BIOGRAPHY

The author came to the United States in 1967 upon the completion of his high school education in Hong Kong. After spending a year at the Santa Ana College, he transferred to the California State University, Los Angeles where he subsequently received his B.S. degree in chemistry in 1971 with honors from the University and from the chemistry department. He transferred to the Massachusetts Institute of Technology in the same year and received a S.M. degree in oceanography in 1973. Since then, he has been a doctoral candidate in chemical oceanography in the joint program of the Massachusetts Institute of Technology and the Woods Hole Oceanographic Institution. He has been nominated for membership in Alpha Gamma Sigma, Phi Theta Kappa, Phi Kappa Phi and Sigma Xi. He is an active member of the American Association for the Advancement of Science, the American Geophysical Union and the American Society of Limnology and Oceanography. He is married to the former Virginia Wai-Shu Chin. His contributions to the literature are as follows:

ABSTRACT

DISSOLVED INORGANIC AND

PARTICULATE IODINE IN THE OCEANS

GEORGE TIN FUK WONG

Analytical methods have been developed for the
determination of iodate, iodide and particulate iodine in
sea water. Iodate is converted to tri-iodide and the absor-
bance of tri-iodide at 353 nm is measured. The precision of
this method is ca. ±3%. Iodide is first separated from most
other anions by an AG 1-x8 anion exchange column and then
precipitated as palladous iodide with elemental palladium
as the carrier. The precipitate is analyzed by neutron acti-
vation analysis. The precision of the method is ±5% and the
reagent blank is 0.005 uM. Marine suspended matter is col-
lected by passing sea water under pressure through a 0.6 u
(37 mm diameter) Nuclepore filter. The iodine content of the
particles is determined by neutron activation analysis. The
method has excellent reproducibility and the filter blank is
ca. 3 ng.

Iodate is depleted in the surface waters of the
Equatorial Atlantic. The depletion is more pronounced than
in the Argentine Basin and possibly reflects the higher pro-
ductivity in the equatorial area. Superimposed on this fea-
ture, a thin lens of water, of a few tens of meters thick and
with high iodate concentrations, can be traced across the
Atlantic. Along the equator, this lens occurs at 80 m at $33^{\circ}W$
and rises upwards to 55 m at $10^{\circ}W$ and it coincides with a
core of highly saline water which is characteristic of the
Equatorial Undercurrent. Longitudinal sections reflect the
complexity of the equatorial current system. At least three
cores of water with high iodate concentrations may be iden-
tified. These waters may be transported to the equatorial
region from the highly productive areas along the north-west-
ern and western African coasts and the Amazon plume.

In anoxic basins, the concentration of iodide in-
creases rapidly in the mixing zone from 0.02 uM to 0.44 uM
in the Cariaco Trench and from 0.01 uM to 0.23 uM in the
Black Sea. The iodate concentration, meanwhile, decreases to
zero. A maximum in the total iodine to salinity ratio is ob-
served just above the oxygen-sulfide interface (15 to 17

-18-

nmoles/g); it is suggestive of particle dissolution in a strong pycnocline. Below the interface, the total iodine to salinity ratio is constant at 12.3 nmoles/g in the anoxic zone of the Cariaco Trench, whereas, in the Black Sea, it increases with depth from 10.0 to 19.4 nmoles/g and suggests a possible flux of iodide from the sediments. By considering the distribution of iodate and iodide in oxic and anoxic basins and our present analytical capability, the lower limit of the pE of the oceans is estimated to be 10.7. Thermodynamic considerations further suggest that the iodide-iodate couple is a poor indicator for the pE of the oceans with a limited usable range of 10.0 to 10.7.

In the Gulf of Maine during the winter of 1974 to 1975, the effect of winter mixing was conspicuous. Uniform concentrations of iodide and iodate were observed in the mixed layer above the sill. The absence of a depletion of iodate and the low iodide concentration (0.04 uM) in the surface waters reflect the low biological activity in this region during winters.

Profiles of particulate iodine are characterized by high concentrations in the euphotic zone (>5 ng/kg), and lower concentrations (<2 ng/kg) at greater depths. Occasionally, high concentrations have also been observed in the nepheloid layer. The iodine-containing particles are probably biogenic. A section in the Western Atlantic from 75°N to 55°S shows evidence of the transport of particles along isopycnals and the re-suspension of surface sediments to considerable distance from the bottom. The standing crops in the top 200 m may be qualitatively correlated with the primary productivity.

Thermodynamic considerations show that iodide is a metastable form at the pH of sea water. Laboratory studies fail to show the oxidation of iodide at measurable rates. Elemental iodine is unstable in sea water and undergoes hydrolysis to form hypoiodous acid in seconds. Hypoiodous acid is also unstable and has a life time of minutes to hours. It may react with organic compounds to form iodinated derivatives or it may be reduced to iodide by a reducing agent. The disproportionation of hypoiodite to form iodate seems to be a slower process. A possible chemical cycle for iodine in the marine environment is proposed.

CHAPTER I.   INTRODUCTION

I.1 Introduction

This thesis presents an investigation on the marine chemistry of the element iodine, a multi-oxidation-state element known to be in redox dis-equilibrium, in an attempt to gain a better understanding concerning biological-chemical interactions in the ocean.

Ever since Sillen's classic paper on ' the physical chemistry of sea water' (1961), many attempts have been made to examine the controls on the chemical composition of the oceans by computing the composition of an equilibrium mixture from the existing thermodynamic information (Garrels and Thompson, 1962; Sillen, 1963; Holland, 1965; Kramer, 1965; Zirino and Yamamoto, 1972). There are two basic assumptions in this model. First, that the ocean is a closed system and secondly, that sufficient time is available for the attainment of a chemical equilibrium. However, the ocean in reality is not a closed system as there are frequent exchanges of both energy and matter among the atmosphere, hydrosphere and the lithosphere. Moreover, since different elements have different residence times in the ocean varying from 100 years for aluminum to 10^8 years for chloride (Brewer, 1975 and references cited therein), it is unclear that there is sufficient time for all elements to reach a chemical equilibrium. Thus, it is not surprising that 'exceptions' are often observed and, even in his classic paper, Sillen (1961) has noted that gross dis-equilibrium does

occur in some elements.

Dis-equilibria are especially noticeable in the bio-active and multi-oxidation-state elements. Some of the better known examples are: iodide-iodate, ammonia-nitrogen-nitrite-nitrate and arsenite-arsenate (Goldberg, 1963; Riley and Chester, 1971; Johnson and Pilson, 1972). Under the oceanic conditions of a pH of 8 and a pE of 12.5 (Sillen, 1961), the reduced species in all these systems should be undetectable within the limits of our present analytical capabilities. However, significant quantities of these reduced species are often found. The predicted and observed concentrations of the different species in these systems are summarized in table I-1-1.

At least two processes are involved in maintaining an observed redox dis-equilibrium. The first one is the perturbation of a stable system to produce the unstable species. This reaction will be thermodynamically unfavorable. The production of these unstable species such as iodide, arsenite and nitrite has often been attributed to biological activity (Tsunogai and Sase, 1969; Johnson, 1972; Fiadeiro and Strickland, 1968) for a number of reasons. First, organisms can utilize solar energy through photosynthetic processes and they may subsequently use this energy, directly or indirectly, to drive these thermodynamically unfavorable reactions. Secondly, organisms possess complicated enzyme systems which can be used as catalysts to lower the activation energies

Table I-1-1 The calculated and observed ratios of the concentrations of the reduced species to the concentrations of the oxidized species in the nitrogen, arsenic and iodine systems in the sea at a pH of 8 and a pE of 12.5

Reaction	log K	log of Calculated Ratio	log of Observed Ratio	Concentration Observed

of these reactions. Thirdly, organisms need an electron acceptor during their metabolic processes. The primary electron acceptor for aerobic organisms is oxygen. In the absence of oxygen, some organisms may use in succession nitrate, sulfate and carbon dioxide as the terminal electron acceptor. During such processes, other species may be directly or indirectly reduced.

The second process is the tendency to re-establish the stable system. The rate of this thermodynamically favorable process will determine the persistence of the disequilibrium. For example, although molecular nitrogen is unstable relative to nitrate (table I-1-1), it amounts to 78% of our atmosphere and its presence is ubiquitous in our oceans. Sillen (1961) suggested that its presence is due to the high internal energy barrier of the N-N bond which greatly reduces its rate of oxidation. However, although this step is thermodynamically favorable, the possibility of biological mediations such as nitrification is not ruled out, and, in such cases, the rate of the reaction may either be enhanced or retarded.

In this study, I have chosen to use the iodine system to illustrate some of the implications of these concepts on the chemistry of the oceans.

