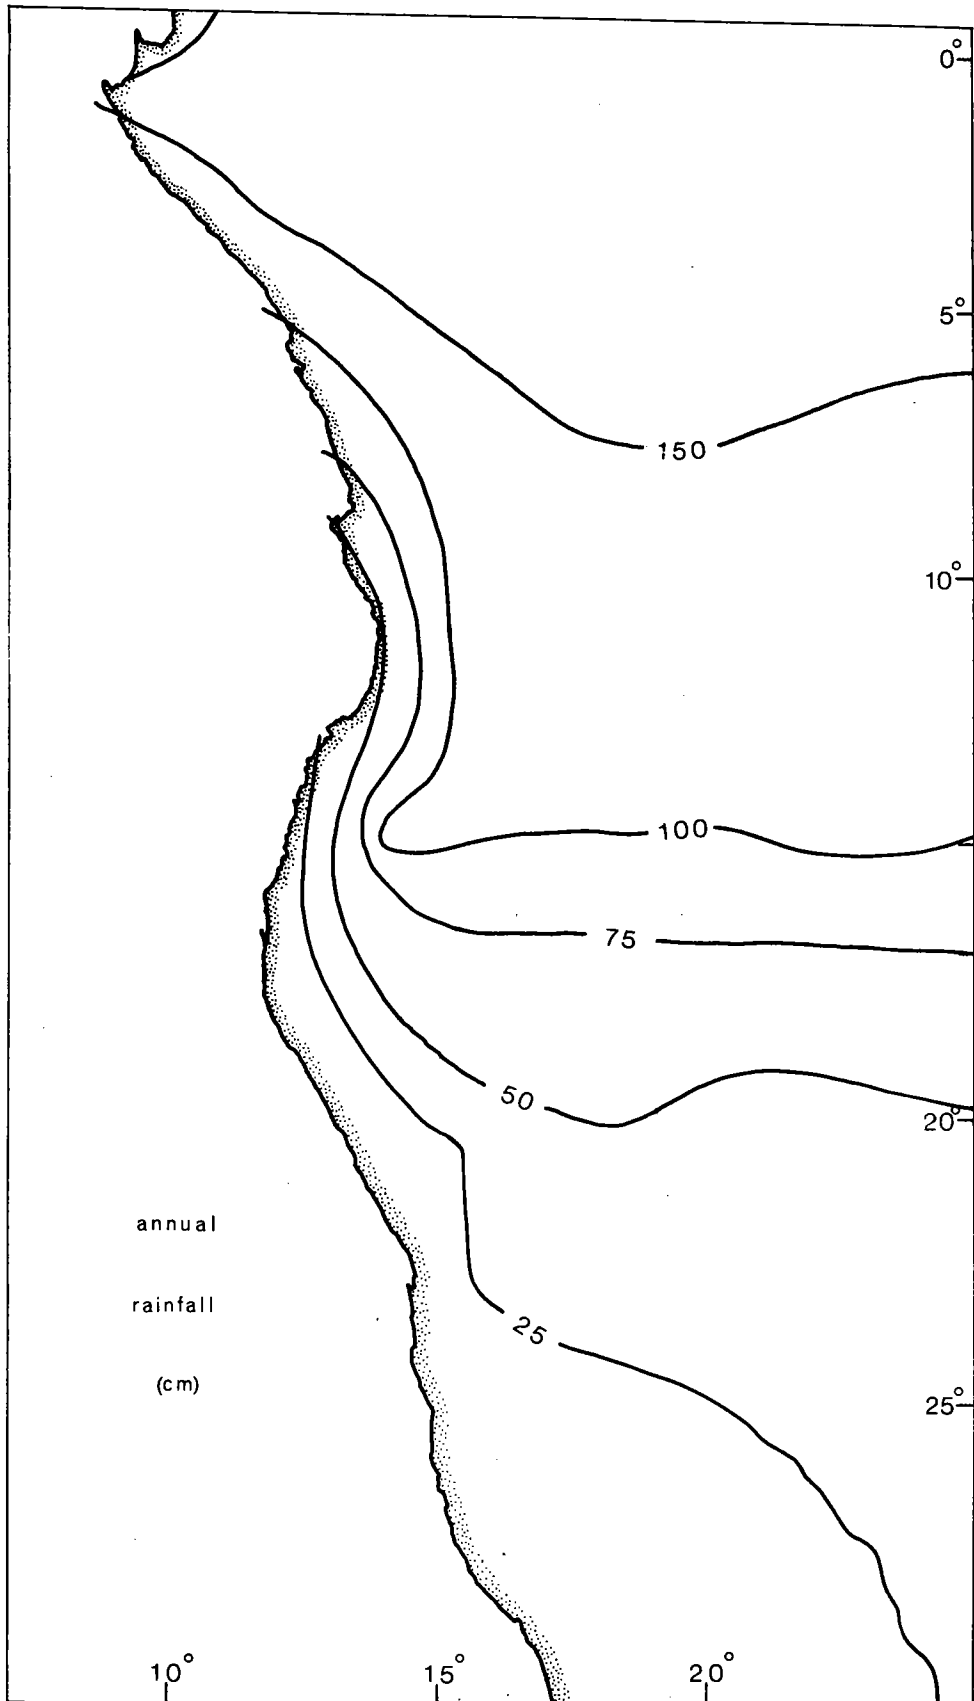

Figure 8

OCEANOGRAPHY

Surface Circulation

The pattern of surface circulation is dominated in the south by the Benguela Current, in the north by the South Equatorial Countercurrent, and between Lat. 10° and 20° S, by their confluence in a complex of surface currents and gyres (Figure 9).

Benguela Current

The Benguela Current, one of the world's major eastern boundary currents, owes its existence to wind stress on the sea surface by south and southeasterly winds and to the density gradients between cold upwelled water along the coast and warmer, lighter water farther west. The water upwelled along the South West African coast is South Atlantic central water, a mixture of sub-Antarctic and sub-tropical waters (Schell, 1968). Drawn to the surface from depths of between 150 and 400 m (becoming shallower at lower latitudes), this deep water is characterized by its low temperature (10° - 14° C), low salinity (34.6-35.0‰), high nutrient content, and low dissolved oxygen content.

The high nutrient content in surface waters causes high levels of biological productivity, up to $3.8 \text{ g C/m}^2/\text{day}$ off South West Africa (Steeman Nielsen and Jensen, 1957). Eutrophication reduces the oxygen levels, resulting in the accumulation of organic, diatomaceous muds on the continental shelf off South West Africa.

Upwelling and the consequent high productivity within the Benguela Current decrease markedly north of about Lat. 23° S as the main branch of the current leaves the coast to flow northwestward and westward (Figure 9). A

Figure 9. Pattern of surface currents over the eastern Angola Basin
(after Moroshkin et al., 1970).

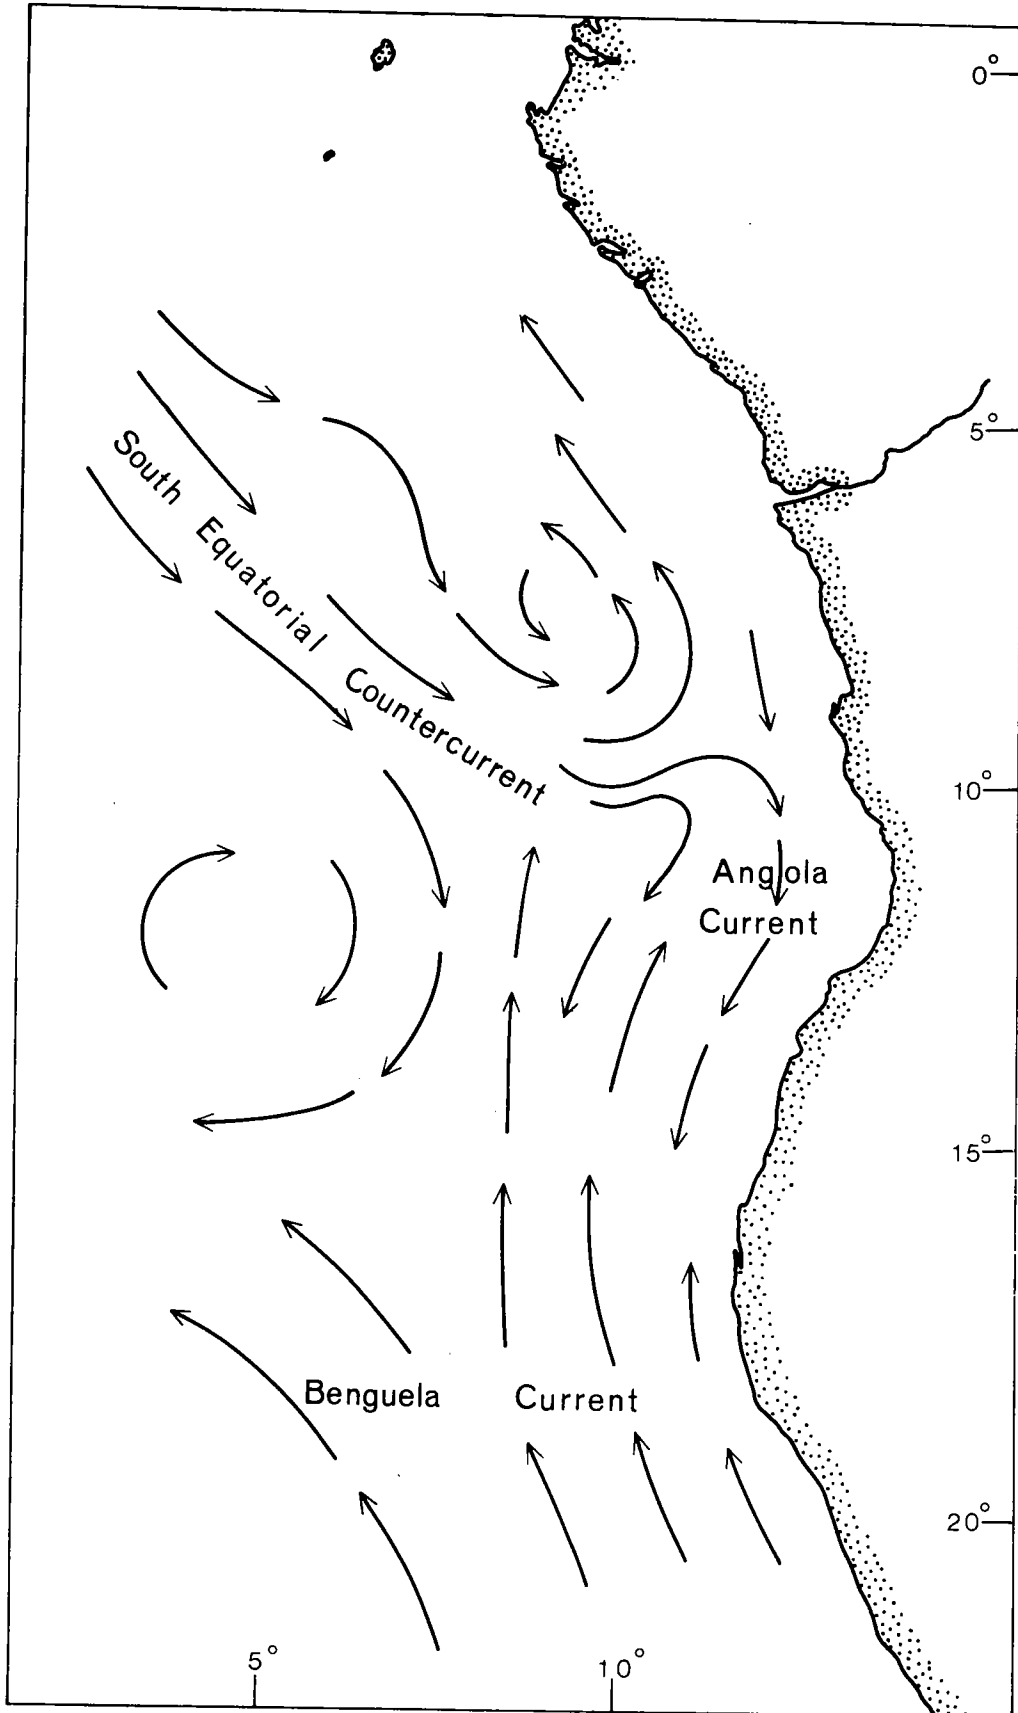

Figure 9

smaller branch continues inshore off the coast of Angola. According to Moroshkin et al. (1970) this bifurcation of the Benguela Current between Lat. 20° and 15° S gives rise to a small zone of divergence over the north flank of the Walvis Ridge. Current velocities also diminish from south to north, being about 25-30 cm/sec off South West Africa and 15-20 cm/sec further north.

A southward-flowing countercurrent has been identified beneath the Benguela Current (Hart and Currie, 1960). The core of this oxygen-depleted current lies at approximately 300-400 m depth at 18° S; the flow is several hundred meters thick and 400 km wide at this latitude. Its presence off South Africa also has been noted by DeDecker (1970). No estimates of current velocity have been made, though van Andel and Calvert (1971) suggest that such a current in the past may account for the erosion they infer to have taken place on the continental shelf between Lat. 20° and 25° S.

South Equatorial Countercurrent

This current flows generally eastward in a broad band between about Lat. 5° and 9° S with velocities on the south of between 7 and 10 cm/sec, increasing to 30-50 cm/sec on the northern edge of the flow. The width and velocity of the flow diminish markedly with depth; at 100 m depth the flow is about 150 km wide with velocities of about 3-5 cm/sec on the south and 15-25 cm/sec on the north.

Between Lat. 8° and 9° E, the current turns south, dividing into two branches. One forms an anticyclonic gyre centered at Lat. $7^{\circ}30'S$ and Long. $9^{\circ}30'E$; the other flows southward providing a source for the Angola Current. This latter name was proposed by Moroshkin et al. (1970) for the narrow, stable, fast (> 50 cm/sec) southward flowing current along the Angolan coast.

The orientation of shoreline features indicates that longshore drift,

from South West Africa to Cape Lopez, is towards the north.

Influx of Fresh Water

The Congo River represents the only major source of fresh water off west Africa between the Niger and Orange Rivers. In terms of discharge it ranks as the second largest river in the world ($1,400 \times 10^9 \text{ m}^3$ annual discharge), its rate of discharge varying between $26,000 \text{ m}^3/\text{sec}$ in August to nearly $60,000 \text{ m}^3/\text{sec}$ in December (Donguy *et al.*, 1965).

Congo River water moves to the northwest as it enters the Atlantic Ocean (Figure 10). At about Long. 11°E , the tongue broadens and moves to the south-southwest as far as about Long. 9°E where salinities of 35‰ are attained. A broad region of slightly lowered salinity can be traced as far south as Lat. 9°S . In reality, however, this view of the Congo discharge is too simplistic: detailed continuous salinity measurements made during the WALDA expedition showed that the Congo River water is distributed in many narrow "streams" of low-salinity water separated by regions of nearly normal salinity.

Deep Circulation

The contrasting bottom water characteristics of the Angola Basin (2.4°C , 34.89‰) and the Cape Basin and western basins of the South Atlantic (1.5°C , 34.77‰) led Wüst (1933) to conclude that Antarctic Bottom Water was prevented from spreading into the eastern basins (Angola and Guinea) by the Walvis Ridge to the south and the Mid-Atlantic Ridge on the west. The differences in salinity and temperature between the Brazil Basin and the Angola Basin are shown in the east-west profile at Lat. 16°S taken from Fuglister (1961) (Fig-

Figure 10. Salinity distribution in surface waters overlying the Angola Basin based on data collected from the N/O "Jean Charcot" during the WALDA expedition of 1971 and from the R/V "Atlantis II" during the Eastern Atlantic Continental Margin Study of 1972.

Figure 10

ure 11).

On the basis of data presented in Fuglister (1961), Shannon and von Rijswijck (1969) believed that a small amount of water enters the Angola Basin through a narrow gap in the Walvis Ridge at about Lat. 31°S. Based on nephelometer studies, Connary and Ewing (1972) reached the same conclusion.

A small amount of bottom water enters the Guinea and Angola Basins through equatorial fracture zones, in particular the Romanche Fracture Zone (Figure 12). Metcalf et al. (1964) determined that the sill depth in these fracture zones was at approximately 3750 meters. In turn, the Guinea and Angola Basins are separated by a sill at approximately 4100 meters depth (Connary and Ewing, 1972).

Wüst (1957) calculated geostrophic currents for the deep waters of the Angola Basin and concluded that the circulation was very sluggish (everywhere less than 5 cm/sec). Temperature and salinity data suggest that essentially homogeneous water exists below 4500 meters. Connary and Ewing (1972) found that the main nepheloid layer occupies the same homogeneous water mass, where settling velocities of particles are balanced by turbulence. They also found that light scattering within the Angola Basin was six times less intense than in the western North Atlantic and four times less than in the western South Atlantic and Cape Basin, further attesting to the sluggish circulation in this basin.