I.2   A brief review of some aspects of the geochemistry of
      iodine

I.2.1   Occurrence

      Iodine, as an element, was not recognized until
the early nineteenth century when Courtois isolated elemen-
tal iodine from seaweed (Courtois, 1813). Elemental iodine
has not been detected in the lithosphere, except as small
traces in certain mineral springs. However, as iodide and
iodate, it occurs widely as a trace constituent (Anonymous,
1951; Sneed et al., 1954; Hills, 1956; Fuge, 1974). Table
I-2-1 summarizes the iodine contents of various rocks and
minerals. Minerals having iodine as an essential consti-
tuent are rare although dietzeite and lautarite have been
found in the Chilean saltpetre deposits. A list of the
known iodine-containing minerals is presented in table I-
2-2.

      The history of investigations on the chemistry of
iodine in marine environments has been briefly reviewed by
Riley (1965a). He traced the first study to 1825 when Pfaff
detected iodine in Baltic Sea water. This report was later
confirmed by Laurens (1835) who found iodine in French
coastal water. Early investigators reported a wide range of
concentrations from 0.017 ug/l (Macadam, 1852) to 8000 ug/l
(Marchand, 1855). Since then, a series of measurements have
been made (Reith, 1930; Skopintsev and Michailovskaya, 1933;
Dubravcic, 1955; Sugawara et al., 1955; Sugawara and Terada,

Table I-2-1   Iodine content of rocks and minerals*

Rock Type	Iodine Content (ppm)	Mineral Type	Iodine Content (ppm)
Amphibolite	0.25-0.38	Apatite	0.23-0.44
Basalt	0.31-0.80	Biotite	0.50
Diabase	0.49-1.04	Calcite	0.23

Kappanna et al., 1962; Tsunogai, 1971a, 1971b; Tsunogai and
Henmi, 1971; Liss et al., 1973; Wong and Brewer, 1974), and,
presently, most investigators agree that the concentration
of total dissolved iodine in sea water is about 60 to 70
ug/l (0.5 uM) (Goldberg et al., 1971).

Relative to sea salt, iodine is more concentrated
in the atmosphere, in rain, in river waters and in inter-
stitial waters. Surface sediments also have high iodine
concentrations. The concentrations of iodine in natural
waters, sediments and the atmosphere are summarized in
table I-2-3.

Table I-2-3 The concentration of total iodine in various geochemical reservoirs and agents

Material	Concentration Range	Average Concentration	I/Cl	Reference
Sea water		60 ug/kg	3×10^{-6}	Goldberg et al. (1971)
Atmosphere

SCM - m^3 of air at standard temperature and pressure.

I.2.2 The speciation of dissolved iodine in sea water

Thermodynamic calculations show that iodate should be the only detectable iodine species in the sea (Sillen, 1961). However, it has been long recognized that at least two species of iodine are present. Winkler (1916) suggested that they are iodate and iodide. The identity of the oxidized species later developed into a controversial subject. Sugawara (1957) supported Winkler's view of iodate as the oxidized species while Shaw and Cooper (1957) thought that hypoiodous acid might be the dominant oxidized species instead. Later investigations by Sugawara and Terada (1958) and Johanneson (1958) confirmed the presence of iodate and Shaw and Cooper (1958) subsequently retracted their hypothesis. The fraction of the inorganic iodide that may be present as ion pairs with the major ions can be estimated from partial molal volumes (Millero, 1969). It is negligible (table I-2-4). Recently, the possibility of the presence of 'organic iodine' has been proposed by Truesdale (1975). He claimed concentrations of up to 5% of the total dissolved iodine in the surface waters of the Irish Sea. Lovelock et al. (1973) detected the presence of methyl iodide. However, its kinetic stability in sea water is low and it is susceptible to exchange reactions with chloride ions to form iodide ions instead (Zafiriou, 1975). The present discussion will deal only with the inorganic species.

Table I-2-4   Ion pairing of the iodide ion with the major
ions in the ocean[*]

r (A)	z^2/r (A^{-1})	$\overline{V}^o_{(calc)}$ (ml/mole)	$\overline{V}^{o\ sw}_{(meas)}$ (ml/mole)
2.16	0.46	41.8	41.4

$$\overline{V}^{o\ sw}_{(elect)} = -7.5 \times z^2/r = -3.45 \text{ ml/mole}$$

% contact ion-pair:

$$\frac{\overline{V}^{o\ sw}_{(meas)} - \overline{V}^{o\ sw}_{(calc)}}{\overline{V}^{o\ sw}_{(elect)}} = \frac{41.4 - 41.8}{-3.45} = 1.2\%$$

r - Pauling crystal radius

$\overline{V}^{o\ sw}_{(meas)}$ - Partial molal volume measured

$\overline{V}^{o\ sw}_{(elect)}$ - Electrostriction partial molal volume

[*] Data from Millero (1969).

I.2.3 The distribution of iodine in the oceans

The average concentration of total dissolved iod-
ine in the oceans is about 0.5 uM (64 ug/1) (Goldberg et
al., 1971). The ratio of iodide to iodate varies with depth
and with geographical locality. The concentration ranges of
iodide and iodate in the open oceans are < 0.01 uM to 0.2 uM
and 0.2 uM to 0.5 uM respectively (Tsunogai and Henmi, 1971).
Iodide maxima and corresponding iodate minima are often
found in surface waters. Below the euphotic zone, iodide
decreases to below the detection limit of about 0.01 uM
while iodate increases to an approximately constant level.
Low but significant iodide concentrations have been observed
in bottom waters (Tsunogai, 1971b; Tsunogai and Henmi, 1971).
Typical profiles of iodide and iodate are shown in figure
I-2-1. The distribution of organic iodine in the water col-
umn is unknown. The concentration of iodine in marine sus-
pended matter has not previously been measured.
Fig. I-2-1 The vertical distribution of iodine at $12^{\circ}01'N$, $158^{\circ}02'E$ in the North Pacific where the depth is 5855 m. (Tsunogai, 1971b)

I.2.4 The biogeochemistry of iodine

The presence of measurable amounts of iodide in the oceans implies that the iodine system in the sea is not at chemical equilibrium with the O_2-H_2O system. Sugawara and Terada (1967) found that the alga Navicula can interconvert iodate and iodide. Tsunogai and Sase (1969) demonstrated that bacteria that are capable of reducing nitrate to nitrite, or their enzyme extracts, can also reduce iodate to iodide. Thus, they proposed the enzymatic reduction of iodate to iodide using nitrate-reductase as the catalyst.

Tsunogai and Henmi (1971) later observed that the concentrations of iodide in the surface waters of various parts of the Pacific can be qualitatively correlated to their primary productivity. Wong and Brewer (1974) reported that in the Argentine Basin, iodate is linearly related to the micronutrients phosphate and nitrate, and consequently to apparent oxygen utilization (AOU) as well. They obtained the molar ratios of AOU:NO_3^-:PO_4^{-3}:IO_3^- of 2440:357:23:1. These relationships and the recent detection of methyl iodide (Lovelock et al., 1973), which is a possible metabolite, in sea water, suggest that iodine may be intimately involved in the marine biochemical cycles.

Indeed, iodine can be found in the body tissue of all marine species (Hansen, 1963). (The concentrations of iodine in various organisms are shown in tables I-2-5 and I-2-6.) It is an essential nutrient for red and brown

algae (Bowen, 1966) and Shaw (1959, 1962) reported that only iodide can be absorbed. Marine plankton also take in and excrete iodine, mostly in the form of iodide (Kolemainen, 1969; Kuenzler, 1969). For land plants, a suitable amount of iodine is actually necessary for optimal growth (Hanson, 1963) and it is also essential for mammals (Bowen, 1966). However, although iodine has long been classified as a bio-phile (Goldschmidt, 1954) and its metabolic pathways in the higher mammals have already been intensively studied (Gross, 1962), its physiological functions in marine organisms in general are not well documented. Thus, the link between iodine and biological activity in the sea is still based on indirect observations.

I.2.5 Iodine in the sediments and interstitial waters

Price and co-workers (Price et al., 1970; Price and Calvert, 1973) have studied the distribution of iodine in sediments. They observed high iodine content in surface sediments which decreased rapidly with depth and also decreased from oxidizing to reducing sediments. A linear relationship between iodine and organic carbon content was shown. Shishkina and Pavlova (1965) have also reported enrichment of iodine in sediments and the iodine content was found to increase with increasing organic content and the degree of fineness of the sediments. Bojanowski and Paslawska (1970) measured iodine in interstitial waters and reported the range of iodine concentrations to be 0.35 to 1.9 mg/kg. Recently, Pavlova and Shishkina (1973) further reported that the concentration of iodine in intersitital waters increases with depth. These observations suggest intense diagenesis and post-depositional migration of iodine in recent sediments and indicate a possible flux of iodine from the sediments into the ocean. This was proposed by Tsunogai (1971b) who observed a low but significant excess of iodide in the bottom waters.

I.2.7 The marine geochemical cycle of iodine

Since iodine is involved in many geochemical pro-
cesses as described earlier, its geochemical cycle will no
doubt be complex. Miyake and Tsunogai (1963) presented a
scheme for the cycling of iodine in the oceans and it has
subsequently been modified twice (Tsunogai and Sase, 1969;
Tsunogai, 1971b). The latest version is shown in figure I-2
-2. Many of the values of the fluxes involved are specula-
tive and unconfirmed. However, the relative magnitudes of
the processes in the cycle are worth noting.

The permanent loss of iodine to the sediments by
burial is the smallest flux. It is at least three orders of
magnitude smaller than other fluxes and suggests the cyclic
nature of iodine in the water column. Three cycles can be
readily identified. By far, the most important cycle quanti-
tatively is the incorporation of iodine into the organisms
in the surface layers and subsequent re-mineralization at
depth. The regenerated iodine is transported back to the
euphotic zone by advection and diffusion. A secondary, and
possibly significant, cycle is the sedimentation of iodine
containing particles which undergo diagenesis in the sedi-
ments. The dissolved iodine thus formed diffuses back into
the water column. The quantitatively almost insignificant
cycle is the input of iodine from river runoff and fallout
and the removal by transferring iodine from the oceans to
the atmosphere.
Fig. I-2-2 The cycle of iodine in the ocean. The figures indicated are the annual rates in a unit of 10^{-4} g at/m^2-yr or 3.6×10^{10} g at/yr in the whole ocean. (Tsunogai, 1971b)

I.2.6 Iodine in the atmosphere

Since the report of an enrichment of iodine in the atmosphere and especially in the marine atmosphere (Rankama and Sahama, 1949; Goldschmidt, 1954; Duce et al., 1963), much effort has been devoted to study the atmospheric chemistry of iodine. It is generally accepted that the ocean is the most likely source of the excess iodine in the atmosphere. However, the mechanism for the transfer of iodine from the ocean into the atmosphere is still unclear. Miyake and Tsunogai (1963) suggested that the transfer is accomplished by the evaporation of the volatile elemental iodine which may be formed by the photo-oxidation of iodide according to the reaction

$$2I^- + \tfrac{1}{2}O_2 + 2H^+ + h\nu = I_2 + H_2O \qquad \text{(I-2-1)}$$
Others (Bolin, 1959; Dean, 1963) favored the transfer of organic iodine into the atmosphere by a bubble bursting mechanism. The volatile methyl iodide has been suggested as a possible candidate (Lovelock et al., 1973). Seto and Duce (1972) found in their laboratory experiments that both the organic and the gaseous iodine are important in determining the total iodine enrichment on marine atmospheric particles.

I.3 The scope and organization of the research

My efforts in studying the marine chemistry of iodine can be sub-divided into three sections. First, techniques were developed for the analysis of dissolved iodine in both oxidation states, namely, iodate and iodide, and also for particulate iodine with improvements in simplicity, sensitivity and precision over the existing methods. Then, samples were collected for analysis from specific geographical areas with distinct characteristics in their productivity or oxidation potential. Data for dissolved iodine have been obtained from the Equatorial Atlantic, the Black Sea, the Cariaco Trench, the Venezuela Basin and the Gulf of Maine. Samples of marine suspended matter were obtained from the Atlantic through the GEOSECS (Geochemical Ocean Sections Study) program. Laboratory experiments have also been designed to study the stability, and the mechanisms for the interconversion, of the iodine species in sea water.

CHAPTER II. THE ANALYTICAL CHEMISTRY OF IODINE IN SEA WATER

II.1 Introduction

Since iodine is present in the oceans at the uM level, it is considered a trace element. The concentration ranges of iodate and iodide in the open oceans are usually 0.2 to 0.5 uM and <0.01 to 0.2 uM respectively. With such low abundances and narrow ranges of concentrations, precise and sensitive analytical techniques are absolutely necessary for reliable quantitative studies. I have developed a suitable method for measuring iodate in the oceans with a precision of better than 1% in an earlier study (Wong, 1973; Wong and Brewer, 1974). In this chapter, I shall report on methods for measuring iodide and particulate iodine in sea water. Moreover, the method for the determination of iodate has been modified. This modified version is simpler and more suitable for rapid surveys although the precision may be slightly poorer.

II.2 Historical review

Riley (1965) has reviewed the earlier literature through 1962. A few more methods have been reported since then. They are all summarized in table II-2-1.

Analytical schemes for the determination of iodate can be categorized into three groups according to their methodologies: titrimetry (Skopintsev and Mikhailovskaya, 1933; Barkley and Thompson, 1960a, 1960b; Matthews and Riley, 1970; Wong and Brewer, 1974; Truesdale and Spencer, 1974), photometry (Reith, 1930; Dubravcic, 1955; Sugawara et al., 1955; Voipio, 1961; Kappanna et al., 1962; Tsunogai, 1971a; Schnepfe, 1972; Truesdale and Spencer, 1974) and polarography (Petek and Branica, 1968, 1969; Herring and Liss, 1973). The titrimetric methods involve the titration of liberated iodine using the starch-iodine or the tri-iodide ion color as the end point indicator. Amperometric end point detection has also been used. The photometric procedures may depend on: (1) the catalytic action of iodide on the oxidation of arsenic (III) by cerium (IV); (2) the color intensity of the extracted iodine; or (3) the color intensity of the iodine-starch complex. Some of the procedures require tedious initial concentration and separation steps (for example, Reith, 1930; Skopintsev and Mikhailovskaya, 1933; Sugawara et al, 1955; Matthews and Riley, 1970; Tsunogai, 1971a). Others may require stringent control of experimental

Table II-2-1 Analytical methods for the determination of dissolved iodine in sea water

Approx. conc. found (ug/l)	Method of separation and detection	Methodology	Reference
43	Iodate reduced with As_2O_3 + HCl, iodine liberated with nitrite and extracted with CCl_4.	Photometry	Reith 1930.
26-56	Oxidized to IO_3^- with MnO_4^-, reduced the latter with $C_2O_4^=$, treated with I^- and acid, liberated iodine titrated.	Titrimetry	Skopintsev and Mikhailovskaya 1933.
61	Direct method, depending on catalytic action of I^- on reaction between Ce^{4+} and As^{3+}, remaining Ce^{4+} determined.	Photometry	Dubravcic 1955.
Total I = 7-57, IO_3^--I = 0-50	I^- co-precipitated with AgCl, converted to IO_3^- with Br. Reacted with acidified I^-, liberated iodine measured. Total I by reduction of IO_3^- with $SO_3^=$, followed by determination of I^- as described above.	Photometry with starch iodine color	Sugawara et al. 1955; Sugawara and Terada 1957.
Total I=45-70, IO_3^--I= 50-76	IO_3^- reacted with I^-, liberated iodine treated with excess $S_2O_3^=$, which was titrated with IO_3^-. Total I by oxidation of I^- with Br to IO_3^-, which was determined as described above. Total I also determined by its catalytic effect on the reaction of Ce^{4+} with As^{3+}.	Amperometric titration, Photometry with brucine	Barkley and Thompson 1960a, 1960b.

Total I=60-118	Catalytic effect of I^- on reaction of Ce^{4+} with As^{3+}.	Photometry Ce^{4+} color	Voipio 1961; Kappanna et al. 1962.
IO_3^--I=36-172	Direct method. Acidify to pH 3. Remove O_2. Record IO_3^- peak at -0.3 v.	Pulse polarography	Petek and Branica 1968,1969.
-----	Modified Sugawara method, reduction of IO_3^- with $(NH_2)_2 \cdot H_2SO_4$. I_3^- determined by photometry or photometric micro-titration.	Photometry I_3^- color. Titrimetry	Matthews and Riley 1970.
I^--I=0-25 IO_3^--I=25-50	Improved Sugawara method.	Photometry Starch-I_2 color.	Tsunogai 1971a.
Total I=55-90 IO_3^--I=37-64	IO_3^- reacted with iodide-starch mixture directly. Total I by oxidation of I^- with alkaline $KMnO_4$ to IO_3^- and reaction with I^--starch mixture.	Photometry starch-I_2 color	Schnepfe 1972.
IO_3^--I=41-56 I^--I=1-11	Direct method for IO_3^-. Record IO_3^- peak at -1.090 v. I^- determined by difference by oxidizing I^- to IO_3^- by UV irradiation.	Differential pulse polarography	Herring and Liss 1973
-----	IO_3^- react with I^- and acid to form I_3^-. I_3^- color measured or titrated with $S_2O_3^=$. Total I by catalytic effect of I^- on reaction of Ce^{4+} with As^{3+}. Measure brucine color.	Photometry Amperometric titration	Truesdale and Spencer 1974.
IO_3^--I=35-65	IO_3^- reacted with I^-. Liberated I_2 titrated with $S_2O_3^=$ by spectrophotometric titration.	Titration	Wong and Brewer 1974.

conditions (Dubravcic, 1955; Barkley and Thompson, 1960a; Voipio, 1961; Kappanna et al., 1962; Truesdale and Spencer, 1974). Some of the earlier methods (Reith, 1930; Skopintsev and Mikhailovskaya, 1933; Dubravcic, 1955) do not distinguish between the oxidation states and may not have sufficient precision and sensitivity to detail the variations of iodate in the oceans.