Photographic evidence also suggests slow bottom circulation. Heezen et al. (1964) state: "The photographs indicate a generally muddy bottom with fairly abundant tracks and trails, and indicate a tranquil bottom unaffected by ocean currents." (p. 1140).

In light of the proposed slow circulation, the presence of well defined abyssal swells along the continental rise off southern Angola and along the

Figure 12

lower Walvis Ridge seems anomalous. Though they are not as well developed as similar features along the eastern United States, these swells may have the same mode of origin, formed by currents flowing along the continental rise. Since present currents do not seem capable of producing such features, it can be assumed: (1) they were not formed by abyssal currents; or, (2) they were formed at a time when abyssal circulation was more vigorous, perhaps during glacial periods of the Quaternary. At present the lack of data does not permit us to choose between these alternatives, though the regularity in size of these features, their position on the rise, and their form tend to argue against another mode of origin, such as slumping or sliding.

Paleoclimatology and Oceanography

Variations in environmental conditions within the study area during the Quaternary undoubtedly had a significant effect on both the terrigenous and biogenic sources of sediment for the continental margin. Most of the Pleistocene climate research has been conducted in southern and eastern Africa and has been related primarily to the redistribution of early man and other vertebrates in response to climatic changes (e.g., Cooke, 1947; Jones, 1944; Moreau, 1933; Leakey, 1949). Angola, South West Africa, and the western Congo have been very poorly studied, except for a few isolated sites (van Zinderen Bakker, 1963; van Zinderen Bakker and Clark, 1962; Voss, 1970; de Ploey, 1963, 1964, 1965).

Figures 13 and 14 illustrate van Zinderen Bakker's (1967) interpretation of the climatic conditions during glacial intervals. The following are the major differences between glacial and interglacial climatic extremes:

- (1) The center of the South Atlantic Anticyclone (high pressure) shifted northwards (by 8 to 12 degrees) and eastward during glacials.

Figure 13. Schematic interpretation of the climatic features during a glacial southern summer in western Africa (after van Zinderen Bakker, 1967). Horizontal dashed lines indicate pluvial conditions; diagonal lines indicate upwelling.

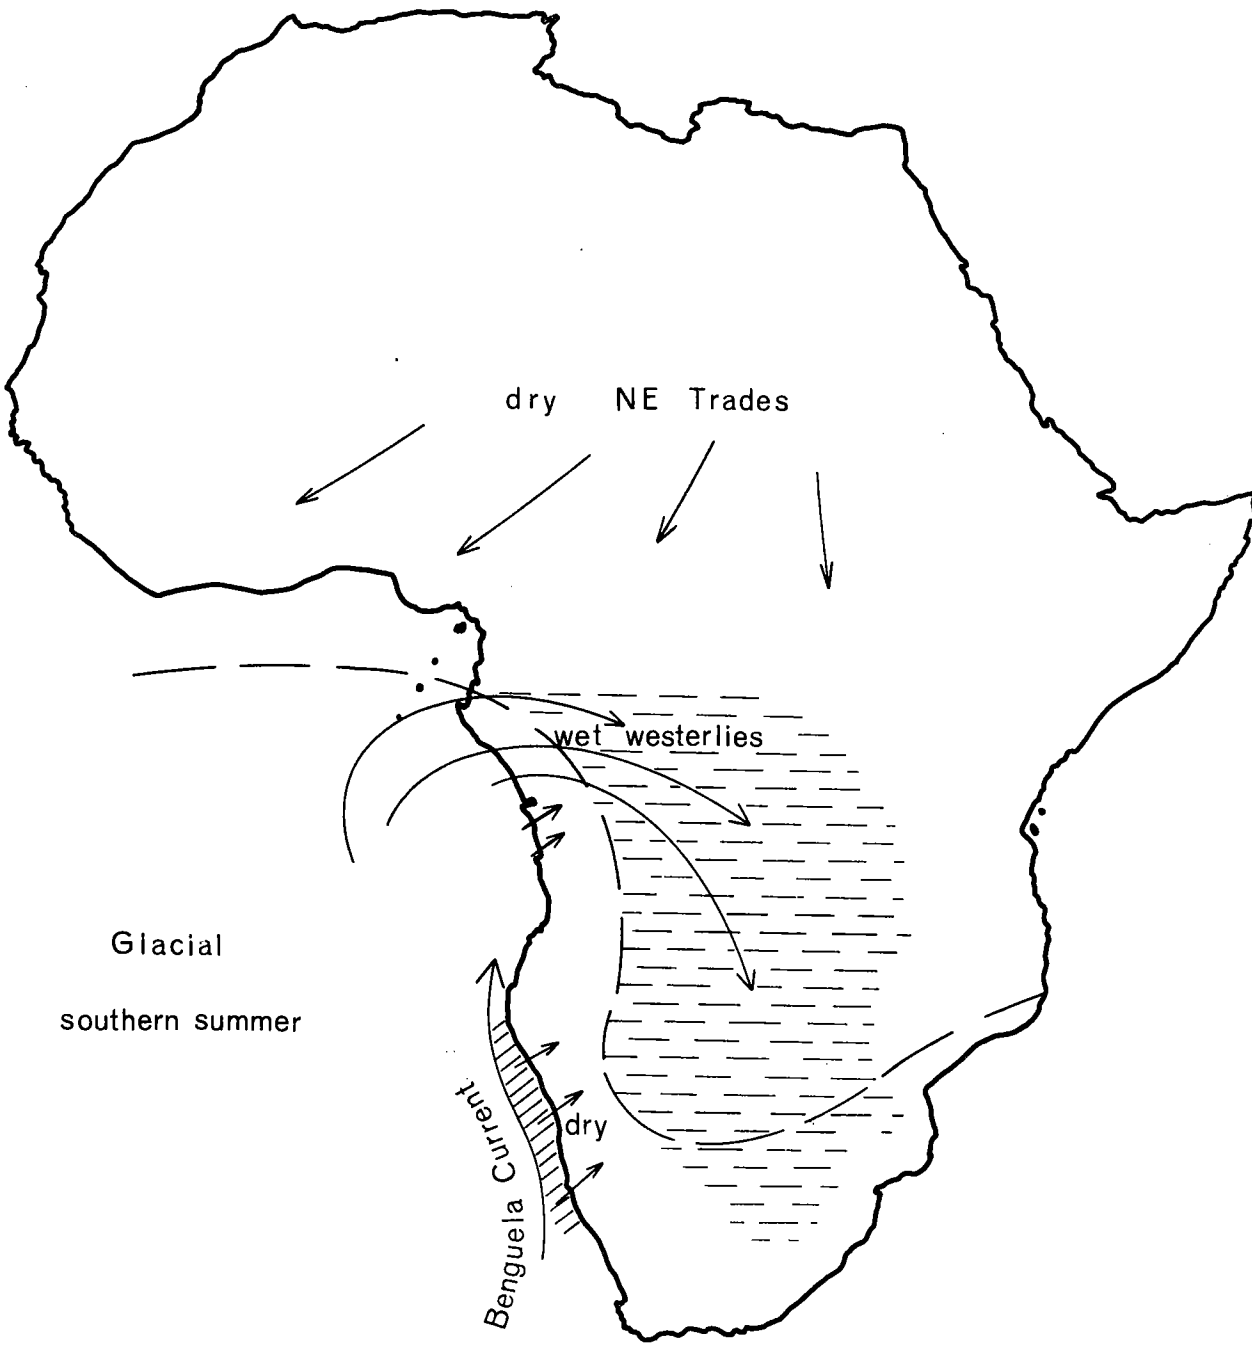

Figure 13

Figure 14. Schematic interpretation of important climatic features during a glacial northern summer in western Africa (after van Zinderen Bakker, 1967).

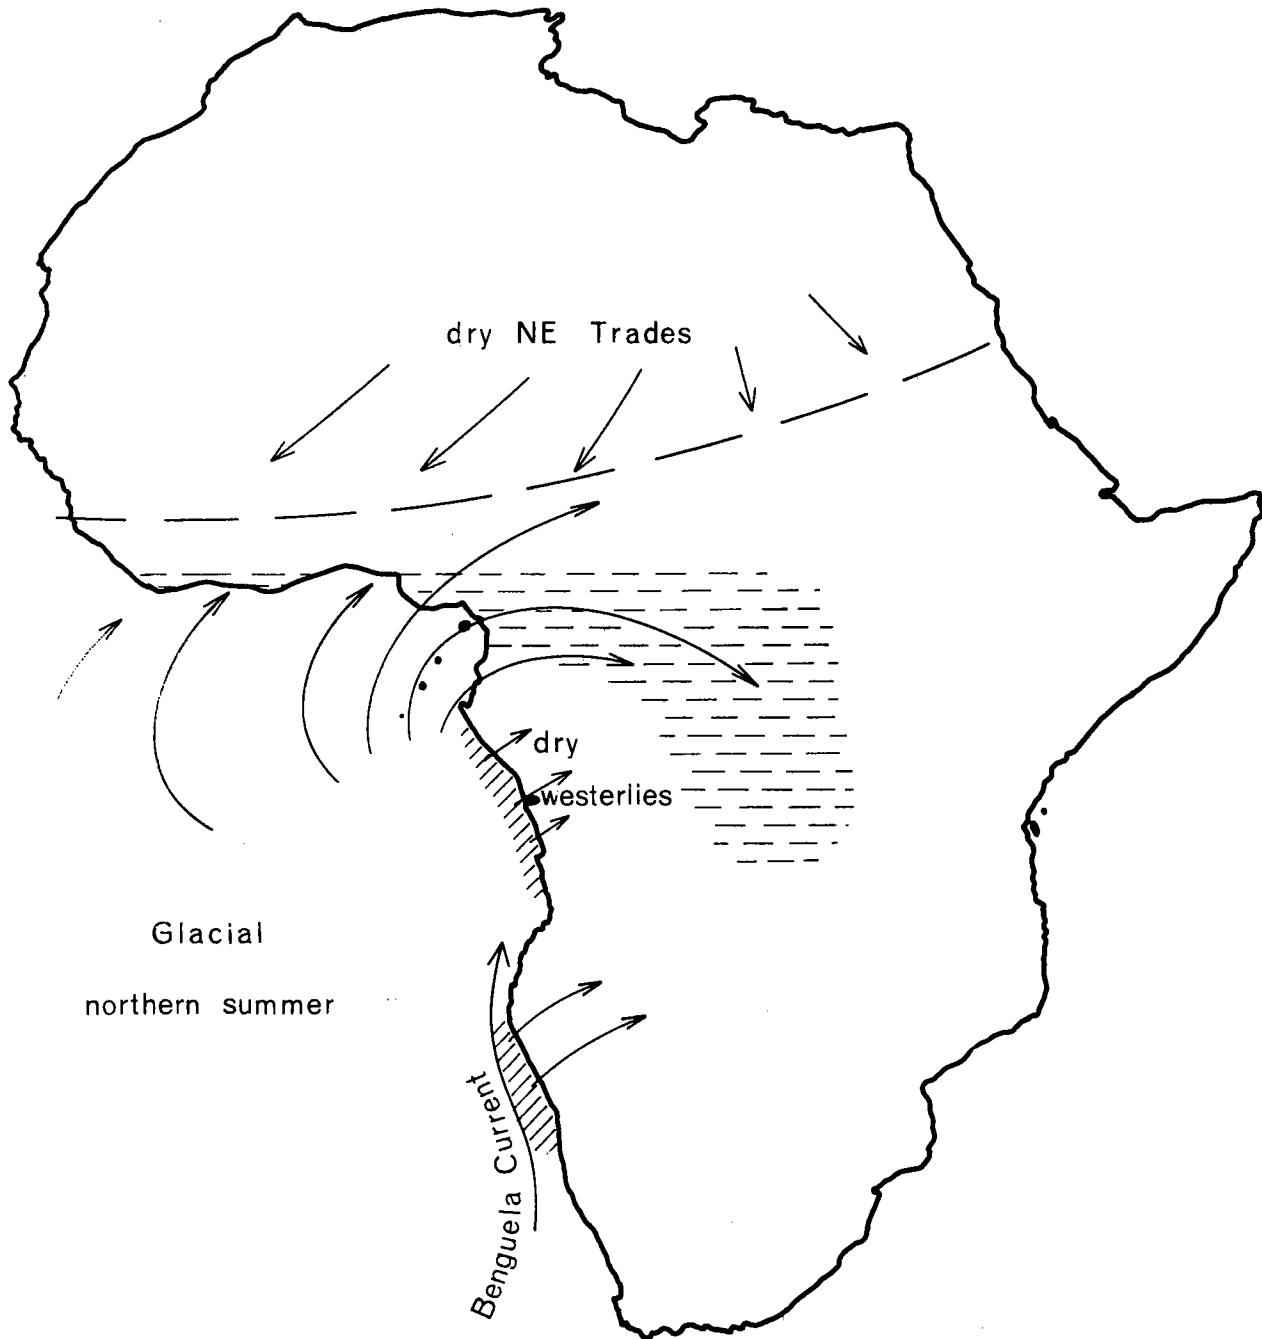

Figure 14

- (2) During glacial summers, pluvial conditions extended southward in the interior from the equator to near the southeast coast of Africa (28°S). During interglacial summers, pluvial conditions were restricted to the Congo Basin (north of Lat. 10°S).
- (3) There was a marked intensification and northward extension of the Benguela Current during the glacial periods. This is indicated by the northward extension of the Namib Desert during glacials. Van Andel and Calvert (1971) also suggest that the Benguela Current flowed faster during times of lowered sea level, in order to account for the erosion surfaces they observed along the shelf off South West Africa.
- (4) Intensive upwelling, particularly during winter, occurred during glacials off the Congo Republic, Gabon, and northern Angola. This did not occur during interglacials.

The direct correlation between glacial conditions in higher latitudes and pluvial conditions in central Africa has been the focus of several investigations and has generated considerable controversy (van Zinderen Bakker, 1966; Flint, 1959). Based on a wide variety of evidence from sites throughout sub-Saharan Africa, van Zinderen Bakker (1972) concludes:

- (1) temperature changes coincident with those of the northern hemisphere also occurred in tropical Africa;
- (2) changes in humidity were correlated with temperature changes; and,
- (3) the "glacial" climate of tropical Africa was drier and the "interglacial" climate wetter than at present.

As van Zinderen Bakker points out, however, this relationship does not apply to extratropical regions.

Glacial aridity in this region was probably further intensified along the Angola and Congo coastal areas by the more northward penetration of the Benguela Current and the onset of upwelling conditions along suitably aligned coastal regions between Luanda and Cape Lopez. According to van Zinderen Bakker (1967), supported by the work of de Ploey (1963) and Clark (1962), there was a "desert climate along the coast and a semiarid region reached farther inland, reaching as far as Leopoldville (400 km inland)." These semiarid conditions also would have reached as far as central Angola, giving it a semiarid, cool climate during glacial periods. Fairbridge's (1964) studies on the distribution of fossil dunes in central Africa also support this conclusion. The dry conditions undoubtedly had a significant effect on the hydrologic regime of the Congo River, the single most important source of terrigenous sediment for the Angola Basin. This is perhaps of even greater relevance since most of the sediment delivered to the ocean is derived from runoff below Stanley Pool (Heezen *et al.*, 1964), a region that was desert or semi-desert during glacial periods.

Data from earlier than approximately 65,000 years B.P. are completely lacking for this region of Africa. In addition, no attempts have been made to determine the precise temperature and rainfall changes that took place between glacial and interglacial periods, though van Zinderen Bakker and Clark (1962) and van Zinderen Bakker and Coetzee (1972) suggest that the region in northeastern Angola experienced temperatures equivalent to at least 500 m greater altitude during the period between 30,000 and 14,000 years B.P. This was followed by a warmer, humid phase (the Makalian Wet Phase) during which a climatic optimum was reached (approximately 7,000 to 4,500 years B.P.).

DISTRIBUTION OF SUSPENDED MATTER

Surface Suspended Matter

Suspended Matter Distribution

Throughout the WALDA expedition and the "Atlantis II" Cruise 67 surface suspended matter samples were taken in an effort to determine the pattern of dispersal of fine sediment in the surface waters off the west coast of Africa. In addition, Forel color determinations were made during daylight hours and clay mineral determinations were made on selected samples collected on silver filters. Temperature and salinity were also recorded when samples were taken.

The results from the "Atlantis II" cruise have been reported by Emery *et al.* (1973). The combined results from the French and American cruises for suspended matter concentration (Figure 15) show several significant features:

- (1) the broad band of high sediment concentration off South West Africa and southern Angola;
- (2) the high concentrations off major rivers, such as the Kunene, Cuanza, and Congo; concentrations 150-200 kilometers from the mouth of the Congo River may exceed 1.0 mg/l;
- (3) the large offshore area with very low (less than 0.12 mg/l) concentrations between Lat. 7°S and 10°S.