Because of its low abundance, the measurement of iodide in sea water is even more difficult. In most cases, iodide is measured as the difference between iodate and total iodine. Consequently, the precision and sensitivity, and thus the usefulness, of such methods are much reduced. The only known direct method is Sugawara's method and its later modifications (Sugawara et al., 1955; Matthews and Riley, 1970; Tsunogai, 1971a). In these methods, iodide is first concentrated from sea water by precipitating mixed silver halides. The precipitate is treated with bromine water to oxidize iodide to iodate. The excess bromine and hypobromite are carefully removed and the iodate is determined by iodometric titration. This method is time consuming and considerable manipulative skill is required to remove the bromine compounds quantitatively. Moreover, the use of rather large amounts of the obnoxious bromine water can become a problem especially on board ship where fume hood facilities may not be available.

Most of the presently available data were mea-

sured by Sugawara's method and its modifications (Sugawara and Terada, 1957; Sugawara, 1957; Sugawara et al., 1962; Tsunogai, 1971b; Tsunogai and Henmi, 1971). Few of the remaining methods have been tested by measuring natural samples from the open oceans. Representative profiles of iodide and iodate are shown in figure I-2-1. Although the claimed precision of the analytical methods used is $\pm 3\%$ for iodide and $\pm 6\%$ for iodate, large haphazard variations are found in these profiles and they are almost certainly due to analytical uncertainties.

In light of the above, the precision and reliability of the existing analytical methods seemed inappropriate for this study. Consequently, I have developed new schemes for the analysis of iodide, iodate and particulate iodine in the oceans.

II.3 The determination of iodate in sea water

II.3.1 Introduction

In my earlier work, I have reported a method for the determination of iodate in sea water by spectrophotometric micro-titration (Wong, 1973; Wong and Brewer, 1974). The precision of this method is better than 1%. I also found that the iodate can be determined colorimetrically by measuring at 353 nm the absorbance of the tri-iodide ions generated by the addition of acid and excess potassium iodide to the sample using a scheme of standard additions. The precision is about ±3% (Wong, 1973). Although its precision is poorer, this method is simpler and will be most appropriate for surveying the large variations (up to 50%) of the iodate concentrations in the surface layers. The addition method has been modified and the results will be reported in this section.

My previous data (Wong and Brewer, 1974) were obtained from frozen samples analyzed in my laboratory at Woods Hole. There was some concern about the possible interference by nitrite. I have tested the sea-worthiness of the titration method and designed schemes to remove nitrite from the samples and the results will also be included in this section.

II.3.2 Experimental

II.3.2.1 Reagents

All reagents used were of the analytical reagent grade.

Standard potassium iodate solution (8 uM). Dissolve 0.856 g (4 mmoles) of potassium iodate in distilled water and dilute to 500 ml. The resulting solution is 8 mM. Prepare an 8 uM solution from this stock solution by successive dilutions.

Potassium iodide solution (10% w/v). Dissolve 2.5 g of potassium iodide in distilled water and dilute to 25 ml. This solution should be prepared daily.

Sulfuric acid (0.1 M). Add 25 ml of concentrated sulfuric acid (18 M) to 400 ml of distilled water in small increments with intermittent swirling and cooling in an ice-water slush bath. Add 25 ml of distilled water. The resulting solution is approximately 1 M. Prepare a 0.1 M solution from this stock solution by a ten-fold dilution.

Sulfamic acid solution (0.1 % w/v). Dissolve 0.1 g of sulfamic acid in distilled water and dilute to 100 ml.

II.3.2.2 Procedure

Filter about 250 ml of surface sea water through a Whatman 40 filter paper. Pipette 40 ml of the filtered sea water into each of a set of four 50 ml volumetric flasks and mark them 0, 1, 2 and 3. Add 1 ml of 0.1 M sulfuric acid and 1 ml of 0.1% sulfamic acid to each flask. Swirl each flask and allow the solutions to sit for 15 minutes with occasional shaking. Pipette 1, 2 and 3 ml of 8 uM potassium iodate solution to the flasks marked 1, 2 and 3 respectively. Add 1 ml of the 10% potassium iodide solution and dilute to volume with distilled water. Again, allow the solutions to sit with occasional swirling for 15 minutes. Then, measure the absorbance of the solution in each flask at 353 nm in a 10 cm cell. Repeat the procedure twice for the same surface sea water. Plot absorbance against the amount of iodate-iodine added and compute the slope (S) of the graph.

Treat each sample in the same manner except omitting the addition of iodate. Note the absorbance (A) of each sample. The concentration of iodate in the samples can be calculated from the formula

$$(IO_3^-) = (A/S) \times 0.197 \text{ uM} \qquad (II-3-1)$$

II.3.3 Results and discussions

Sea water samples were collected in the Equatorial
Atlantic during cruise AII-83 and were analyzed for iodate
on board ship by the colorimetric method. Table II-3-1
shows the raw data for constructing the calibration curves
through out the entire cruise. Figure II-3-1 shows one of
the calibration curves. The slopes of the calibration curves
were calculated by a linear least square fit. Within each
day, the uncertainty of the slope varies from $\pm 0.2\%$ to
$\pm 1.3\%$. The average slope for the calibration curves in six
weeks has 1σ of $\pm 2.3\%$. The precision of the colorimetric
method relies heavily on the consistency of the slope of
the calibration curve as shown in equation II-3-1. Thus, it
is comforting to observe such reproducible results and the
uncertainty of the method can be estimated to be about
$\pm 3\%$.

In order to further check the reliability of the
colorimetric method, I have attempted to intercalibrate
results from this method and the titration method. Figure
II-3-2 shows the data from GEOSECS station 109 (2°S, $4^\circ 33'$W)
and the nearby station AII-83-2052 (2°S, 10°W). The GEOSECS
samples were analyzed by the titrimetric method while
station AII-83-2052 samples were analyzed by the colori-
metric method. The profiles of σ_θ of these stations are
indistinguishable below 40 m while the profiles of salinity
and potential temperature become identical below 500 m. The

iodate profiles, within the precision of the analytical methods, are indistinguishable throughout the entire depth. This agreement indicates that there is no systematic difference between these two methods.

I have also measured iodate in the Venezuela Basin on board ship during cruise AII-79 by the spectrophotometric micro-titration method. No special difficulties were encountered and the method seems to be sea-worthy. This profile of iodate is shown in figure II-3-3. The profile is remarkably smooth and the variation in the deep water is only $\pm 2\%$. A few of the samples were frozen and analyzed in the laboratory four months later. The stored samples give absolute concentrations that are slightly lower than those nearby samples analyzed on board ship as shown in figure II-3-3. However, this difference is insignificant within the uncertainty of the analytical method and may be due to a slight error in calibrating the strength of the sodium thiosulfate titrant, as different titrant solutions have been used. Thus, it is apparently safe to freeze sea water for an extended period of time for the analysis of iodate on a later date. A more detailed study on the effect of storage on iodate analysis has been reported in Wong (1973).

The interference of nitrite on iodometric titrations is well known. The reaction involved is

$$2I^- + 2HNO_2 + 2H^+ = 2NO + I_2 + 2H_2O \qquad (II-3-2)$$
Thus, in an acidic solution, nitrite may oxidize the
Fig. II-3-3 A profile of iodate determined on board ship.
+ denote samples stored frozen and analyzed four
months later.

excess potassium iodide added to produce additional tri-
iodide ions and yield high results. Furthermore, nitrite can
be regenerated from nitric oxide by the reactions

$$2NO + O_2 = 2NO_2 \tag{II-3-3}$$

$$2NO_2 + H_2O = HNO_2 + HNO_3 \tag{II-3-4}$$
Nitrogen dioxide can also oxidize iodide to iodine in an
acidic solution according to the equation

$$NO_2 + 2I^- + 2H^+ = I_2 + NO + H_2O \tag{II-3-5}$$
Thus, theoretically, in the presence of acid and even a
trace of nitrite, iodide may be continuously oxidized to
iodine until it is exhausted. Methods for the removal of
this interference have been well studied (Kolthoff and
Belcher, 1957). Cohen and Ruchhoft (1941) proposed the use
of sulfamic acid for removing nitrite in the Winkler
titrations for dissolved oxygen by the reaction

$$NH_2SO_2OH + HNO_2 = H_2SO_4 + N_2 + H_2O \tag{II-3-6}$$
This reaction is rapid and quantitative and the products
do not react with any iodine species. Thus, I have adopted
the use of sulfamic acid as a precaution against the
interference by nitrite.