The plume of high sediment concentration from the Congo closely parallels the salinity distribution (Figure 10). Within the low salinity region off the Congo, the "Atlantis II" results were consistently lower than the WALDA results (Figure 16), although they converged at salinities above 35‰. These discrepancies were apparently not the result of a systematic analytical error since the "Atlantis II" results off southern Angola were consistently higher than the WALDA data, and elsewhere were quite compatible. Rather, this dif-

Figure 15. Distribution of total suspended matter (mg/l.) off southwestern Africa based on samples collected from the N/O "Jean Charcot" during the WALDA expedition of 1971 and from the R/V "Atlantis II" during the Eastern Atlantic Continental Margin Study of 1972. Solid points are locations of deep-water stations.

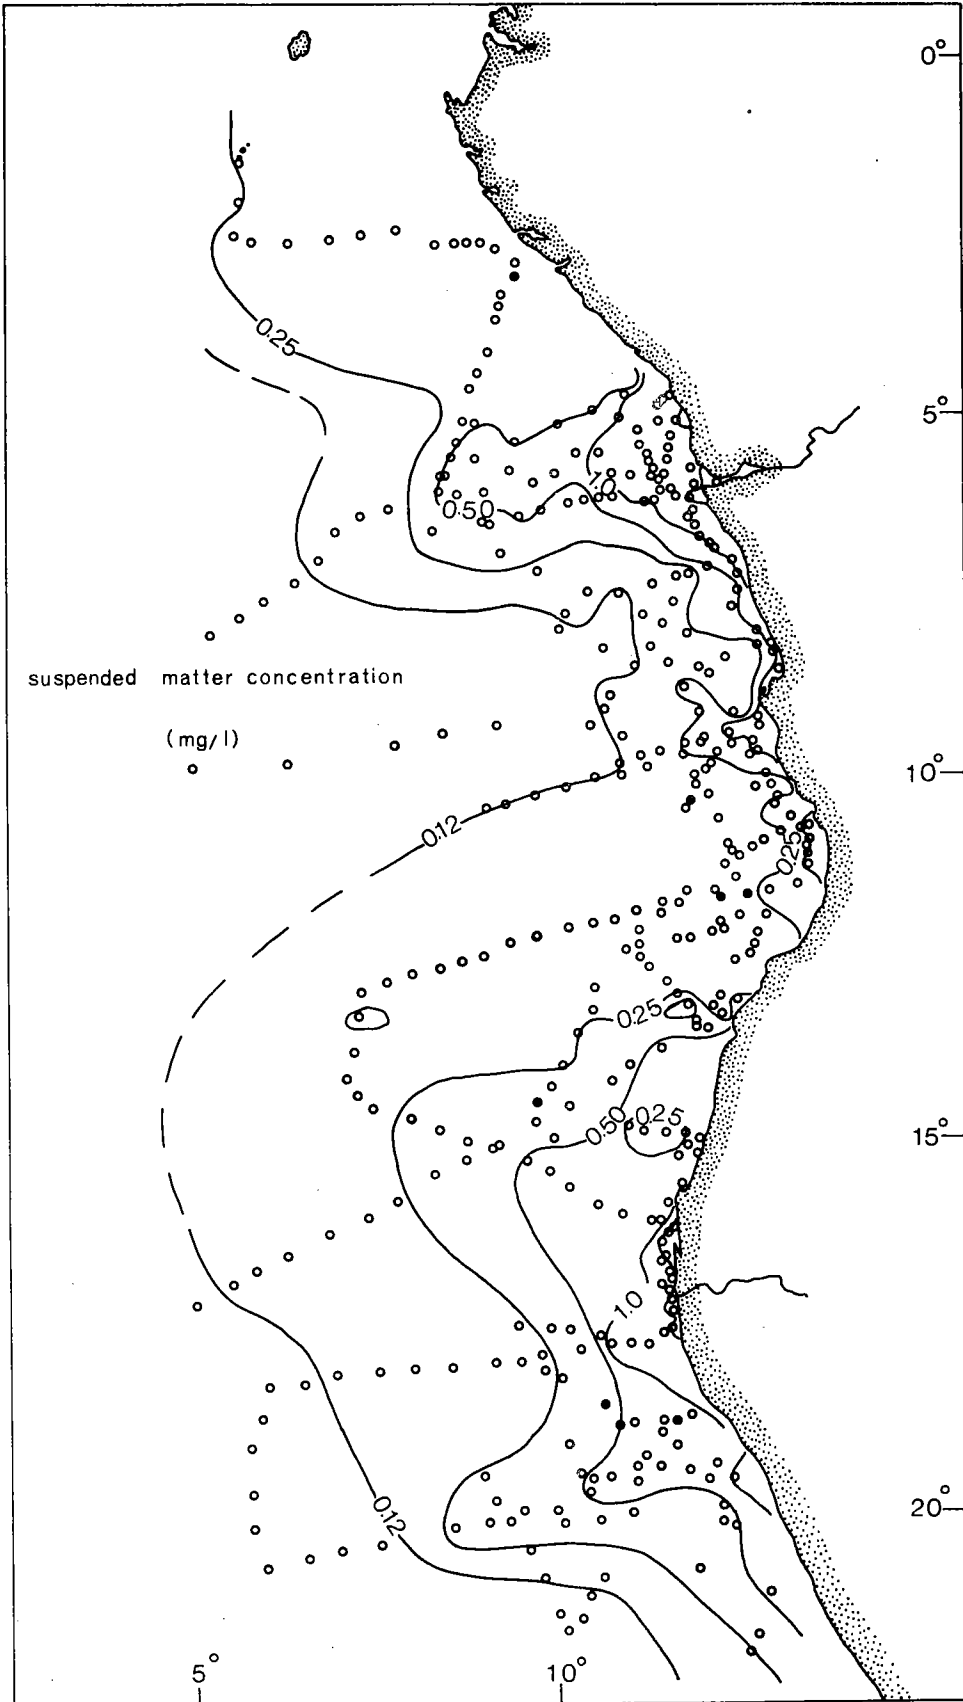

Figure 15

Figure 16. Relationship between salinity and total suspended sediment concentration off the Congo River based on data from the "Atlantis II" (○) and the "Jean Charcot" (●).

Figure 16

ference probably reflects that change in river discharge between June and July, the times of the two cruises. On the average, approximately 5×10^3 m³/sec more water is discharged in June than in July (Donguy et al., 1965).

One possible explanation for these differences is that during periods of high river discharge, the distance from the river mouth to a particular isohaline is greater than at times of lowered discharge. This increased distance may permit more suspended matter to leave the surface waters and to sink towards the bottom than would occur during periods of lower flow rate. This would be particularly true if the sediment-discharge relationship were found to be a convex-upward curve; as pointed out by Bornhold et al. (1973), considerably more detailed studies are needed to establish the exact mechanisms controlling the dispersal of fine sediment into the ocean from major rivers.

The high suspended matter concentrations off South West Africa and southern Angola are directly related to the Benguela Current and the high biological productivity associated with it (Steeman Nielsen and Jensen, 1957). Combustible organic matter concentrations exceed 0.25 mg/l in a band several hundred kilometers wide along the coast south of 14°S (Emery et al., 1973). In addition, organic concentrations are high off major rivers such as the Congo and Kunene; much of this organic material probably is derived from the continent, as evidenced by the frequent observation of roots and branches of trees offshore from these rivers. In addition, however, much of the measured organic matter off major rivers probably results from increased phytoplankton productivity produced by the high nutrient concentrations in the river waters.

The suspended matter distribution off central Angola, Congo, and Gabon is closely related to the circulation scheme proposed by Moroshkin et al. (1970). The zone of low sediment concentration off central Angola corresponds to the eastward influx of water originating in the South Equatorial Counter-

current. The path of Congo River water as it enters the Atlantic is also controlled by the bifurcation of the South Equatorial Countercurrent as it approaches the coast (Figure 9). Further north, suspended matter from the shelf off Gabon is carried northward into the Gulf of Guinea (Bornhold et al., 1973).

The results of Forel color determinations (Figures 17 and 18) closely parallel the total sediment concentration, as do Secchi disc transparency results (Figure 19) (Emery et al., 1969; Manheim et al., 1970; Bornhold et al., 1973).

Composition of Suspended Matter

X-ray diffraction studies of 21 suspended matter samples collected on silver filters revealed significant latitudinal differences in the importance of particular clay minerals. Off southern Angola and South West Africa, montmorillonite is dominant with lesser amounts of illite and kaolinite. North of central Angola, however, montmorillonite is much less abundant and the clay-mineral assemblage is dominated by kaolinite. This is particularly evident within the plume of river water from the Congo where kaolinite is extremely abundant. Talc was present in all of the samples analyzed; this mineral has also been noted in other studies of suspended matter in open ocean waters (Emery et al., in press; Summerhayes, personal communication). Chlorite was detected in only a few of the samples.

Twenty sections of Millipore filters of suspended matter were mounted in cedar oil and viewed under a petrographic microscope. Commonly observed constituents included: diatoms, radiolaria, silicoflagellates, dinoflagellates, marine algae, fecal pellets, organic aggregates, and inorganic grains.

Fecal pellets (Figure 20) were elongated, oval, dense aggregates of

Figure 21

diatom debris and organic matter. Organic aggregates were, by contrast, more diffuse "mats" of organic matter with diatoms and inorganic debris adhered to the surface (Figure 21).

Considerable latitudinal variation is apparent in the density and diversity of diatoms and other components. Silicoflagellates and dinoflagellates are particularly abundant in the southern part of the area (south of Lat. 10°S). Diatoms reach their highest diversity in the southernmost part of the region (south of Lat. 15°S) and in samples off the Congo River mouth; between about Lat. 8° and 15°S very impoverished diatom floras are found. Fecal pellets and organic aggregates follow the same trend as diatoms, with the latter being very abundant off the Congo River mouth.

Suspended Matter in the Deep Water

In addition to surface water data, ten stations (Figure 15) were occupied during the WALDA expedition where suspended matter concentrations were measured on the near-bottom water off the Angola Basin. These samples were taken with either a 30-liter Niskin bottle or two van Dorn samplers placed approximately 10-15 meters above a bottom camera. Because of the very precise way in which the camera was maintained at or near the bottom, it was felt that very little sediment was roiled into suspension by the camera frame.

The near-bottom suspended matter concentrations in the Angola Basin exhibit a linear decrease with depth below 1000 meters (Figure 22a). Three stations (filter numbers 129, 130, and 160), which show distinctly lower values, were taken within the rough topography of the Angola diapir field. The topography of the Angola diapir field protects the near-bottom water from the lateral transport of suspended matter (possible originating from the Congo River as suggested by Connary and Ewing, 1972). The uniformly linear

Figure 22

decrease in sediment concentration for the other five station, and the absence of any major discontinuities, also suggests that no well-developed nepheloid layers exist at depths down to 3600 m. Variations in light scattering values with depth closely parallel the observed trend in sediment concentration from the present study (Figure 226). Connary and Ewing (1972) state that intermediate nepheloid layers (less than 4000 m) are only of local extent. The main nepheloid layer occupies the homogenous water mass below about 4000-4500 meters.

RECENT SEDIMENTS

Surface sediments from the continental shelf, slope, rise, and abyssal plain were analyzed for texture, percent calcium carbonate, clay minerals, and organic carbon in an effort to determine the nature of sedimentation during the Holocene in the eastern Angola Basin. The samples were also studied under a binocular microscope and the abundances of the major components were noted. The results of the analyses of surface sediments are found in Appendix II. The methods used in the analyses are outlined in detail in Appendix III.

Surface Distribution of Calcium Carbonate

Calcium carbonate content of surface sediments varies considerably throughout the study area (Figure 23). Continental shelf sediments off Gabon, Congo, and Angola are characterized by carbonate values of less than 20%. Sample density is too scattered in most areas to detect any trends among these samples, although inner shelf samples appear to contain, in general, less than 10% CaCO_3 , whereas outer shelf samples contain between 10 and 20%.

Carbonate values on the continental rise off central Angola are approximately 25-45%, diminishing seaward to less than 20%. This seaward diminution is primarily controlled by the increasing carbonate dissolution with depth below 5000 m as evidenced by the corroded appearance of foraminiferal tests. The Congo Cone is characterized by carbonate values of less than 15% as a result of the tremendous influx of terrigenous sediment through the Congo canyon system. The sediments on the Walvis Ridge and Guinea Rise contain more than 80% carbonate. The Walvis Ridge, isolated from major terrigenous sediment sources, is dominated by biogenic sediments, as is the Guinea Rise, located

Figure 23. Distribution of calcium carbonate in surface sediments from the eastern Angola Basin and adjacent areas.

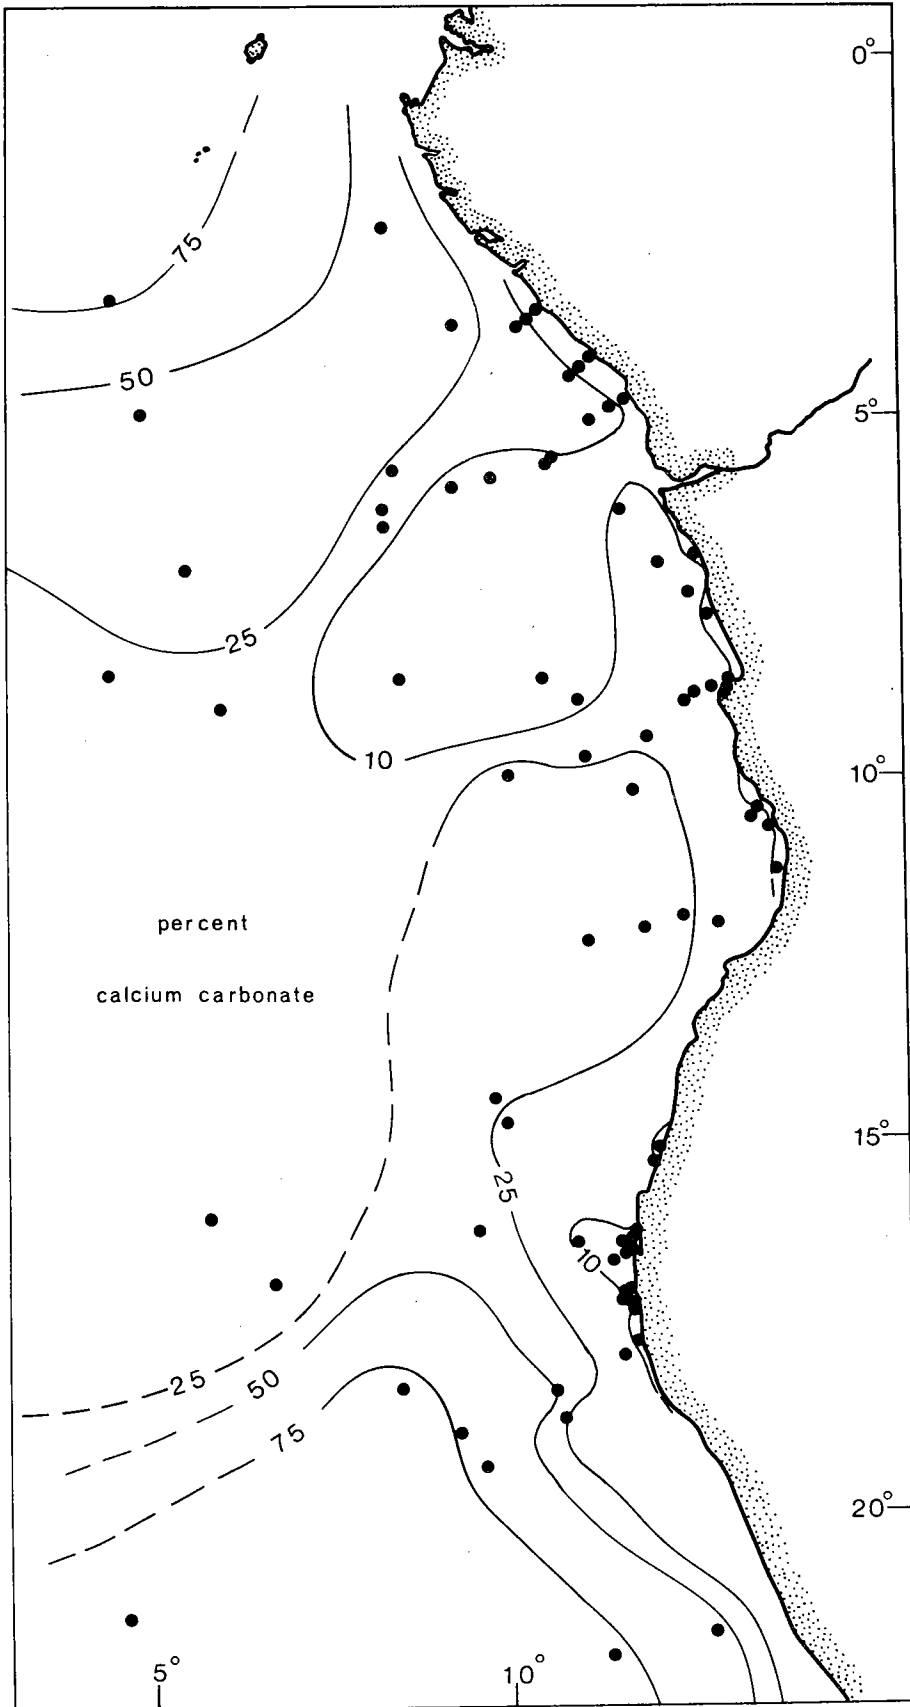

Figure 23

in a region of high surface carbonate productivity.