Nitrite occurs at very low concentrations in the
open oceans. In deep waters, its concentration is less than
0.024 uM (Wada and Hattori, 1972). In the surface layers,
the concentration is quite variable. I have tested for
possible interference in the oxic zone of the Cariaco
Trench. I chose two close by samples that were about 100 m

above the oxic-anoxic interface at 158 m and 162 m. Sulfamic acid was added only to the sample at 158 m. The concentrations of iodate of these two samples were found to be 0.463 uM and 0.462 uM respectively and should be considered indistinguishable within the analytical uncertainties. The maximum nitrite concentration in the Cariaco Trench was reported to be 0.6 uM and occurs at a slightly shallower depth (Okuda et al., 1969). It seems likely that the nitrite, because of its extremely low concentrations in the open oceans, will not significantly affect the analysis. However, in the surface layers, nitrite concentrations in excess of 5 uM have been observed (Fiadeiro and Strickland, 1968). Thus, it would be advisable to take proper precautions against an interference from nitrite by destroying it with sulfamic acid.

II.4 The determination of iodide in sea water by instru-
     mental neutron activation analysis

II.4.1 Introduction

        I have previously reported on the distribution of
iodate in sea water (Wong, 1973). In this section, I shall
describe a simple and sensitive method for the determina-
tion of iodide.

        The nuclear characteristics of iodine make it a
particularly favorable candidate for instrumental neutron
activation analysis. It occurs in nature as the mono-iso-
topic I-127 with a rather large (n,γ) cross section of 5.6
barns. Upon bombardment with thermal neutrons, I-128 is
formed. It has a half life of 25 minutes and undergoes β-
decay emitting γ rays with energies of 442.7 KeV, 526.3 KeV
and 743.5 KeV and relative intensities of 100:9:1 (Adams
and Dams, 1969), and β-particles with energies of 1.13 MeV,
1.67 MeV and 2.12 MeV and relative intensities of 2:16:76
(Wilson, 1966). Instrumental neutron activation analysis
has been used extensively to determine the total iodine
content of biological (Bowen, 1959; Ohno, 1971; Heurtebise,
1971; Malvano et al., 1972), industrial (Cosgrove et al.,
1958; Ballaux et al., 1969) and some meteorological (
Duce et al., 1965; Owens and Warburton, 1973; Moyers and
Duce, 1974) materials. However, all of these methods
involve a post-irradiation separation of iodine from
the sample matrix, and because of the short half life

of I-128, the usefulness of the methods is much reduced. I have applied neutron activation analysis to the determination of iodide in sea water. Post-irradiational chemical manipulations of the samples have been eliminated in favor of a simple pre-irradiation separation step. The simplicity and higher sensitivity of this method yield distinct advantages over the existing methods.

The procedure involves a separation of iodide in the sample from iodate, other halides and most other anions by passing sea water through an ion exchange column containing the strongly basic AG 1-x8 resin in the nitrate form. Iodide, being retained in the column, is recovered by eluting the column with a 2 M sodium nitrate solution. The iodide is selectively precipitated from the eluate as palladous iodide in the presence of excess palladous ions using elemental palladium as a carrier. The elemental palladium is produced by reducing some of the excess palladous ions with sodium thiosulfate. The precipitate is filtered and analyzed by instrumental neutron activation analysis.

II.4.2 Experimental

II.4.2.1 Reagents

All reagents used were of the analytical reagent grade.

Sodium nitrate solution (2 M). The reagent should be recrystallized so as to be free from iodine. Dissolve 340 g of sodium nitrate in distilled water to form 2 l of solution.

Sodium thiosulfate solution (1.5 mM). Dissolve 0.37 g of sodium thiosulfate pentahydrate and 0.1 g of sodium carbonate in freshly boiled, distilled water to make 1 l of solution.

Standard palladium solution (1 mg Pd^{+2}/ml). Dissolve 0.67 g of ammonium chloropalladite in about 150 ml of distilled water. Add 41.7 ml of concentrated hydrochloric acid and dilute to 250 ml.

Standard rubidium sulfate solution (1000 ppm Rb^{+}). Dissolve 0.78 g of rubidium sulfate in distilled water and dilute to 500 ml.

Standard potassium iodate solution (10 ug I/100 ul). Dissolve 0.1687 g of potassium iodate in distilled water and dilute to 1 l.

Bio-rad AG 1-x8 resin, 100 - 200 mesh in chloride form.

II.4.2.2 Preparation of the ion-exchange column

Transfer about 100 g of the AG 1-x8 resin to an
erlenmeyer flask. Add 150 ml of 1:4 (v/v) hydrochloric acid.
Swirl the mixture vigorously. Allow the resin to settle
and decant the supernatant liquid. Repeat this procedure
with 150 ml of distilled water, then 150 ml of 0.5 M sodium
hydroxide solution and then with 150 ml of distilled water
again. Repeat this cycle three times. Wash the resin once
with 150 ml 2 M sodium nitrate solution and store it in 2 M
sodium nitrate solution overnight. Pack the resin into glass
columns,with an internal diameter of 1 cm, to a length of
11 to 12 cm.

II.4.2.3 Flux monitor

Pipette 100 ul of the standard rubidium sulfate
solution onto a 0.45 u 47 mm diameter Nuclepore filter. Dry
the filter under an infrared lamp. Press the filter into a
pellet of size approximately 8 mm in diameter in a stainless
stell pellet press as described by Spencer et al. (1972).
One of these pellets will accompany each sample or standard
throughout the irradiation and counting procedure.

II.4.2.4 Standard

Pipette 100 ul of the standard potassium iodate solution onto a 0.45 u 47 mm diameter Nuclepore filter. Dry it under an infrared lamp and then press it into a pellet. Treat the standard exactly the same as a sample pellet.

II.4.2.5 Procedure

Pass 250 ml of a sea water sample through the ion-exchange column at a rate of 2 ml/minute using a peristaltic pump to control the flow rate. Wash the column with approximately 5 ml of distilled water. Discard the eluate. Elute the column with a 2 M sodium nitrate solution at the same rate. Discard the first 30 ml of the eluate. Collect the next 80 ml in a 125 ml erlenmeyer flask. Add 1 ml of the standard palladium solution and 2.5 ml of the 1.5 mM sodium thiosulfate solution. Swirl the mixture vigorously and let it sit for 5 minutes. Place the flask in a hot water bath at $80^{\circ}C$ for 30 minutes, then allow the mixture to cool. Collect the precipitate by filtering the mixture through a 0.45 u 47 mm diameter Nuclepore filter. Wash the filter with distilled water. Dry the filter in a dessicator for at least two hours. Press the filter into the form of a pellet to give it desirable physical characteristics for neutron irradiation and counting.

Irradiate the sample together with a rubidium flux monitor for 5 minutes in a thermal neutron flux of

about 4×10^{12} n cm^{-2} sec^{-1}. Let the pellets cool for 30 minutes. Count both pellets for 800 seconds on a Ge(Li) detector coupled with a pulse height analyzer.

A schematic presentation of the procedure is shown in figure II-4-1.

Fig. II-4-1   An analytical scheme for the determination of
iodide in sea water.

II.4.3 Results and discussion

Strongly basic anion exchange columns such as
AG 1-x8 have been shown to be a very effective means to
separate the halide elements, chloride, bromide and iodide,
from each other (Atteberry and Boyd, 1950; Degeiso et al.,
1954; Zalevskaya and Starobinets, 1969). Recently, this
technique has been used to concentrate iodide from melted
snow (Owens and Warburton, 1973). The affinities of the
various anions for the resin are in the order (Wheaton and
Bauman, 1951):

$$I^- > \text{phenolate} > HSO_4^- > ClO_3^- > NO_3^- > Br^-$$
$$> CN^- > HSO_3^- > NO_2^- > Cl^- > HCO_3^- > IO_3^-$$
$$> HCOO^- > Ac^- > OH^- > F^-.$$
Thus, when sea water is passed through the column with the
resin in the nitrate form, few anions other than iodide
will be retained.

I have followed the behavior of iodide during
column loading and elution by using both an iodide specific
electrode and the radioactive isotope I-125. Figure II-4-2
summarizes the behavior of the halides during the loading
and elution of the column. The electrode potential produced
by each halide at the concentration used in the experiment
differs. Bromide and chloride give a positive electrode
potential, whereas iodide at a concentration of 10^{-6} M or
Fig. II-4-2 The loading and elution behavior of halides as determined by an iodide electrode. The sample is a mixture of 25 ml of sea water and 5.3 ml of 1 mM KI. The flow rate is 0.5 ml/min.

above gives a negative electrode potential. By making use
of this property, one can readily identify the peaks in the
elution diagram. The iodide peak was later further confirmed
by radioisotopic studies. As reported in previous work
(Atteberry and Boyd, 1950; DeGeiso et al., 1954; Zalevskaya
and Starobinets, 1969), chloride and bromide are eluted
earlier than iodide. In fact, since the resin is in the
nitrate form, a large portion of the chloride and bromide
is not retained in the loading process. I have followed the
changes in total halide concentration during the loading of
250 ml of sea water onto the column, and the subsequent
elution, by potentiometric titration of fractions of the
eluate with silver nitrate using the iodide electrode to
detect the end-point. The results are summarized in figure
II-4-3. Again, they show that most of the chloride and
bromide escapes from the column prior to elution. The
residual amount is eluted after passing 20 ml of 2 M
sodium nitrate solution through the column. I have also
used I-125 to study the elution behavior of iodide. I-125
has a half life of 60 days and is a pure γ emitter, emitting
γ rays of 35 and 27 KeV. The half life is convenient for
tracer use, however, the low γ ray energies cause some
counting problems. Figure II-4-4 summarizes the results of
such a study. The major portion of the activity is confined
to the 10 ml fractions of 6 to 10. Quantitative recovery is
ensured by collecting fractions 4 to 11.
Fig. II-4-3 Changes in the concentration of total halide in the eluate during loading and elution of 250 ml of sea water.
Fig. II-4-4 The elution behavior of iodide from 250 ml
of sea water. Error bars show 1 S.D. calculated from
three 1 minute counts. Background is 332 ± 15 cpm.