Clay Minerals

An investigation of the clay-mineral composition of Angola Basin sediments was undertaken in order to: (1) attempt to define the present clay-mineral provinces; and, (2) attempt to describe the changes in clay-mineral abundances throughout the late Pleistocene and Holocene.

Methods

The less-than-2-micron fraction was separated by centrifugation, sedimented on a silver filter (Selas Flotronics; 0.45 μ nominal pore size), and scanned at 2°/minute on a Norelco x-ray diffractometer (nickel filter, Cu K α , 40 Kv, 40 ma). The sample was then glycolated by the vapor pressure technique and scanned again. Some samples were then heated to 400° and 500°C and reanalyzed.

The method for determining mineral percentages is based on weighted peak area and is summarized by Biscaye (1965). This method was selected primarily for comparison purposes: Biscaye is the only other worker to have analyzed the deep-sea clay-mineral composition of sediments in this region of the South Atlantic. As Biscaye (1965) pointed out, however, "the weighted peak-area percentages...are constructs and, at best, are untestable approximations of real percentages."

The following clay minerals were identified in this study: montmorillonite, kaolinite, illite, and chlorite. Chlorite and kaolinite were estimated using the 3.58Å/3.54Å doublet, following Biscaye's (1964) method. The crystallinity (v/p) of montmorillonite was also calculated; this is the ratio of the low angle "valley depth" to the peak height of the 17Å glycolated

montmorillonite peak.

Chlorite

Chlorite concentration is uniformly low at mid-low latitudes and only gains relative importance (greater than 10%) at higher latitudes (Goldberg and Griffin, 1964; Biscaye, 1965). Within the study area, chlorite was consistently less than 5% of the total clay fraction. This value agrees with Biscaye, but is under the 10-15% range determined by Goldberg and Griffin (1964).

Montmorillonite

Goldberg and Griffin (1964) stated that montmorillonite distribution is generally related to sea-floor volcanism. Biscaye (1965), on the other hand, discounted any clear association between volcanism and montmorillonite abundance and concluded that any relation between this clay mineral and latitude or source is obscured by the fact that it can be formed under a wide variety of conditions, both subaerial and submarine. Studies of atmospheric dust by Chester et al. (1972) in the southeastern Atlantic show a very complicated latitudinal distribution pattern for montmorillonite.

The observations of Biscaye (1965) are clearly supported by the present study (Figure 24). Montmorillonite varies, in general, between 30 and 60%. A notable exception occurs in the vicinity of the Congo and Kunene Rivers, where dilution by kaolinite and illite reduces montmorillonite concentrations to less than 20%.

All of the values of crystallinity except two are positive and average about 0.30, with some as high as 0.74. The values display no systematic variation within the study area, although a slight trend toward low values in the northernmost part of the region tends to support Biscaye's conclusion

Figure 24. Distribution of montmorillonite in surface sediments of the eastern Angola Basin.

Figure 24

that tropical weathering is not conducive to well-developed crystallinity in montmorillonite.

Kaolinite

Kaolinite abundance corresponds directly to the intensity of tropical weathering on adjacent land masses (Yeroshev-shak, 1961; Goldberg and Griffin, 1964; Biscaye, 1965). The latitudinal variations seen within the present study area (Figure 25) clearly support this concept. Concentrations of less than 10% are evident over the Walvis Ridge and the southern Angola Basin and increase to a maximum of 60% on the Congo Cone.

Illite

The concentrations of illite in offshore areas of west Africa reflect the soil composition on adjacent land areas. Illitic soils are dominant in the arid regions of southern Angola and South West Africa and give way to kaolinitic soil groups nearer the equator (van der Merwe, 1966). Therefore, the pattern of illite concentration is nearly the inverse of that of kaolinite (Figure 26). Values between 40 and 60% characterize the Walvis Ridge region and the nearshore areas off Angola. North of 10°S, however, concentrations are generally less than 20%.

Methods of Transport to the Deep Sea

The major mechanisms for the delivery of clay minerals to the marine environment, fluvial and eolian, change in relative importance throughout the study area. The Congo, as the single most important source of fine sediment for the Angola Basin, is the major supplier of kaolinite with lesser amounts probably originating in the Niger River system (Porrenga, 1965) and other small

Figure 25. Distribution of kaolinite in surface sediments of the eastern Angola Basin.

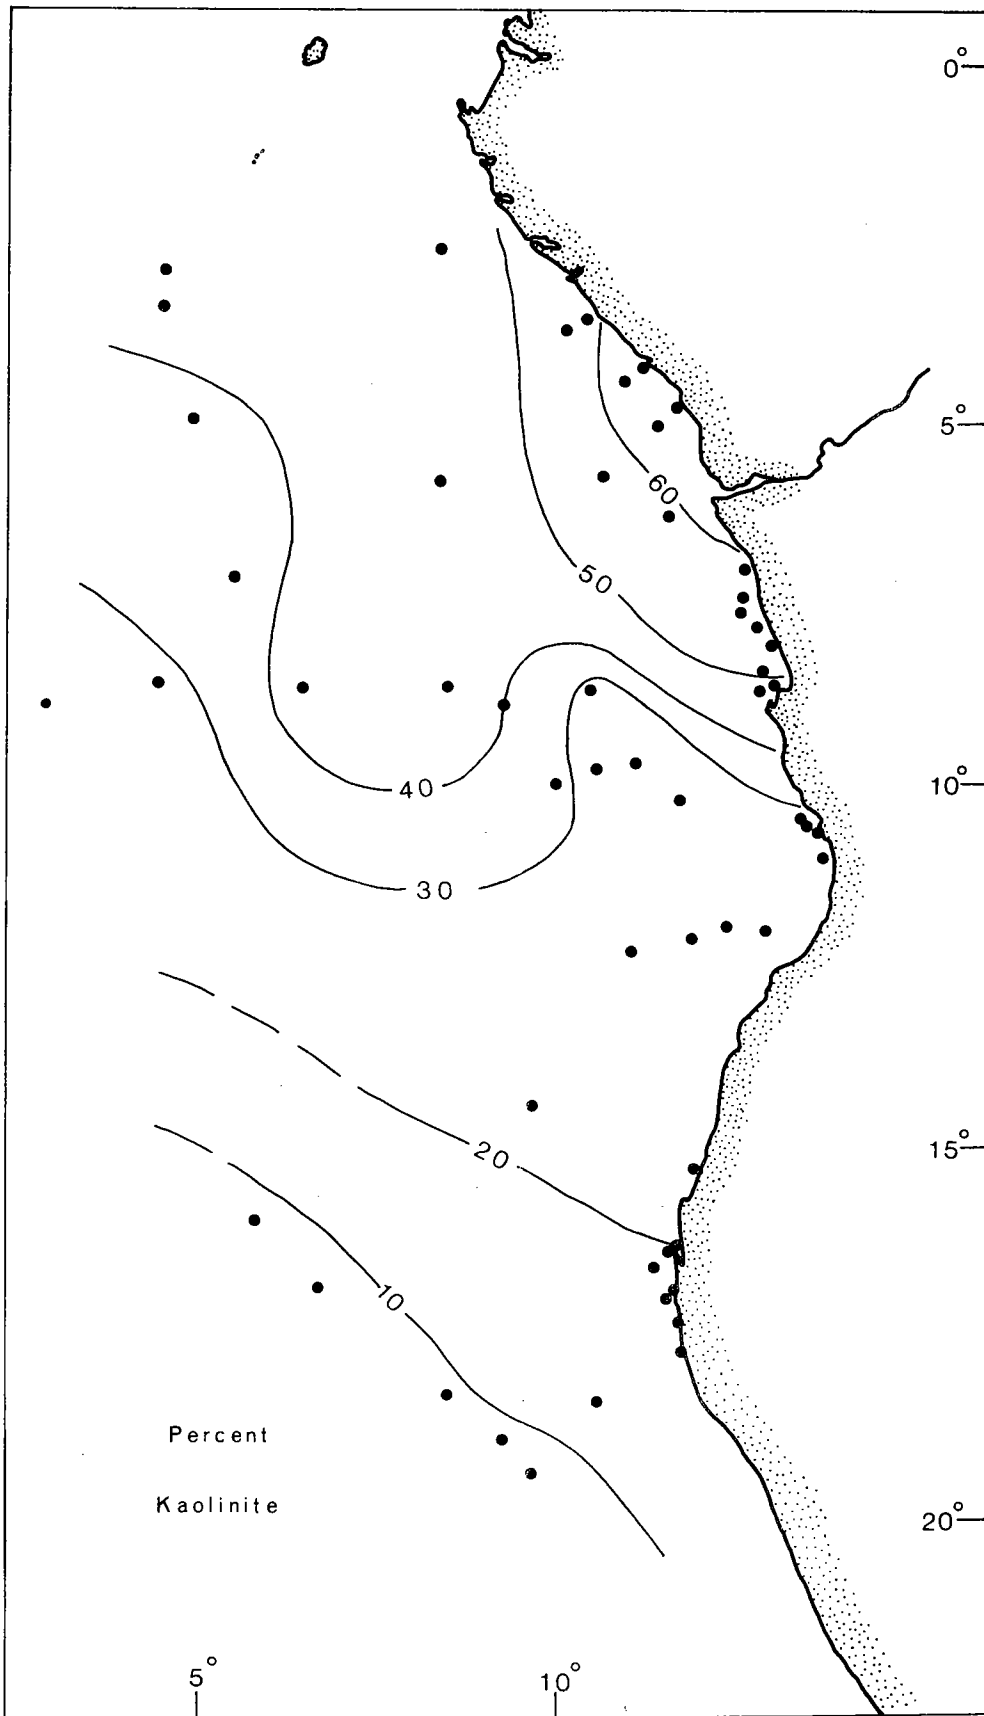

Figure 25

Figure 26. Distribution of illite in surface sediments of the eastern
Angola Basin.

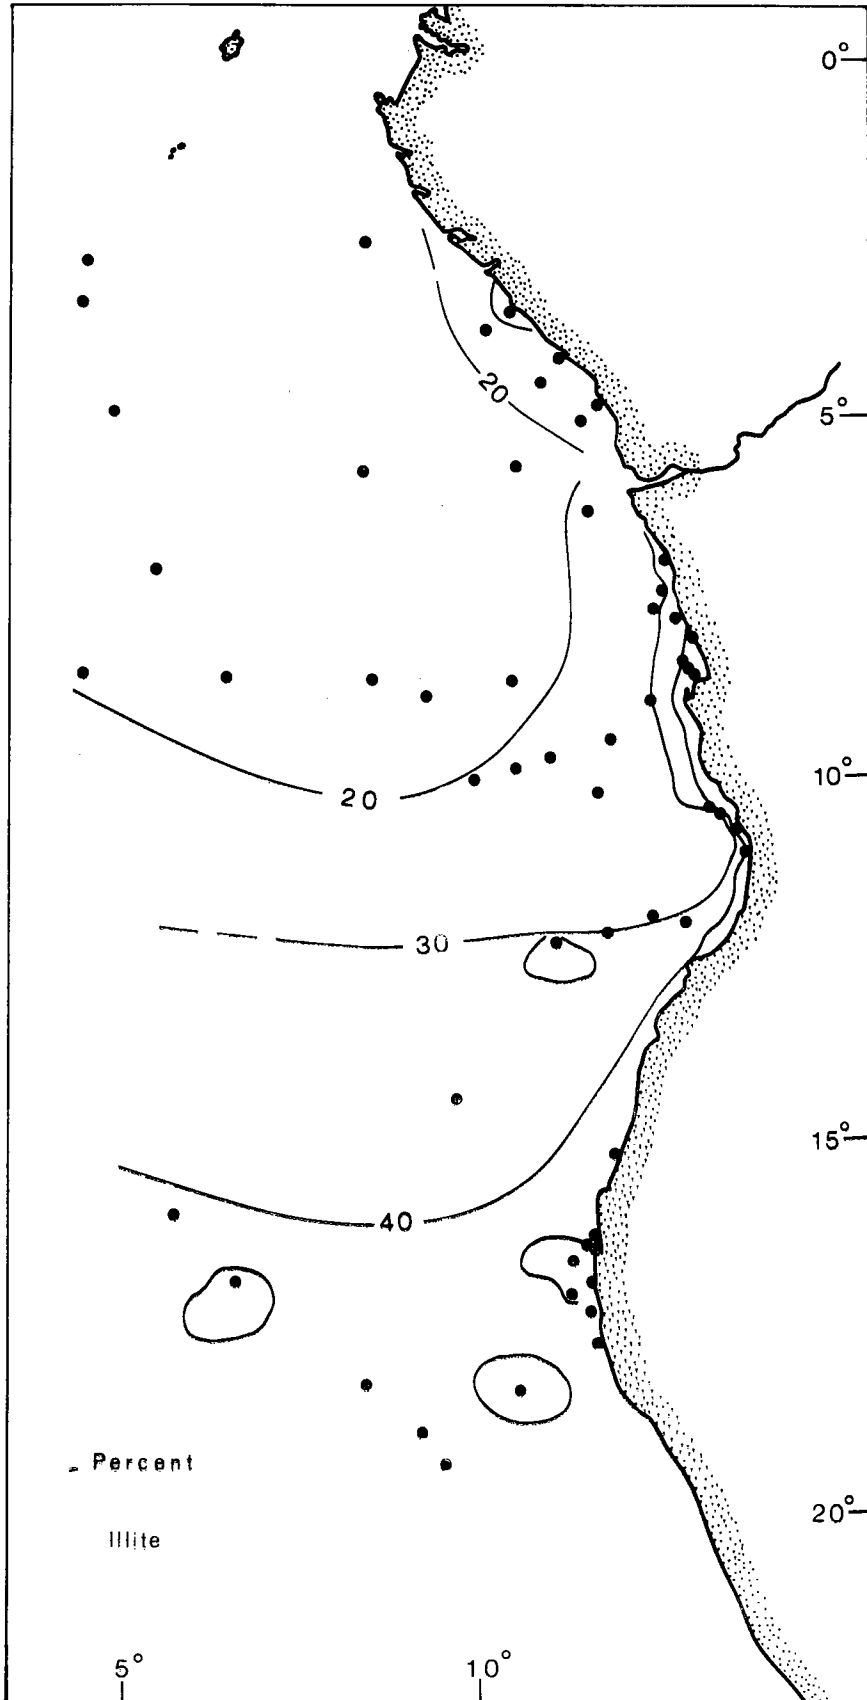

Figure 26

rivers of Cameroons (Berthois et al., 1968), Gabon and the Congo Republic (Brazzaville). Eolian input of kaolinite to the Angola Basin is not significant at the present time.

Illite and montmorillonite, on the other hand, are dominant clay minerals in the soils of South West Africa and South Africa. In view of the paucity of large rivers in this area, eolian transport probably is more important than farther north (Chester et al., 1972). The prevailing southeast trade winds carry dust northward from the Namib Desert into the Angola Basin and the strong, easterly Berg winds, although only occurring 10% of the time in South West Africa, account for large volumes of sediment being blown offshore. Illite and montmorillonite also are brought to the study area by the Orange and Kunene Rivers; suspended terrigenous material from both eolian and fluvial sources becomes entrained in the Benguela Current and is carried northward into the Angola Basin area.

LATE QUATERNARY SEDIMENTS

Piston cores from the Angola Basin were routinely sampled by the writer at 20 cm intervals and analyzed for percent sand, percent calcium carbonate within the silt and clay fraction, abundance of the planktonic foraminifera species, the abundance of fecal pellets, and the ratio of planktonic foraminifera to radiolaria. The results of the routine analyses are included in Appendix II and the methods used for the textural and carbonate analyses are presented in Appendix III. The sand fractions of the samples were studied under the binocular microscope and the abundances of the major components were noted.

In addition, clay mineral and organic carbon analyses were conducted on samples selected from the major stratigraphic units (defined on the basis of micropaleontology) within several of the cores. These data are also presented in Appendix II.