I have also studied the ion exchange capacity of
the column for iodide. The results are shown in figure
II-4-5. After passing 1 l of sea water (four times the
sample size) through the column, the capacity has not yet
been reached and break through does not occur.

Palladous ion is a well known selective precipi-
tant for iodide (Winkler, 1918; Vogel, 1953) in the presence
of bromide and chloride. However, in producing elemental
palladium as the co-precipitant, care must be taken to
control the amount of reducing agent used. Excess thio-
sulfate will slowly reduce palladous iodide causing poor
and variable yield. Thus, an excess of palladous ions should
always be maintained and this is evident from the persis-
tence of the slight straw yellow color in the supernatant
liquid. The elemental palladium thus produced forms large
spongy clumps and is ideal for separation by filtration.

I have tested the yield of this procedure using
the radioactive isotope by comparing the activities in
sample pellets and in standards. The standard is prepared
by adding carrier iodide to the same amount of tracer and
then precipitating the iodide as palladous iodide with
excess palladous ions. Table II-4-1 shows the results of
the study. The three samples gave activities that, within
the counting and handling uncertainties, were indistin-
guishable from the standards.

Since palladium is used as the precipitant and

one of its stable isotope (Pd-108) has a large thermal
neutron cross section of 12 barns, dead time can present a
serious counting problem. Natural palladium contains 26.7%
of Pd-108. During neutron activation, Pd-108 is transformed
to Pd-109m or Pd-109. Pd-109m decays to Pd-109 with a half
life of 4.75 minutes by emitting γ-rays of 188.9 KeV (Adams
and Dams, 1969). Pd-109 in turn decays to Ag-109 with a
half life of 13.5 hours via β-decay and emits γ-rays of 88
KeV and 311.5 KeV in the process. I have minimized the
amount of palladium in the precipitate to the least amount
that can be easily handled. A relatively long cooling period
of 30 minutes is used. In addition, I have used pellets
containing a rubidium standard for each sample or iodide
standard as a dead time and neutron flux monitor.

Figure II-4-6 shows the γ-ray spectra of a blank
filter, a standard iodate-iodine sample and a Woods Hole
surface water sample. The major γ peaks are identified on
the spectra. The region around the iodine γ peak of 442.7
KeV is expanded in figure II-4-7. The blank is insignificant
and for all practical purposes can be ignored. In the sample,
the peak shows no shoulder, suggesting no spectral inter-
ferences within the resolution of the detector (2.5 KeV
FWHM for Co-60 1.33 MeV gammas). The ratio of the photo-
peaks at 442.7 KeV, 526.3 KeV and 743.5 KeV in the standard
and the sea water sample are 100:7.4:0.7 and 100:7.6:0.5
respectively. They agree with each other well. This further
-76-

suggests that there are no spectral interferences.

The reagent blank from the sodium nitrate solution has been determined five times. The results are shown in table II-4-2. The average reagent blank is 0.0046 uM with a standard deviation of 0.00145 uM.

The iodide concentrations in three sub-samples from one sample of surface water collected near Woods Hole were determined by this method. The results are shown in table II-4-3. The average concentration including the reagent blank is 0.123 uM and the standard deviation is 0.006 uM. This precision is better than or comparable to the precision of the presently available methods (for example, Tsunogai, 1971b).

Figure II-4-8 shows a profile of dissolved iodide from near surface waters in the Equatorial Atlantic. As in other parts of the oceans (Tsunogai, 1971b; Tsunogai and Henmi, 1971), the iodide concentration is highest at the surface and decreases rapidly with depth to an almost constant level of less than 0.01 uM. The absolute concentrations agree well with others reported in the literature (Tsunogai, 1971b; Tsunogai and Henmi, 1971). The smoothness of the profile is as expected and gives confidence in the reliability of the method. The data presented here have not been corrected for the reagent blank. The three data points from 400 m to 750 m have an average concentration of 0.007 uM which is indistinguishable from the blank of 0.005 uM. This shows

that there is no serious contamination problem during the
pre-irradiation manipulations.

II.5 The determination of iodine in marine suspended matter

II.5.1 Introduction

Previous studies have demonstrated the bio-active nature of iodine (Bowen, 1966; Sugawara and Terada, 1967; Tsunogai and Sase, 1969) and I have briefly discussed its biogeochemistry in section I.2.4. My own study also indicates a slight depletion of total dissolved iodine in surface waters of the oceans. This evidence suggests that a significant portion of iodine may be present in the particulate form like the other micro-nutrients such as nitrogen and phosphorus (Menzel and Ryther, 1964; Holm-Hansen et al., 1966; Hobson and Menzel, 1969; Holm-Hansen, 1972). Thus, a knowledge of the heretofore unknown distribution of particulate iodine may be essential for a better understanding of the geochemical cycling of iodine in the oceans.

Neutron activation analysis has frequently been used for the determination of the bulk chemical composition of suspended matter because it is non-destructive; it has high sensitivity for many elements; and it gives a multi-element analysis (Spencer et al., 1972). I have extended this method to the determination of iodine in marine suspended matter as iodine also has many favorable nuclear characteristics for neutron activation analysis as described in section II-4-1.

II.5.2 Experimental

II.5.2.1 Reagents

All reagents used were analytical reagent grade.

Standard potassium iodate solution (1 ug I/100 ul). Dissolve 0.1687 g of potassium iodate in distilled water and dilute to one liter. Further dilute this stock solution ten fold to form the standard solution.

Standard rubidium sulfate solution (100 ppm Rb^+). Dissolve 0.78 g of rubidium sulfate in distilled water and dilute to 500 ml. Dilute 25 ml of this stock solution to 250 ml.

II.5.2.2 Sampling

For each sample, about 10 l of sea water was filtered by air pressure through a pre-weighed Nuclepore filter (0.6 u pore size, 37 mm in diameter) immediately after sample collection. Incoming air was filtered and passed through non-metallic lines to avoid contamination. The filter was carefully rinsed with distilled water to remove sea salt and then stored in a clean plastic box.

II.5.2.3 Sample preparation for irradiation

The filter is equilibrated in a room at constant humidity. Then, it is pressed into a pellet by using a hand press in order to minimize geometry problems and to increase its resistance to irradiation damage and fragmentation during analysis. The resulting pellet is approximately 4 mm x 1 mm. Filter blanks are prepared identically.

II.5.2.4 Standard

Pipette 100 ul of the standard potassium iodate solution onto a 0.6 u 37 mm diameter Nuclepore filter. Dry it under an infrared lamp and then press it into a pellet. Treat the standard exactly the same as a sample pellet.

II.5.2.5 Flux monitor

Pipette 100 ul of the standard rubidium sulfate solution onto a 0.6 u 37 mm diameter Nuclepore filter. Dry the filter under an infrared lamp. Press the filter into a pellet. One of these pellets will accompany each sample or standard throughout the irradiation and counting procedure.

II.5.2.6 Irradiation and data processing

Irradiate the sample together with a rubidium flux monitor for 10 minutes in a thermal neutron flux of about 4×10^{12} n cm^{-2} sec^{-1}. Let the pellets cool for 5 minutes. Count both pellets simultaneously for 800 seconds on a Ge(Li) detector coupled with a pulse height analyzer. Analyses of the spectra are carried out via magnetic tape and the computer program GAMANL. Upon irradiation, the radioactive I-128 is formed from the monoisotopic stable natural I-127. It decays with a half life of 25 minutes and its gamma ray with an energy of 443 KeV is used for analyses.

II.5.3 Results and discussion

The spectra of a standard pellet and a sample are shown in figures II-5-1 and II-5-2. The major photopeaks are identified on the spectra. The ratios of the major photopeaks of I-128 at 443 KeV, 526 KeV and 744 KeV in the standard and the sample are 100:7:1 and 100:6:1 respectively. The peak at 443 KeV which is used for calculating the iodine concentrations shows no shoulder. This evidence suggests that there are no detectable spectral interferences within the resolution of the detector (2.5 KeV FWHM for Co-60 1.33 MeV gammas).