Stratigraphy of Deep-Sea Cores

Several criteria were used in an effort to establish the absolute and relative stratigraphy of the piston cores in the Angola Basin. These included the carbonate content of the less-than-62 μ fraction, the abundance of certain species of planktonic foraminifera (Globorotalia menardii, G. menardii var. flexuosa, G. tumida), the ratio of foraminifera to radiolaria, and color differences between major units.

All of the cores used in this study were late Pleistocene in age except two (CH99-42 and KW 18), both of which were from the Angola diapir field region and were Pliocene in age. The late Pleistocene cores were in general

younger than $200-300 \times 10^3$ years B.P., and several did not penetrate through the Riss/Würm (125,000 yr B.P.) interglacial.

The ideal pelagic section for the late Quaternary in the Angola Basin consists of the following units:

- (1) a light-colored, 30-60 cm upper unit, highly calcareous, weakly siliceous, with a typical tropical-transitional foraminiferal fauna;
- (2) a very dark green-gray, 1-2 meter unit, low in carbonate, more highly siliceous (particularly radiolaria), with abundant organic matter, pyritized burrows and fecal pellets; foraminifera are rare;
- (3) a unit of alternating light and dark layers similar to units (1) and (2); the overall carbonate content is higher than (2) with warm-water foraminifera occurring in the light-colored, calcareous zones;
- (4) a dark green-gray, low carbonate, highly siliceous unit with few foraminifera similar to unit (2).

Despite local variations, this general pattern appears to hold throughout the study area.

A very similar sequence of lithologies was described for cores from the Guinea Basin (Lavrov and Savel'yeva, 1971). Diatoms, however, were found to be a more important constituent of their cores and radiolaria were apparently of very minor importance.

Abundance of the *Globorotalia menardii* Complex

Ericson and Wollin (1956) proposed that the abundance of the *Globorotalia menardii* complex was a reliable index of climatic oscillations in the tropical and sub-tropical Atlantic. Since then many other "warm" and "cold" sensitive species have been used to establish climatic curves (e.g., Ruddiman, 1971; Lidz, 1966; Imbrie and Kipp, 1971). As Kennett and Huddleston (1972)

point out, however, there is never complete agreement among workers as to which species are "cool" and which are "warm"; they conclude, as did Ericson and Wollin (1956), that the G. menardii complex is one of the most sensitive warm-water indicators. The last appearance of the form G. menardii var. flexuosa is taken to mark the upper part of the X-zone or the Riss/Würm interglacial, and provides a key datum in those cores containing G. menardii.

Although several cores from the Angola Basin did not contain representatives of the G. menardii complex, many other cores could be confidently correlated on this basis (Figure 27). The upper 50-100 cm in most of these cores is characterized by a warm-water foraminifera fauna, including abundant G. menardii. This zone, the Z, is taken to be the Holocene, the lower boundary of which is marked by a severe reduction with depth in the importance of G. menardii. The underlying unit is characterized by a general absence of G. menardii except for a brief recurrence in the middle of the Y zone; this brief recurrence is thought to mark the Würm I/Würm II interstadial, the peak of which occurred at about 60×10^3 yr B.P. A major reappearance of abundant G. menardii, G. tumida, and G. menardii var. flexuosa occurs at between 2 and 3 meters in most cores and marks the top of the X zone. This zone is marked by several peaks of G. menardii abundance and extends approximately 2 meters in most cores. A severe reduction again occurs at the W/X boundary. The W zone is characterized by a general absence of G. menardii in its upper part with a gradual increase in its lower sections; correlations become more difficult within the W and earlier zones.

Core V19-280 possesses two peaks of G. menardii abundance within the upper 2 meters, underlain by a long (2 meters) section in which this faunal complex is absent. G. menardii var. flexuosa exists in abundance near the

Figure 27. Abundance of individuals of the Globorotalia menardii complex in cores from the eastern Angola Basin. The X-Y-Z zones are based on the relative abundance of this group of foraminifera (Ericson and Wollin, 1956).

top of the core. On the basis of the above evidence, it was concluded that the upper part of this core lies at about the top of the X zone (75,000 years B.P.).

Paleoclimatic Curves and Stratigraphic Zonation

The late Quaternary paleoclimatic curve of Emiliani (1971) was used for comparison, but was placed within the Broecker and van Donk (1970) time scale. This time scale was adopted for the present study as it appears to be most compatible with results of other kinds of Quaternary stratigraphic investigations (e.g., Mesolella et al., 1969) and has been widely used elsewhere in the Atlantic.

This climatic curve was subdivided into the X-Y-Z units and subunits of Ericson and Wollin (1956) and modified from the recent detailed work of Kennett and Huddlestun (1972) in the western Gulf of Mexico. The X-zone represents the interglacial or generally warm interval extending from 75×10^3 yr B.P. to 127×10^3 B.P. (Broecker, 1971; McIntyre and Ruddiman, 1972). Kennett and Huddlestun (1972) indicate that the X-zone in the Gulf of Mexico extends from about 95×10^3 B.P. to 127×10^3 yr B.P. (Figure 28). Their work has been modified in the present study (Figure 28) to make the X-zone better correspond with other work in the Atlantic, thus eliminating the subdivisions Y₇ and Y₈ and adding X₆ and X₇. As they point out, the western Gulf of Mexico is unique in that Globorotalia menardii disappeared approximately 20,000 years earlier than in the Caribbean or the rest of the tropical Atlantic.

Figure 28. Paleoclimatic curves from Kennett and Huddlestun's (1972) work in the western Gulf of Mexico and Emiliani's (1971) work in the Caribbean and Atlantic. The zonation on the right of the figure was adapted from that of Kennett and Huddlestun (1972) for use in the Angola Basin.

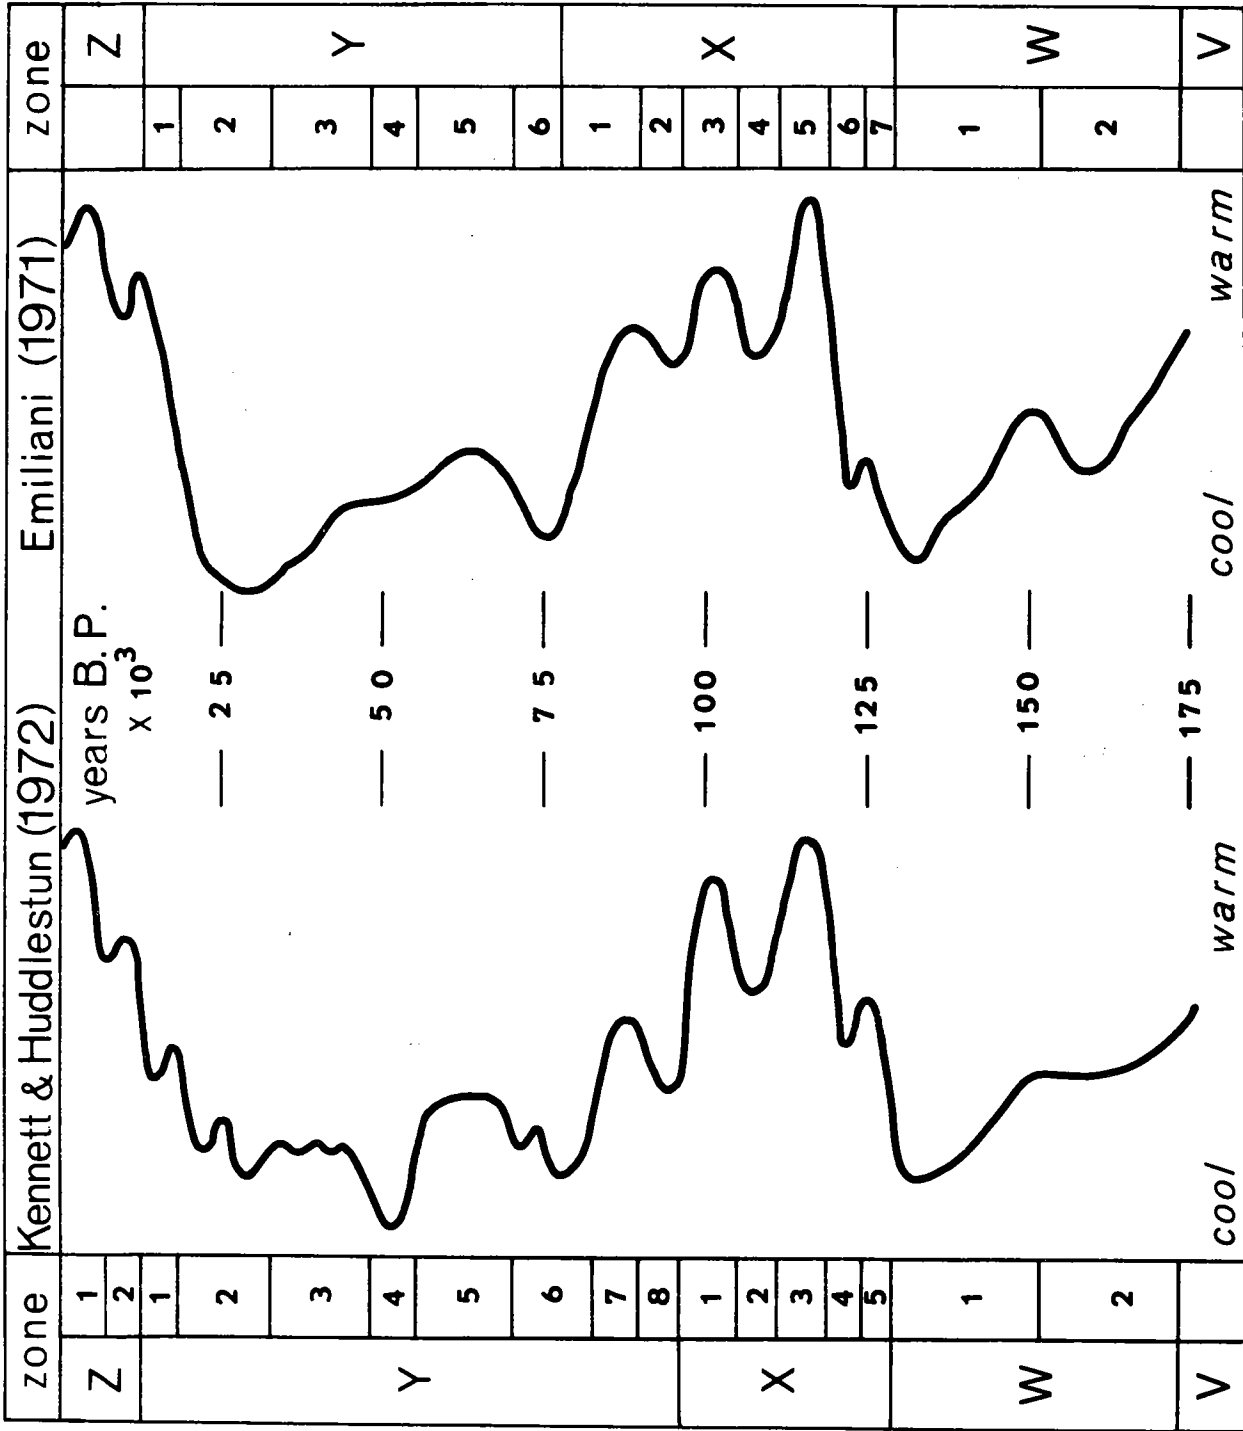

Figure 28

Planktonic Foraminifera/Radiolaria

The relative abundance of planktonic foraminifera has been used by many investigators as a method of subdividing the Quaternary. Emiliani (1955, 1964) used percent sand (as an indication of foram abundance) to demonstrate climatic variations within cores from the Caribbean and found a good agreement with oxygen isotope data obtained on the same samples. Payne and Conolly (1972) found a good direct correlation between foraminifera abundance and inferred Quaternary paleotemperatures in cores taken between Australia and Antarctica. Duncan *et al.* (1970) used the ratio of planktonic foraminifera to radiolaria in piston cores off Oregon to demonstrate late Quaternary climatic changes. They found that the Holocene was characterized by a relatively high abundance of radiolaria, whereas the glacial intervals exhibited higher concentrations of planktonic foraminifera.

Foraminifera/radiolaria curves in many Angola Basin cores also show good correlations with inferred climatic curves based on other criteria (Figure 29). As with carbonate curves, however, the correlation is the inverse of that found in northeast Pacific cores: interglacials are characterized by higher planktonic foraminifera abundances than glacials.

Variations in Calcium Carbonate Abundance

Variations in calcium carbonate content have been shown to be correlated with climatic change (e.g., Schott, 1935; Arrhenius, 1952; Ruddiman, 1971; Hays and Perruzza, 1972). In general, glacial periods have been characterized in Atlantic deep-sea sediments by low carbonate values and interglacials by high values. This pattern contrasts with the Pacific Ocean, where precisely the opposite correlation exists. The factors controlling these climatically

Figure 29. Vertical changes in the foraminifera/radiolaria ratio in cores from the eastern Angola Basin.

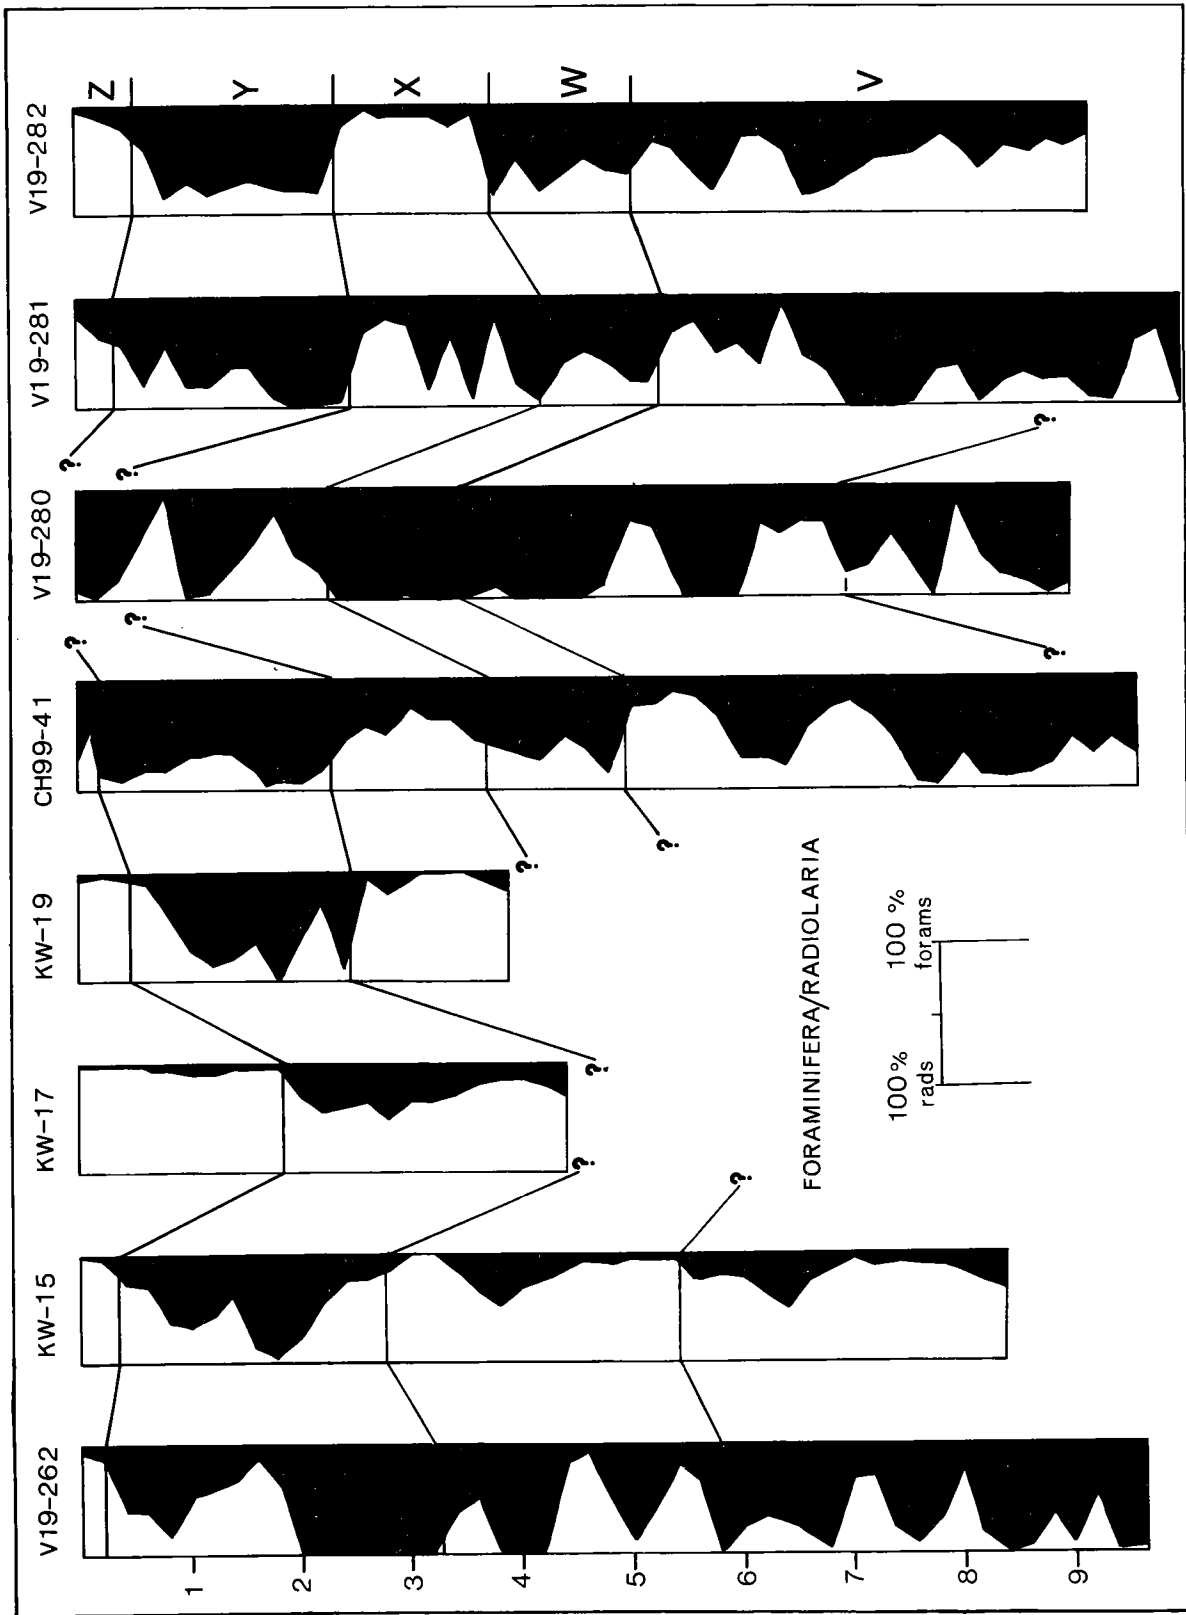

Figure 29

related variations include:

- (1) changes in carbonate productivity in surface waters;
- (2) varying rates of terrigenous dilution; and
- (3) changes in the rate of carbonate dissolution.