Since neutron activation analysis is such a sensitive method, blanks may constitute a serious problem. For analyses of suspended matter, the filter blank is the major source of uncertainty. Since no chemical treatment is involved, there is no reagent blank. In the method reported here, iodine impurities in the rubidium sulfate which acts as the flux monitor will be included as a blank too. The results of a series of tests are shown in table II-5-2. The blank for iodine is quite variable even within one batch of filters. The average blank for batch #2718 is about 3 ng with a standard deviation of 51%. Since about 10 l of sea water was processed for each sample, this blank is equivalent to about 0.3 ng-I/kg. In an earlier batch I observed no detectable blank from the filters. The magnitude of the blank is small relative to the sample concentrations in surface waters where concentrations above 10 ng/kg are frequently encount-

ered. However, in deep waters, the blank may be significant since the concentrations in the samples drop to about 1 ng/kg. Thus, proper cautions must be taken in interpreting small changes in concentration in the deep waters.

As a short cooling time is used, dead time is another possible problem. Residual sea salt on the filter can cause high dead time and consequently high counting uncertainties. Countings were made based on clock time. At first, dead time corrections were calculated from the mean value by the dead time meter. Later on, the pulser counts accumulated in channel 4000 which also served as an energy calibration was used. The pulser gives a signal fed into the analyzer at the rate of 60 cps. The difference between the observed and preset counts will be the sum of the dead time losses. A further improvement was made by using the area of the major peak of the rubidium sulfate flux monitor. Since the same amount of rubidium is used each time, the difference in counts between samples and standards can be used to correct for dead time losses as well as geometry differences and flux variations.

Since the half life of I-128 (25 minutes) is short, the irradiation technique used permits the irradiation of only one sample at a time. Standards were irradiated periodically each day and the iodine contents in the samples are calculated by comparing their activities to those of the standards. This procedure assumes a constant neutron flux and negligible geometry differences between

standards and samples. The consistency of the neutron flux
is checked by the Rb flux monitor which accompanies each
sample during irradiation and the results are shown in table
II-5-2. Over a six months period, the fluctuations were of
the order of $\pm 4\%$. Most of this variation can probably be
attributed to counting errors.

The reproducibility of the method has also been
checked by repeated analyses of one set of samples over a
one year time span. The results are presented in raw counts
in table II-5-3. The agreement is excellent with a corre-
lation coefficient of 0.97 and a slope of 1.00.

The contribution of residual sea salt to the mea-
sured concentrations of particulate iodine can be easily
estimated. The iodine to salinity ratio in sea water is
1.7×10^{-6} (w/w) (Brewer, 1975).Total suspended matter in
the oceans measured by the present collection method is
usually less than 0.03 mg/kg. Even if it is 100% sea salt,
the iodine content will only correspond to 0.05 ng/kg
which is much lower than the observed concentrations of
> 1 ng/kg. Since the residual sea salt should only be a
minor portion of the total suspended matter, the contri-
bution from sea salt should be minimal and the iodine
content of the material retained on the filter should
represent the true concentration of iodine in marine
suspended matter.

Figure II-5-3 shows a profile of particulate

iodine in the North Atlantic. A concentration maximum is observed in the surface waters. Below this maximum, the concentration decreases rapidly with depth to a background level in the deep water of about 1 to 2 ng/kg. A slight increase in concentration is also observed in the bottom water. Duplicate samples obtained at 2890 m give concentrations of 1.1 and 0.9 ng/kg. The average deviation of these two samples ($\pm$0.1 ng/kg) is small and is well within the variability of the blank. The profile is remarkably smooth and all the features can be explained with our present oceanographic knowledge as discussed in section III.4.

CHAPTER III. FIELD OBSERVATIONS

III.1 The distribution of iodine in the upper layers of
       the Equatorial Atlantic

III.1.1 Introduction

The marine biogeochemistry of iodine has been briefly discussed in section of I.2. In this section, I shall report the distribution of iodate and iodide in the Equatorial Atlantic. The Equatorial Atlantic is one of the more productive regions in the open oceans (Ryther, 1963; Koblentz-Mishke et al., 1970). The primary productivity is generally in the range of 150 to 500 mg C/m^2/day. In the upwelling areas along the African coast, values above 1000 mg C/m^2/day have been reported (Corcoran and Mahnken, 1969). This region is also characterized by large salinity and temperature gradients in the upper layers and is thus strongly stratified (Metcalf et al., 1962; Metcalf and Stalcup, 1967). Consequently, vertical mixing is much restricted and the characteristics resulting from biological-chemical interactions may be amplified and preserved. With closely spaced samples and closely spaced stations, I have attempted to study the finer structure in the distribution of iodine in the upper layers of the oceans.

III.1.2 Sampling and analytical method

Sea water samples were collected from the Equatorial Atlantic during cruise AII-83 of the R/V Atlantis II during the GARP (Global Atmospheric Research Program) Atlantic Tropical Experiment (gate). Five transects were made between 2°N and 2°S along the longitudes 33°W, 28°W, 22°W, 16°W and 10°W. The cruise track and the locations of the stations are shown in figure III-1-1. Samples from stations 2044-2046, 2048, 2050-2052, 2056-2060, 2062-2064, 2066-2071, 2073-2081 and 1083-2089 were analyzed for iodate. Samples from stations 2048, 2068, 2078 and 2086 were analyzed for iodide as well.

The samples were analyzed for iodate on board ship by a colorimetric method modified from the titration method (Wong and Brewer, 1974) as described in section II.3. The precision of the method is about ±3%. Samples for iodide analysis were frozen immediately after sampling and were shipped to Woods Hole for later analysis by neutron activation analysis as described in Wong and Brewer (1976) and in section II.4. The precision of the method is ±5% and the reagent blank is about 0.005 uM. The iodide data reported here have not been blank corrected. The complete listing of iodate and iodide measurements is compiled in Appendix A. Detailed hydrographic data may be obtained from Bruce and Katz (1976).
Fig. III-1-1 The cruise track and station locations of cruise AII-83. Solid circles denote stations with iodate data. Solid squares denote stations with both iodate and iodide data.

III.1.3 Results and discussion

Figure III-1-2 shows the distribution of iodate from the surface to 200 m depth in a zonal section along the equator. The most prominent feature is the low iodate concentration in the upper 30 to 40 m. The iodate concentration in this region is less than 0.30 uM. A concentration less than 0.10 uM was observed at station 2079 (1°S, 28°W). Below 140 m, the iodate concentration is uniformly higher at about 0.40 to 0.45 uM. At 33°W the concentration below 120 m approaches 0.50 uM, similar to deep water concentrations in the South Atlantic (Wong and Brewer, 1974). The lower iodate concentrations in the surface waters of the Equatorial Atlantic, relative to that in the Argentine Basin (0.39 to 0.40 uM, Wong and Brewer, 1974), probably reflect the higher productivity in this region.

Superimposed on these features, figure III-1-2 shows a lens of water with high iodate concentration extending across the Atlantic. It occurs at 80 m at 33°W and rises upwards to 55 m at 10°W. The concentration in the core of this lens ranges from 0.45 to 0.60 uM, generally higher than the concentrations at greater depths. Thus, this feature appears as a maximum between the iodate-poor surface water and the less iodate-rich deeper waters. This core of high iodate water correlates with the Equatorial Undercurrent as defined by its salinity (Metcalf et al., 1962; Metcalf and Stalcup, 1967; Neuman, 1969). Figure

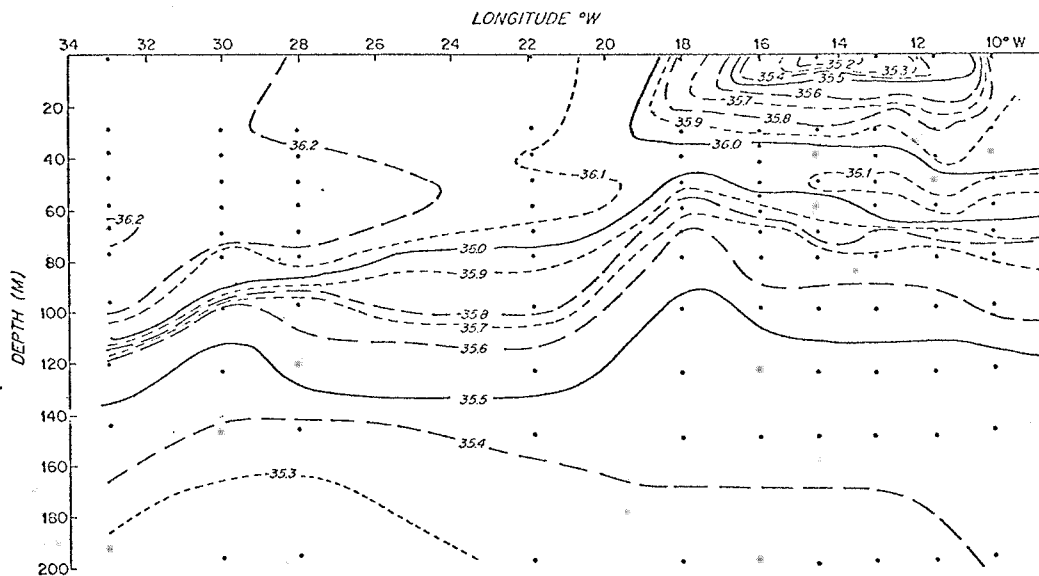

Fig. III-1-3 Salinity along the Equator of the Atlantic.