Figure 30 shows profiles of carbonate abundance in several of the Angola Basin cores in which pelagic sedimentation was dominant. The time scale was based on: (1) the projection of deduced sedimentation rates; (2) comparison with other Atlantic cores; and (3) Globorotalia menardii abundance. Core V19-262 provides an ideal example of the variations in calcium carbonate seen in cores from the eastern Angola Basin. The major units, defined on the basis of carbonate content can be correlated with the X-Y-Z zones based on foraminifera; for this reason, these units will be given X-Y-Z designations even though G. menardii may not exist within the core.

Most cores are characterized by a rapid decrease in carbonate content with depth in the upper 50-60 cm. This zone corresponds to the Holocene, the Z zone of Ericson and Wollin (1956), and begins approximately 12,000 years B.P. Cores from regions of presently high carbonate productivity (Walvis Ridge and the Guinea Rise) show variations in carbonate content from as high as 85% at the surface to less than 10% at the base of the Holocene. In some cores (e.g., V19-261, KW15, KW19) maximum carbonate values are not at the surface but are 20-40 cm down in the cores: this may represent a slight climatic deterioration since the climate optimum; in other cores this section may have been removed during the coring operation.

Below this surface unit is a one to two-meter unit of low carbonate content, broken only by a small subunit of slightly higher carbonate (Y_3). This unit is taken to be correlative with the Y zone of Ericson and Wollin (1956) and comprises the Würm I and II glacial intervals and the intervening inter-

Figure 30. Vertical changes in the calcium carbonate content of the less-than-62 μ fraction in cores from the Angola Basin.

Figure 30

stadial (Würm I/Würm II), as evidenced by the slightly higher carbonate values. Often the lowest carbonate values encountered in these cores are from this unit.

Below this zone is a generally more calcareous unit containing three major carbonate maxima and exhibiting a wide range of carbonate values. Differences between maxima and minima within this unit can be as great as 50% as in core V19-262, but are usually in the order of 20 to 30%. This unit is correlative with the X zone of Ericson and Wollin (1956), the Riss/Würm interglacial.

Correlations become more difficult in units underlying the X-zone. There appear, however, to be two minima in carbonate separated by a slight maximum. This unit is thought to correspond to the W zone of Ericson and Wollin (1956).

This basic scheme is only evident in areas dominated by pelagic sedimentation and is totally non-existent in cores from the Congo Cone. Elsewhere slumping and turbidity current erosion and deposition obscure the general pattern described here.

Core CH99-38, though of exclusively pelagic character, contains virtually no carbonate along its entire length. Taken at 5371 m the sediments at this location probably have always been below the carbonate compensation depth. Other cores (e.g., V19-281, V19-261, V19-262) contain pelagic sections in which no carbonate is present; in other cores carbonate components show evidence of dissolution in certain sections. These units can be as much as one to two meters in length and correspond to increases in pellets, siliceous components, organic content, and pyritized burrows. Although one might expect a general reduction in total CaCO_3 with climatic deterioration, carbonate productivity in the surface water should not cease entirely. For this reason these non-calcareous units may reflect changes in the position of the car-

bonate compensation depth; the mechanism by which this might have been achieved will be discussed in a later section.

As mentioned previously, carbonate content can be affected in three ways: (1) by changes in carbonate productivity; (2) by terrigenous dilution; and (3) by carbonate dissolution. Ruddiman (1971), Broecker (1971), and Hays and Perruzza (1972) concluded that the lower carbonate values during glacial intervals reflect the increased deposition of terrigenous sediment in the ocean, not a decrease in carbonate productivity. Several problems are associated with this interpretation. If carbonate productivity is assumed to remain constant, as stated by Hays and Perruzza (1972), then a threefold change in percent carbonate (e.g., from 30% to 10%) between interglacials and glacials must be accompanied by higher terrigenous inputs and consequently higher sedimentation rates. In core V22-196, Hays and Perruzza (1972; p. 358) show that average interglacial carbonate values are approximately 30% and glacial values 10%. However, interglacial sedimentation rates are $5.4 \text{ cm}/10^3 \text{ years}$ and glacial sedimentation rates are $5.0 \text{ cm}/10^3 \text{ years}$. Clearly a sedimentation rate which remains relatively constant from interglacial to glacial intervals cannot account for a threefold decrease in the observed carbonate content if carbonate production is held constant. Other mechanisms, presumably changes in carbonate productivity or dissolution, must be important factors in reducing carbonate content.

This conclusion is further substantiated by results from the Angola Basin: although carbonate values during glacials can be as much as four to five times lower than during interglacials, glacial sedimentation rates are comparable to interglacial rates. Increased terrigenous dilution during glacials is not consistent with work carried out on land in areas adjacent

to the Angola Basin. As mentioned previously, the region of the Congo as far inland as Kinshasa was a desert or semi-desert during glacial intervals. Recent work by Degens and others (personal communication, 1973) on equatorial lakes and by van Zinderen Bakker and Coetzee (1972) supports the view that cooler periods in higher latitudes were equivalent to drier periods in equatorial Africa.

Sedimentation Rates

On the basis of the above criteria, sedimentation rates for glacial and interglacial intervals were determined for the best controlled cores in the study area (Table 1). An average glacial sedimentation rate was determined for the entire Y zone, although it was realized that this comprises the Würm I and Würm II glacial maxima separated by an interstadial (Würm I/ Würm II). An average interglacial sedimentation rate was calculated for the Riss/Würm interglacial ($127-75 \times 10^3$ years B.P.).

Pelagic sedimentation rates for both glacial and interglacial intervals average approximately $3-5 \text{ cm}/10^3$ years, with very little difference, in general, between warm and cool periods. This is in marked contrast to the Guiana Basin off the Amazon River, described by Damuth and Fairbridge (1970), where they inferred greatly increased sedimentation rates during cool intervals. The land areas adjacent to both the Guiana and Angola Basins experienced arid to semi-arid conditions during glacial periods. Damuth and Fairbridge (1970) believed that an increase in sedimentation rates during glacials occurred in response to a deforestation of areas which are presently tropical rain-forest, and to the growth of mountain glaciers in the Andes, the source of the Amazon. Two important features, however, distinguish the

TABLE 1.

SEDIMENTATION RATES IN THE EASTERN ANGOLA BASIN

<u>Core</u>	<u>Glacial</u> (cm/10 ³ yr)	<u>Interglacial</u> (cm/10 ³ yr)
V19-261	6.0	5.7
V19-262	4.4	5.0
KW-15	4.0	4.4
KW-19	3.3	3.1
CH99-41	3.2	2.9
V19-280	-	4.1
V19-281	3.2	3.3
V19-282	3.0	2.7

Congo River system from that of the Amazon: (1) the sources of Congo River water are not in areas which were extensively glaciated during glacial maxima; and, (2) most of the sediment carried by the Congo into the Atlantic Ocean is derived from the area within 400 km of the coast. Thus, although during cool periods of physical weathering in the deforested areas near the coast may have been intensified, the discharge of the Congo and its lower tributaries undoubtedly decreased significantly (dePloey, 1965; Fairbridge, 1964) resulting in relatively constant sedimentation rates throughout the late Quaternary in the eastern Angola Basin.

Sand and Silt

Emiliani (1955, 1964), Ericson and Wollin (1956), Ewing et al. (1958), and Ericson et al. (1961) showed that the weight percentage of sediment larger than 62μ (or 74μ) often displayed a high correlation with inferred paleotemperatures in Globigerina-ooze cores from the Atlantic Ocean. Several cores from the eastern Angola Basin exhibit agreement between the percentage sand and carbonate values for the less-than- 62μ fraction, the abundance of the Globorotalia menardii complex, and the foraminifera/radiolarian ratio. The best correlations are apparent in cores from the Walvis Ridge and from the Guinea Rise, where normal pelagic sedimentation is less influenced by coarse terrigenous sediment input than the Angola continental rise and abyssal plain (Figure 31). Correlations between carbonate and percent sand are not as great as those found elsewhere in the Atlantic principally because of the relatively large input of siliceous components.

In addition to planktonic foraminifera, radiolaria, and diatoms, the sand fraction disseminated throughout the hemipelagic sections of the Angola Basin cores commonly consists of fine quartz, feldspar, mica, glauconite,

Figure 31. Relationship between percent sand ($> 62\mu$), calcium carbonate content of the silt and clay, and the foraminifera/radiolaria ratio in core V19-281 from the southern flank of the Guinea Rise.

Figure 31

manganese micronodules, fecal pellets, pyritized foraminifera and diatoms, pyritized burrows, echinoid spines, benthonic foraminifera, ostracods, and bryozoa. Fish teeth and black, perfectly spherical, shiny, non-magnetic particles are occasionally found (Figure 32).

Mica, glauconite, and manganese show definite latitudinal differences in their contribution to the sand fraction. Manganese micronodules are more common in the northern part of the basin than in the southern. Mica is particularly abundant in cores from the Angola continental rise and is absent from the pelagic sections of cores V19-280, 281, and 282 from the southern flank of the Guinea Rise. Not unexpectedly, continental shelf sediments from off South West Africa and Angola contain appreciably more mica than sediments from the shelf off Congo and Gabon. Illite (mica) in the clay fraction also is considerably more abundant in the southern part of the study area (see previous section).

Glauconite is also noticeably more prevalent along the Angola, Congo, and Gabon continental margins than on the north flank of the Walvis Ridge or on the Guinea Rise. The source and mode of origin of this glauconite is discussed below. No vertical variations in glauconite abundance were apparent in cores from this area.

Pyrite is a very abundant component of Angola Basin cores and displays vertical variations in importance within cores. It occurs in two general forms: (1) as replacements or fillings of planktonic foraminifera and diatom frustules; and (2) as replacements of burrows of benthic organisms. The latter are long, narrow "rods" exhibiting a fine, botryoidal surface texture (Figure 33). Both modes of occurrence can range from well-developed pyrite with a high metallic luster to a poorly developed black iron sulfide precursor

Figure 32

Figure 33. Photomicrograph of pyritized burrows from Angola Basin core V19-278. Scale bar represents 0.5 mm.

Figure 33

of pyrite (hydrotroilite ?) with a dull nonmetallic luster; burrows are more commonly of the latter type. In general, pyrite is most abundant in low-carbonate sections of the cores from this region and often can constitute the entire sand fraction (e.g., CH99-40; V19-278, 120 cm). A similar relationship between pyrite and dark gray-black sediment sections in the Guinea Basin was noted by Lavrov and Savel'yeva (1972).

Turbidites

The contribution to the Angola Basin sediments of silt and sand derived from turbidity currents varies from negligible on the northern flank of the Walvis Ridge and the southern flank of the Guinea Rise (except near volcanic islands and major seamounts) to extremely important on the Angola abyssal plain and the Congo Cone (Figure 34). Cores V19-263, 264, and 265 from the southern abyssal plain are dominated by sub-angular to sub-rounded, fine to medium quartz sands with appreciable mica, benthonic foraminifera, radiolaria, and fecal pellets. Minor constituents include glauconite, pyritized burrows, planktonic foraminifera, byrozoa, ostracods, sponge spicules, and small, polished dark grains (phosphorite ?). Very large, frosted and very well rounded, quartz grains were found in core V19-264. The great abundance of quartz and mica and the almost complete absence of mafic minerals indicates that these turbidites originated on the Angola continental shelf and slope and not on the nearby Walvis Ridge.

Sand layers in cores from the Angola rise and from the sediment ponds within the Angola diapir field consist of essentially the same components as the sand disseminated throughout the pelagic sections.

Heezen et al. (1964) discussed in detail the composition, texture, and distribution of silt and sand on the Congo Cone. Two heavy mineral suites

Figure 34. Average centimeters of sand and silt layers per meter of core in the eastern Angola Basin.

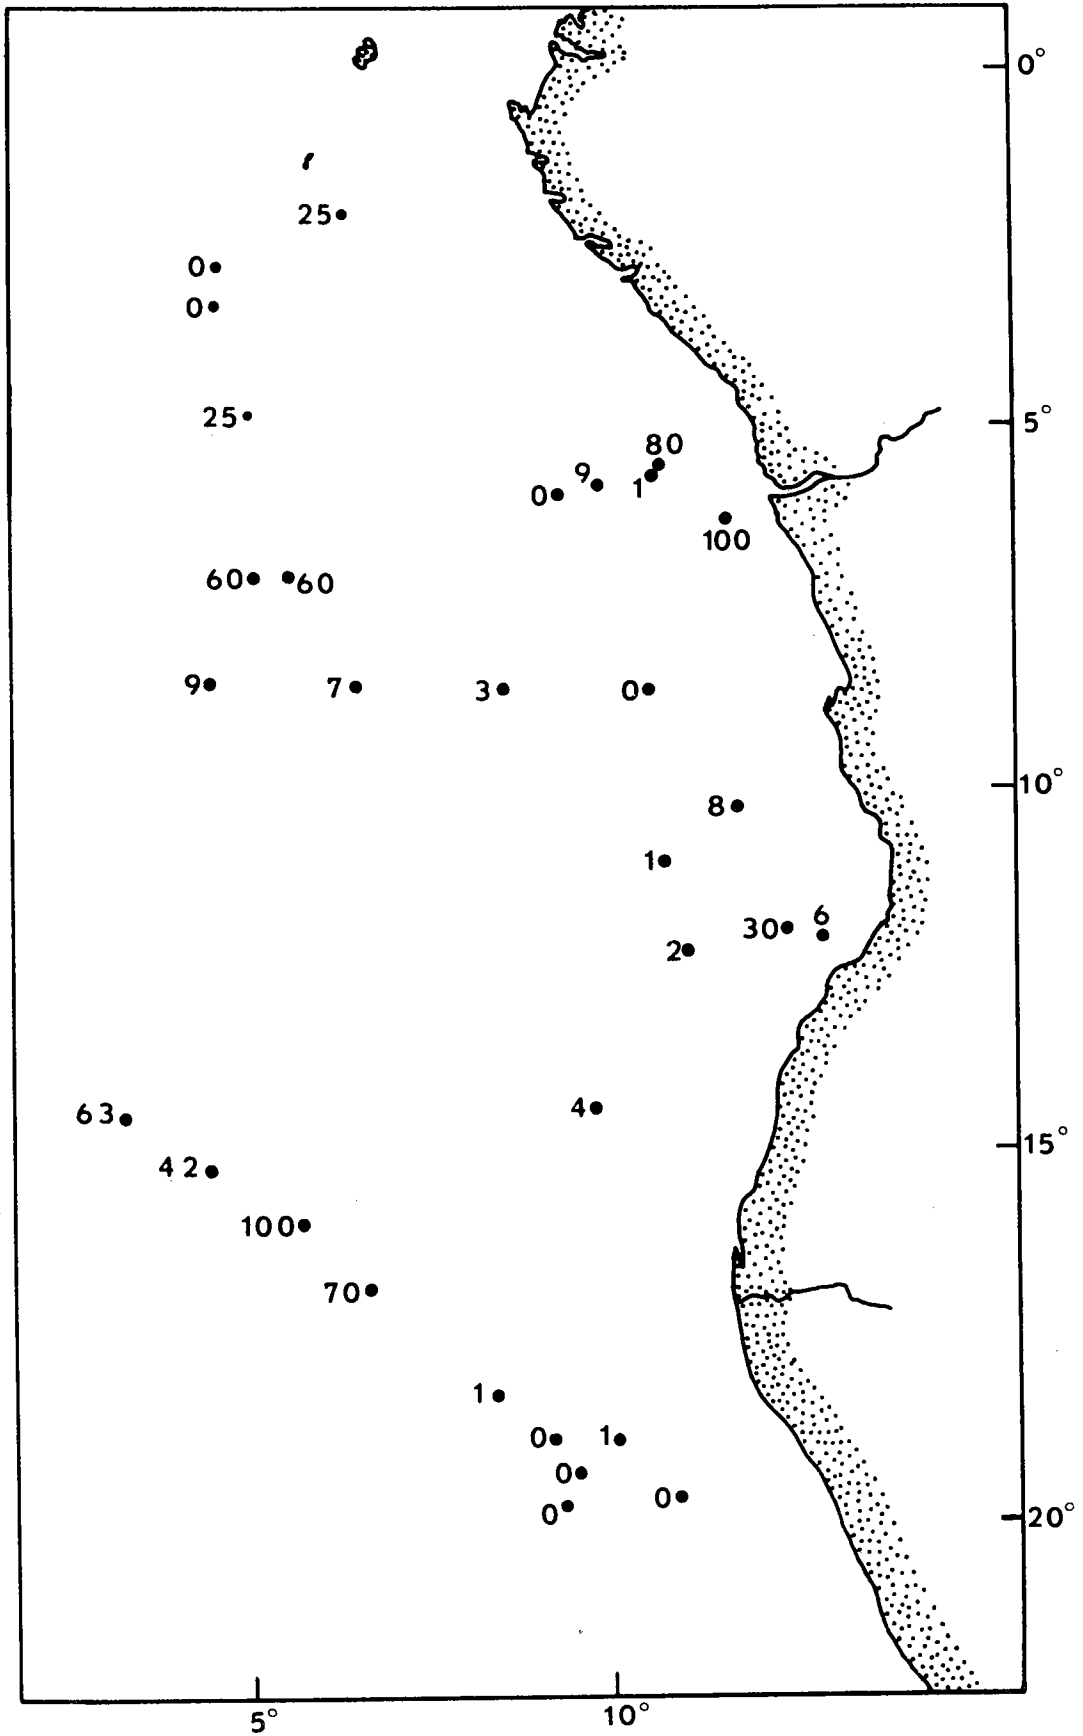

Figure 34

were identified, one containing abundant black opaque minerals, the other containing hematite. The former is thought to have been derived from sediment transported by longshore drift into the canyon head. The latter was found commonly in association with terrestrial plant material and is believed to have come directly from the Congo River. Based on the frequency of submarine cable breaks, Heezen et al. (1964) estimated that the Congo Canyon is presently experiencing approximately fifty major turbidity currents per century.

Fecal Pellets and Authigenic Silicates

Three types of pellets were found within the study area: (1) a grey, dull, "speckled" ellipsoidal type of dominantly smectite composition; (2) a shiny, brown-grey, ellipsoidal variety of chamosite composition (Emel'ianov and Senin, 1969); and (3) a shiny dark-green-black ellipsoidal to irregular variety of glauconite composition (Giresse, 1965; 1969).

According to Emel'ianov and Senin (1969) chamositic pellets develop within estuaries, such as the Ogooue or Congo, at depths of less than 70 meters and locally can constitute more than 40% of the sediment. Goethite is an important constituent of these pellets particularly at depths shallower than 40 m. These pellets are very abundant in samples from the Congo and Gabon continental shelf (Figure 35) and are commonly found in areas from the Congo Cone and continental rise, and are abundant within turbidite units in these areas.

Grey pellets (Figure 36) are ubiquitous components of both pelagic and turbidite units of Angola Basin cores, particularly from the southern part of the study area. Since they are not restricted to turbidite units, and since they are not found in adjacent continental shelf sediments, these pellets are believed to have been produced in situ in the deep sea. The abundance of

Figure 35. Photomicrograph of chamosite pellets from the continental shelf off the Congo Republic. Scale bar represents 0.5 mm.

Figure 35

Figure 36. Photomicrograph of grey pellets from core KW15 on the continental rise off southern Angola. Scale bar represents 0.5 mm.

Figure 36

this variety of pellet shows significant variation with depth in cores and displays a good correlation with the abundance of other components, as exemplified by core KW15 (Figure 37). Pellets, in general, are significantly more common in zones of low carbonate. This is particularly apparent for the suite of cores from the southern part of the study area; cores V19-280, V19-281, V19-282 from the Guinea Rise do not contain appreciable amounts of pellets and do not exhibit any clear variations with depth.

Glauconite is a very abundant constituent of both continental shelf and offshore sediments in this area. It generally occurs as either shiny, dark green-black to light green pellets or as replacements of foraminifera tests. The dark green-black variety is particularly abundant on the shelf off Congo and Gabon (Giresse, 1965; Giresse, 1969; Giresse and Kouyoumontzakis, 1971) (Figure 38). Light green glauconite, usually in the form of replaced foraminifera tests, is much more common in cores from the Angola Basin (Figure 39). The abundance of the latter type in the pre-Quaternary core KW-18 suggests that much of the glauconite within the Quaternary cores may have been reworked from older sediments exposed during slumping and sliding associated with the diapiric tectonism of the Angola diapir field. Glauconite is generally absent in cores from the Walvis Ridge and the Guinea Rise.

According to Emel'ianov and Senin (1969) glauconite is presently forming in the estuaries of the Ogooue and Congo Rivers at depths below 50 m and on the Congo, Gabon and Angola continental shelves. The richest shelf concentrations of glauconite (10-90% of the total sediment) occur off the Kunene River along the outer shelf.

Figure 39

Vertical Changes in Clay Mineral Abundance

In an effort to assess lateral variations in the clay mineral assemblage through the late Pleistocene and Holocene, samples were analyzed from the major stratigraphic units of five cores from the Walvis Ridge to the Guinea Rise. Ten to fifteen samples in each core were analyzed and the results summarized in Figure 40 for montmorillonite, illite, and kaolinite.

As can be seen, several apparently significant trends exist within individual cores, although no clear relationship to climatic change for the basin as a whole is evident. The same overall trends observed in the surface sediments are apparent in these cores: illite decreases and kaolinite and montmorillonite increase from south to north. The reason for the lack of any clear vertical changes in clay mineral assemblage within the entire basin is not obvious in the light of the available data. However, the more intense circulation of bottom water in the Angola Basin during glacials, inferred from other evidence, may have redistributed clay minerals throughout the basin, thus obscuring vertical variations.

Organic Carbon

Organic carbon content, determined on selected samples from the major stratigraphic units of several cores in the Angola Basin, changes markedly between cool and warm periods, as shown by the inverse correlation between organic carbon and the carbonate content and the abundance of the G. menardii complex (Figure 41 and 42). Averages for organic carbon were computed for the Holocene and the X₁, X₃, X₅, and X₇ zones - warm intervals - and for the Würm I and II and the X₂, X₄, and X₆ zones - cool intervals (Table 2). Cool periods are generally characterized by considerably higher organic carbon

Figure 40. Vertical distribution of clay minerals within five cores from the eastern Angola Basin.

Figure 42

values than warm periods, averaging from 0.8 to 1.4% higher. This difference between warm and cool intervals was shown by a Student's t-test to be significant at the 95% confidence level.

Organic carbon values measured in these Angola Basin cores in general are much higher than those reported elsewhere on continental rises, particularly sediments deposited during glacial and cool periods (Table 2). Stevenson and Cheng (1972) demonstrated differences between warm and cool intervals in the Argentine Basin similar to those described here, but their highest measured values were 1.6-1.7% as opposed to 3.2% in the Angola Basin. Froelich et al. (1971) also showed higher organic carbon values corresponding to low carbonate zones in cores from the continental rise off Cape Hatteras, though their maximum values were only about 1.5%. The higher organic carbon values corresponding to low carbonate values in the Angola Basin can be attributed to the inferred higher surface productivity and estimated bottom conditions conducive to its preservation. The latter will be discussed in more detail in a later section.

TABLE 2.
AVERAGE PERCENT ORGANIC CARBON IN
GLACIAL AND INTERGLACIAL SECTIONS OF ANGOLA BASIN CORES

<u>Core</u>	<u>Cool Intervals (%)</u>	<u>Warm Intervals (%)</u>

DISCUSSION

The northern and central parts of the Angola Basin derive fine sediment mainly from the Congo River system. As Shepard and Emery (in press) indicate, the Congo River is unique in that its submarine canyon originates over 21 km inland from the river mouth. Thus, virtually all of the river's bed-load is delivered to the deep-sea, in contrast to other large tropical river systems, such as the Amazon, whose sediment is mainly dispersed along the adjacent continental shelf by longshore currents. The large lobe of kaolinitic sediment over the Congo cone and Angola abyssal plain, in the northern and central regions of the Angola Basin, reflects the source of sediment in the Congo Basin and its delivery to the deep sea through the Congo Canyon system. As well, suspended matter dispersal follows a similar areal pattern: kaolinitic sediment is carried in suspension between 200 and 300 km from the river mouth where it becomes entrained in a complex surface current system. The Angola Current carries this sediment southwards over the central part of the eastern Angola Basin and longshore currents carry suspended sediment northwards along the coast of Gabon into the southern Gulf of Guinea.

At the present time the contribution of fine sediment to the southern Angola Basin is primarily accomplished by the northward transport in suspension of illitic and montmorillonitic material mainly from South West Africa in the Benguela Current system. Both the Orange and the Kunene Rivers are undoubtedly important contributors of fine sediment to the Benguela Current and ultimately to the Angola Basin; Emel'ianov and Senin (1969), however, point out that much of the Orange River sediment load is retained on the South West African shelf and is not carried very far northwards.

Thus, although its suspended load is only one tenth that of the Orange (15×10^6 tons/yr versus 153×10^6 tons/yr), the Kunene River represents a very important source of terrigenous sediment in the southern Angola Basin. In addition, eolian transport of sediment is important in the delivery of fine sediment both directly to the Angola Basin and to the Benguela Current which then carries it northward into the basin (Emel'ianov and Senin, 1969).

During interglacials, high organic productivity was restricted to the continental margin along South West Africa and did not extend very far into the Angola Basin. The highest concentrations and diversities of diatoms, seen in suspended matter samples, were found south of Lat. 15°S where the Benguela Current begins to leave the coast. Farther north, the eastward incursion of the South Equatorial Countercurrent brings unproductive water over much of the Angola Basin as shown by the impoverished diatom floras observed in suspended matter samples between latitudes 8° and 15°S ; this water is distributed both southward by the Angola Current and northward by longshore currents along the coast of Gabon into the southern Gulf of Guinea. The general sterility of water masses over most of the Angola Basin is interrupted only where major rivers, such as the Congo, deliver sufficient nutrients to support small localized areas of higher primary productivity. The relatively low organic carbon values in surface sediments and in sediments from interglacial intervals (average 1.0%) throughout the basin reflects this distribution of primary productivity.

At the present time there appears to be very little lateral transport of fine sediment within the deep basin. Suspended matter concentrations from deep stations taken during the WALDA expedition display a linear

decrease with depth and do not suggest the presence of any nepheloid layers above 4500 m. Nephelometer studies (Connary and Ewing, 1972), bottom photographs (Heezen et al., 1964), and geostrophic current calculations (Wüst, 1957) also support the view that very little lateral sediment dispersal is presently occurring in the deep Angola Basin. On the other hand, the presence of continental rise swells off southern Angola and the lack of any decipherable trends within the clay-mineral distribution pattern within the late Quaternary suggests that bottom circulation must have been intensified previously, probably during glacial periods.

Climatic deterioration during the late Cenozoic apparently had a significant effect on oceanographic conditions, both surface and deep, and thereby on the nature of marine sedimentation throughout the world ocean. Watkins and Kennett (1971, 1972), Kennett and Brunner (1973), and Hayes et al. (1973) have shown that the growth of Antarctic continental glaciation, beginning in the Miocene, led to markedly increased rates of bottom water production and to erosion and non-deposition in parts of the Southern Ocean. Farther to the north, Johnson (1972) showed that erosion in the equatorial Pacific by northward-flowing bottom water began during the late Cenozoic. Emery and others (in prep.) account for the presence of continental rise swells along the southern flank of the Walvis Ridge and the South West African continental rise and for the dissection of the western Cape abyssal plain by the flow of Antarctic Bottom Water, possibly commencing in the late Cenozoic. Fluctuations in the rate of production and the effects of this bottom water would be expected to have occurred during the Quaternary in response to the advance and retreat of continental ice sheets (Gordon, 1971). The observed topographic features on the continental rise in the southern

Angola Basin can be accounted for by the influx of bottom water during glacial intervals, periods of greater bottom water production. This proposed change in deep circulation is consistent with the model discussed below (and schematically shown in Figure 43), based on geochemical and compositional changes within cores, which attempts to account for the variations in volume and nature of bottom water during the late Quaternary in the Angola Basin.

At present time virtually no bottom water enters the Angola or Guinea Basins. The sill depth (3750 m) (Metcalf et al., 1964) of the equatorial Atlantic region is slightly above the upper level of bottom water in the western South Atlantic (Figure 11) and only a very small volume of water passes into the Guinea Basin where it is quickly mixed and loses its identity (Metcalf et al., 1964). During glacial intervals, however, the greater production of bottom water would have raised the level above sill depth, permitting the continuous flow of bottom water into the eastern basins; this influx would have continued until the level again fell below sill depth (during interglacials) (Figure 43). A rise in the level of bottom water in the western equatorial Atlantic of only one to two hundred meters could conceivably have led to the emplacement of a layer of bottom water up to several hundred meters thick in the Angola and Guinea Basins. The intensity of deep circulation would have diminished following a glacial maximum, as less bottom water of progressively lower density would enter the Angola Basin.

In addition to creating a more intense circulation scheme, greater production of bottom water during glacial intervals also probably had an important effect both on the level of the lysocline in the Angola Basin and on

Figure 43. Schematic interpretation of bottom conditions in the Angola Basin during (a) glacial maxima; (b) an intermediate stage of warmer climate; and (c) interglacial maximum. (See text for further explanation of the model).

Glacial

Interglacial

Figure 43

the extent of reducing conditions on the sea floor. As Worthington (1968) suggested, bottom water derived during the coldest periods would be of higher salinity and slightly lower temperature than that forming today. This dense water (1.0286 - 1.0287) would fill the deeper parts of the sea floor and, subsequent to a glacial maximum, become nearly stagnant since its upward displacement could only be effected through geothermal heating. This vertical mixing could take several thousand years, during which time oxygen levels would be depleted and carbon dioxide levels would be increased leading to greater rates of solution of carbonate on the sea floor. The increased rate of production of bottom water during glacials would result in a much greater influx of corrosive water through the Romanche Fracture Zone into the Guinea and Angola Basins. This dense water, which was probably initially more undersaturated with respect to calcite than present bottom water (Berger, 1968) remained in the deepest parts of these eastern basins until mixed with the overlying water.

Berger deduced that the lysocline presently lies at approximately 4700 meters depth in the northern Angola Basin and at 5200 meters in the south. This latter figure is about 800 m deeper than the level in the Brazil Basin (Figure 44). The severe reduction in carbonate observed in the deep-sea cores from the Angola Basin suggests that the lysocline was at least 500 to 600 meters shallower during glacials than interglacials. Based on Worthington's (1968) estimate of the geothermal mixing rate of "climax bottom water" (15, 000 years for a layer 1000 m thick), it would require approximately 7,500 to 9,000 years to completely mix a layer of this water 500 to 600 meters thick in the Angola Basin. Since only a part of the bottom water entering the basin during glacials would be of this type, however, this

Figure 44. Depth of the lysocline (m) in the equatorial South Atlantic (after Berger, 1968).