III-1-3 shows the corresponding distribution of salinity along the equator. A core of high salinity water can be readily identified. It is located at about 75 to 95 m at 33°W and again rises upwards to 50 m at 10°W. The striking similarity tends to suggest that high iodate concentration is a significant property of this advective core

Sharp maxima in iodate concentrations have not been previously reported. One reason may be inadequate sampling coverage. The lens of high iodate water reported here has a thickness of only ten to twenty meters and can easily be missed. During the GEOSECS (Geochemical Ocean Sections Studies), a station (station 109, 2° 00'S, 4° 33'W) was occupied in this region and a profile of iodate was obtained (Wong and Brewer, 1974). Figure III-1-4 shows that profile and a profile from a closeby station occupied during the present cruise (station AII-83-2052, 2° 00'S, 10° 00'W). In GEOSECS station 109, the iodate maximum was not observed because of poor sample coverage in that depth interval. Even in this study, with samples 10 m apart, one may still miss the depth with even higher iodate concentration.

The longitudinal sections of iodate along 33°W, 28°W, 22°W, 16°W and 10°W show the complexity of the circulation in the Equatorial Atlantic. Along 33°W (figure III-1-5), there is a high iodate core at 80 m centered around the equator. This feature coincides with a high

salinity (>36.2 ‰), high oxygen (>4 ml/l) and eastward flowing core, and represents the Equatorial Undercurrent. There is a second region of high iodate concentration at 100 m at 1° 32'N. This northern core is associated with lower salinity and oxygen content and is flowing westwards. Sections of salinity, oxygen and current speed along 33°W are shown in figures III-1-6 to III-1-8.

Along 28°W, the picture is more complex. Three cores with high iodate concentrations can now be identified (figure III-1-9). Between 0 and 40'N, a core at 60 m is associated with high oxygen, high salinity and an eastward flow. At 2°N, a core is associated with lower oxygen, lower salinity and a westward flow. These two cores correspond to those two described previously. However, the northern core has apparently intruded into the equatorial core and some mixing may have occurred. Moreover, there is evidence of a parcel of water with low iodate concentration at 18'S mixing with the equatorial core and it is associated with a corresponding oxygen maximum and a westward flow. The third core is around 1°S. Relative to the equatorial core, this southern core has lower salinity, lower oxygen content and a slower eastward flow. Sections of salinity, oxygen and current velocity along 28°W are shown in figures III-1-10 to III-1-12.

Along 22°W, one can identify the equatorial and the southern cores by their association with higher salinity,

higher oxygen, fast eastward flow and lower salinity, lower oxygen and slower eastward flow, respectively. The Equatorial Undercurrent is centered at 70 m and 22'S. Apparently, there is mixing between the Undercurrent and the southern core. The data are summarized in figures III-1-13 to III-1-16.

Along 16°W (figures III-1-17 to III-1-20), these three cores of water are discretely separated from one another. Their relative magnitudes in salinity, oxygen and direction of flow are the same as previously described. In between the cores are regions of lower iodate concentration which are associated with oxygen maxima. Here the Equatorial Undercurrent is at 0° and at a depth of 50 m.

At 10°W (figures III-1-21 to III-1-24), these three cores of water with high iodate concentrations can again be identified although their properties have become much more uniform than before. Among these three cores, the equatorial core, which supposedly represents the Undercurrent, still has the highest salinity and oxygen content, and an eastward flow and it is centered at 40'N and at 70 m depth. However, it does not coincide with the region with the highest salinity and highest eastward flow in this section anymore. Instead, this regions corresponds to a region of higher oxygen content and lower iodate at about 20'S and 50 m depth where the iodate maximum is absent. The northern core still maintains its characteristically low salinity and oxygen content. However, instead of moving

westward, it is flowing towards the east at a slow speed of 0 to 10 cm/sec. There is a fourth region of high iodate at $2^{\circ}N$ and 120 m depth. There is a suggestion of such a core at $28^{\circ}W$ and $2^{\circ}N$. However, with the limited data, its relationship to the other cores is unclear at this point. The properties of the northern, equatorial and southern cores of water with high iodate concentrations at various longitudes are summarized in table III-1-1.

The sources of these high iodate cores are unclear at this point. The iodate maxima observed in this region are situated in the pycnocline as shown in typical profiles in figures III-1-25 to III-1-28. If iodate is being depleted in the surface water by organisms then, upon death, a major portion of these organisms may sink and re-mineralize at this pycnocline since the high density stratification tends to decrease the sinking speed of the particles. This is also evident from the corresponding phosphate profiles (figures III-1-25 to III-1-28) where a sharp increase in phosphate is observed in the same depth interval. However, the phosphate profile does not show a maximum. This may be due to the differences in phosphate and iodate regeneration and utilization rates. If the major portion of the re-mineralization process occurs within a depth of few tens of meters, iodate concentrations higher than those observed in deep water will be found.

The high iodate concentration observed in this

study may be caused either by advection or in-situ production. Based on the present data, in-situ production seems less likely. First, the profiles of iodide (figures III-1-25 to III-1-28) do not show any extraordinary features at the iodate maximum. If iodide is the intermediate in the formation of iodate by re-mineralization, one would expect to see a corresponding maximum close to that depth. Secondly, there is no systematic east to west variation in the iodate concentrations although it is known that productivity increases towards the African coast (Corcoran and Mahnken, 1969); however, alternatively, this may be explained by the inability to sample at exactly the depth with the highest iodate concentration at every station.

Advection can qualitatively describe these observations. Productivity is known to be high along the northwestern and western coastal regions of African due to upwelling (Ryther, 1963; Corcoran and Mahnken, 1969). Waters with high iodate concentration may be formed here. These waters are swept towards the equator by the North and South Equatorial Currents. Metcalf and Stalcup (1967) (produced in graphic form by Philander, 1973) showed that the Undercurrent is sandwiched between two branches of the South Equatorial Current. The edges of these Currents may form the northern and southern cores of high iodate waters. High productivity has also been observed along the north eastern Brazilian coast around the mouth of the Amazon (Zeitschel,

1969) and thus high iodate water may also be found there. The Equatorial Undercurrent is an extension of the Northern Brazilian Current (Metcalf and Stalcup, 1967). Some of the water from the South Equatorial Current may be entrained too. Consequently, it can also have high iodate concentrations. There are regions with no iodate maxima in between the cores. These may be waters untouched by these currents and subsequently show the normal distribution of iodate in the water column. Part of the high variability of iodate concentrations in the Undercurrent may also be contributed to the meandering of the Undercurrent. The core of the Undercurrent oscillates in both the vertical and horizontal planes (Rinkel, 1969; reviewed in Philander, 1973) with a periodicity of weeks (Duing et al., 1975). Consequently, in a longitudinal section, one may be sampling the Under-current at different phases repeatedly. However, present evidence suggests that the meandering of the Undercurrent is confined between $1^{o}N$ and $1^{o}S$ (Duing et al., 1975). Thus, the cores observed at $2^{o}N$ and $2^{o}S$ cannot be part of this system.

These observations raise some questions concern-ing the marine geochemistry of iodine. First, these surface water masses are relatively young. If iodate is generated by the re-mineralization of organisms, the rate of oxidation of iodide will have to be high if iodine occurs in organisms as iodide (Shaw, 1962). I have not been able to demonstrate

the oxidation of iodide chemically in sea water in the laboratory at any measurable rate (see chapter IV for details). A biologically catalyzed oxidation of iodide is one of the possibilities. Sugawara and Terada (1967) have suggested such a mechanism based on their laboratory experiments with algae. Furthermore, the exact source of the water masses with high iodate cannot be established until a better understanding of the circulation in the Equatorial Atlantic can be obtained and a study of the distribution of iodine in the highly productive areas is made.

III.2　The marine chemistry of iodine in anoxic basins

III.2.1　Introduction

Anoxic conditions in natural waters are generated when vertical mixing and advective transport, usually in restricted basins, are insufficient to replenish the oxygen consumed by organisms. All the anoxic basins have strong pycnoclines which hamper vertical mixing and shallow sills which effectively minimize the renewal of the anoxic deep waters by advection. The strong pycnocline may be maintained either by a sharp temperature gradient or a sharp salinity gradient. As a result of inhibited mixing, the residence time of the anoxic water is long and, consequently, the changes caused by biological-chemical interactions are large. Thus, although anoxic basins, by volume, constitute an insignificant portion of the world oceans, they have attracted much attention from chemical and biological oceanographers (Richards, 1965; Spencer and Brewer, 1971; Tuttle and Jannasch, 1973; Brewer and