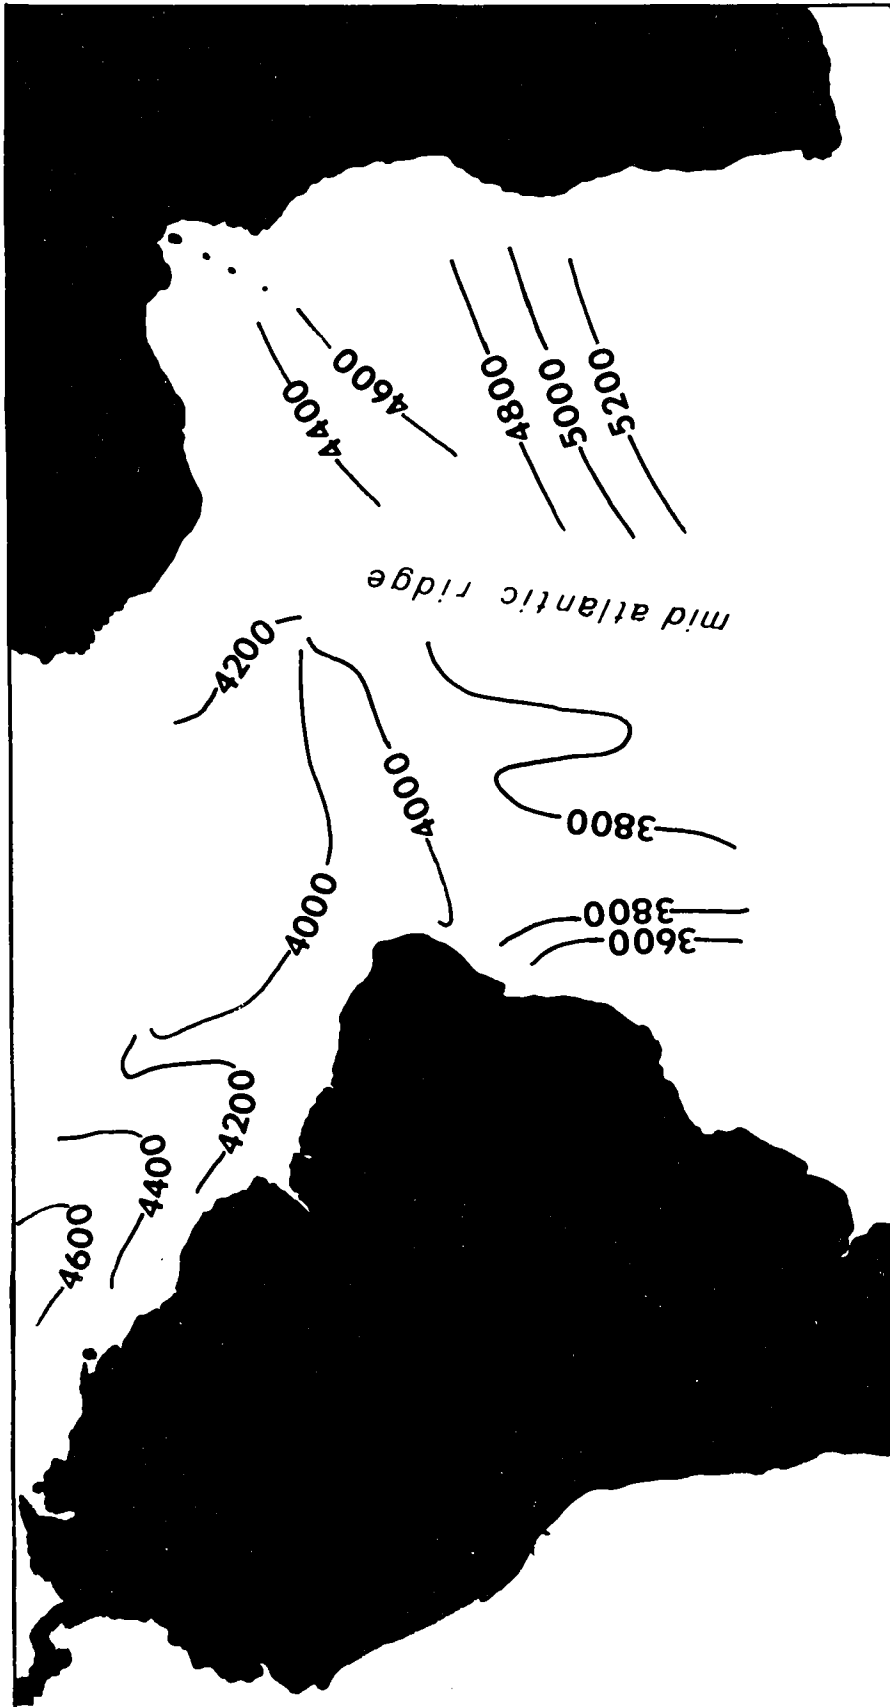

Figure 44

estimate is probably too high. Based on sedimentation rates inferred for Angola Basin cores and changes in carbonate content, a period of between 4,000 and 6,000 years would be sufficient to destroy the layer of bottom water derived during glacials.

More reducing conditions in the Angola Basin would have developed in response to changes in both bottom circulation and surface oceanographic conditions. van Zinderen Bakker (1967) deduced that the Benguela Current, and its associated upwelling, extended northward into the Angola Basin during glacials as a consequence of the northward displacement of the South Atlantic Anticyclone. As well, upwelling was initiated along the suitably aligned section of the coast between Luanda, Angola, and Cape Lopez. Both of these changes in surface oceanographic conditions led to greater surface productivity and to the delivery of great amounts of organic matter to the sea floor in the eastern Angola Basin. As a result, organic carbon levels from glacial sections of Angola Basin cores are approximately twice those from interglacial sections. van Andel and Calvert (1971) suggested that the Benguela Current was intensified during glacials in order to account for the erosion they observed on the South West African shelf; this would have led to greater upwelling and higher influx of organic matter into the Angola and Cape Basins.

The increased delivery of organic matter resulted in higher benthic productivity as shown by the greater abundance of fecal pellets and burrows during glacials. Higher benthic productivity, in turn, would have reduced oxygen levels and increased carbon dioxide levels, thereby lowering pH and facilitating the production of pyrite which is commonly found in these sections of the cores. The rate at which reducing conditions developed pro-

bably increased markedly following the height of glaciation as bottom water became isolated in the deeper parts of the basin.

With regard to the Peru Current, Berger (1970) concluded that greater than average solution of calcium carbonate would be expected in response to the rapid delivery of organic matter to the sea floor. The observed drastic reduction in carbonate during glacials in the deep Angola Basin is in agreement with Berger's findings. The undersaturation of bottom water with respect to calcite during glacials would be maintained not only by the increased influx of organic matter, however, but also through the decreased rate of carbonate input. This is shown by the very marked shift from a dominantly foraminiferal plankton assemblage in interglacials to a more radiolarian assemblage during glacials in cores from well above the lysocline. This change is undoubtedly a result of colder water being brought to the surface during glacials by the upwelling in the Benguela Current and along northern Angola, Congo, and Gabon. Thus, the greater solution of carbonate during glacial intervals was not only effected through the influx of cold, corrosive bottom water, but also through the increased rate of supply of organic matter and the decreased rate of carbonate input (Figure 43).

Previous investigators have emphasized the importance of terrigenous dilution in the reduction of carbonate contents of glacial sections of cores from the equatorial Atlantic. The relatively uniform pelagic sedimentation rates inferred for the Angola Basin throughout the late Quaternary do not support the concept that terrigenous dilution is the dominant controlling factor in this area. Based on work on land by dePloey (1963, 1964, 1965) and Fairbridge (1964) there is considerable evidence that, in fact, the Congo discharge was probably less during glacials than at present and that its sediment load was at most the same. Although glacial aridity in the lower

Congo Basin led to higher rates of physical weathering, the more readily available sediment was apparently not removed to the deep sea in appreciably greater quantities than at present. This is in marked contrast to the model which Damuth and Fairbridge (1970) proposed for the Amazon-Guiana Basin system. Glacial aridity in northeastern South America resulted in deforestation and hence in greater physical weathering and erosion and a much higher transport of sediment to the deep sea. The Amazon, fed by Andean glaciers, had a much higher discharge during glacials than interglacials. Changes in carbonate content in cores from the Angola Basin can be accounted for by variations in surface carbonate productivity and by changes in sea-floor solution of carbonate tests resulting from fluctuations in bottom water conditions.

CONCLUSIONS

Sedimentation in the eastern Angola Basin throughout the late Quaternary has been strongly influenced by the prevailing climatic and the oceanographic regimes, both surface and abyssal. High rainfall in modern equatorial west Africa leads to large fluvial sediment input from the Congo and other tropical rivers and results in high sedimentation rates over much of the continental margin. During glacial intervals the onset of arid and semi-arid conditions on the adjacent land areas led to higher rates of physical weathering. The overall lower river discharge during these periods, however, prevented appreciably greater volumes of sediment from being transported to the Angola Basin, as evidenced by the relatively uniform sedimentation rates throughout the Quaternary.

At the present time high surface productivity is restricted to the waters south of the Angola Basin and is associated with the northward flowing cold Benguela Current. During cooler periods of the Quaternary, however, the northward extension of the Benguela Current along the coast of Angola and the onset of upwelling off Congo and Gabon resulted in much greater surface productivity and led to organic-rich sediments on the underlying continental margin and to higher benthic productivity. A shift from calcareous to more siliceous biogenic components also occurred in response to this change in surface oceanography.

At present very little bottom water enters the eastern basins of the South Atlantic resulting in a deep lysocline, the widespread accumulation of calcareous sediments over much of the area, and very sluggish deep circulation. During glacial maxima, however, much more bottom water flowed into and filled the deeper parts of the Guinea and Angola Basins. This corrosive

water significantly raised the lysocline, leading to the dissolution of carbonate at depths which are presently dominated by calcareous sediments. The more vigorous deep circulation during glacials also created continental rise hills along southern Angola and the Walvis Ridge. The isolation of this "climax bottom water" in the Angola and Guinea Basins during warmer periods resulted in the gradual onset of reducing conditions, the preservation of organic-rich sediments, and the development of authigenic sulfide minerals. This condition persisted until the "old" bottom water could be mixed, primarily by geothermal heating, with the overlying water mass.

The model proposed to explain the changes in sedimentation during the late Quaternary in the Angola Basin may find profitable application in other restricted basins in the world ocean.

APPENDIX III

Analytical Methods

Percent Sand

1. Approximately 1 to 2 grams of sediment were placed in a pre-weighed 50 ml. beaker and dried for at least 8 hours at 110°C.
2. The samples were removed to a dessicator to cool and then weighed. Sample weight was determined by subtracting the beaker weight from the total weight.
3. About 20 to 30 ml of sodium metaphosphate solution were added to each beaker and the samples were disaggregated. The samples were left to stand approximately 24 hours.
4. The samples were washed through a 62.5 μ sieve and the silt and clay fraction collected in a 250 ml. beaker.
5. When thoroughly washed, the sand fractions were rinsed into 50 ml beakers and placed in an oven at 110°C until completely dry.
6. The silt and clay fractions were allowed to stand undisturbed for one to two days.
7. The sand fractions and beakers weighed and the percent sand calculated. The sand fractions were placed in labeled vials.

Percent Calcium Carbonate in the Silt and Clay Fractions

1. After standing for 1 to 2 days, the clear supernatants were poured from the 250 ml. beakers containing the silt-clay fraction and the remaining sediment washed into the same 50 ml beakers as used in determining percent sand.
2. The silt-clay fractions were dried for about 12 hours at 110°C.
3. The samples were placed in a dessicator to cool and then weighed. Sample weights were determined by subtracting the beaker weights from the total

weight.

4. 2N HCl was added to each beaker and the beakers were allowed to stand for about one hour.
5. During this time, Millipore^R filters were weighed and placed in numbered petrie dishes corresponding to the sample numbers.
6. Distilled water was added to the beakers and the supernatants were washed (decanted) onto their corresponding Millipore filters. Distilled water was added to the samples and decanted several times.
7. The filters were washed several times with distilled water.
8. The filters were placed in the beakers with their samples and dried at 110°C for about 8 hours or until dry.
9. The samples and filters were cooled in a dessicator and weighed.
10. The acidified sample weight was determined by subtracting the filter weight and the beaker weight from the final weight.
11. Carbonate content was determined by:

$$\frac{(\text{original weight}) - (\text{acidified weight})}{\text{original weight}} \times 100$$

Percent Organic Carbon

1. A 0.25 to 1.0 gram sample was dried at 110°C for 8 hours and weighed.
2. The sample was acidified in 2N HCl to remove calcium carbonate.
3. The sample was washed into a Leco^R filter crucible and rinsed several times with distilled water.
4. The crucible was covered with metal foil and labelled.
5. The sample was combusted in a Leco induction furnace and the percent organic carbon determined.

Clay Mineral Analyses

1. Samples were acidified in acetic acid and disaggregated completely.
2. The less-than- 2μ fraction was separated by centrifugation.
3. The supernatant in each centrifuge tube was poured through a Selas Flotronics^R silver filtered and then air dried.
4. The silver filters were placed in a Norelco X-ray diffractometer (Cu K α , 40 ma, 40 Kv) and scanned from 2° to 40° 2θ at $2^\circ/\text{min}$.
5. The filters were then placed in a dessicator containing ethylene glycol and glycolated at 70°C for at least 4 hours.
6. The filters were then scanned again from 2° to 40° above the previous untreated trace.
7. Certain of the samples were then heated to 400°C and 550°C and rerun.

A baseline was sketched on the glycolated trace and the areas of the major peaks determined by counting the enclosed squares within the peak and the baseline. The following peak weightings were used (Biscaye, 1965) to determine the percentages of the clay minerals:

- 1 x area of the 17\AA glycolated montmorillonite peak
- 4 x area of the 10\AA glycolated illite peak
- 2 x area of the 7\AA kaolinite-chlorite peak

Kaolinite and chlorite were divided based on the relative areas of the two peaks in the kaolinite-chlorite 3.5\AA doublet (kaolinite, 3.58\AA ; chlorite, 3.54\AA).

The four weighted peak areas were summed and the weighted area of each mineral times 100 was divided by the sum of the areas to give the percentage of each mineral.

BIOGRAPHY

Brian Douglas Bornhold

Born: Kitchener, Ontario, Canada - December 13, 1945

Education: University of Waterloo
Waterloo, Ontario
1963-1968; B.Sc., 1967

Duke University
Durham, North Carolina
1968-1970; A.M., 1970

Massachusetts Institute of Technology -
Woods Hole Oceanographic Institution
Woods Hole, Massachusetts

Professional Experience:

May 1968 - Sept. 1968	Canada Centre for Inland Waters Burlington, Ontario Sr. Field Assistant
April 1967 - Sept. 1967	Geological Survey of Canada Dr. P. F. Karrow Laboratory Assistant
May 1966 - August 1966	Rio Tinto Canadian Exploration 120 Adelaide Street West Toronto, Ontario Geologist's Assistant
May 1966 - Sept. 1966	Lorne x Mining Corporation Ashcroft, British Columbia Geologist's Assistant
Jan. 1965 - April 1965	Tamper Division Canada Iron Lachine, P.Q. Engineer's Assistant
April 1964 - Aug. 1964	Tamper Division, Canada Iron Lachine, P.Q. Engineer's Assistant

Academic Awards:

- 1968 - 1969 Duke University Geology Department Fellowship
- 1969 - 1970 National Science Foundation Predoctoral Traineeship in Oceanography, Duke University Marine Laboratory
- 1970 - 1973 Woods Hole Oceanographic Institution Research Fellowship

LATE QUATERNARY SEDIMENTATION IN THE EASTERN ANGOLA
BASIN by Brian D. Bornhold, 213 pages, November 1973.
N00014-67-A-0108-0004 and National Science Foundation
Grants GA-29460 and GA-35454.

Recent sedimentation in the eastern Angola basin includes calcareous oozes in the north and south (Guinea Rise and Walvis Ridge) and hemipelagic lutites and terrigenous turbidites on the Congo Cone and on the Angola rise and abyssal plain. Slumped and ponded sediments are dominant within the Angola diapir field. Illite and montmorillonite are abundant in the southern part of the basin, reflecting the source in soils of South West Africa and northward transport in the Benguela Current system. Kaolinite dominates the clay-mineral assemblage in the north-central part of the basin, reflecting a source in the tropical-humid Congo Basin and transport to the deep-sea through the Congo River and canyon systems. Piston cores from the continental rise revealed major fluctuations in the surface oceanographic conditions, primary productivity, and near-bottom depositional environment during the late Quaternary. Sediments deposited during glacial intervals contain markedly lower carbonate, higher levels of organic carbon, and more abundant siliceous biogenic components, fecal pellets, and pyrite. Sedimentation rates during the past 200-300 x 10³ years remained relatively constant on the rise, averaging 3-5 cm/10³ years. Several oceanographic changes are deduced from sediment composition and geochemistry.
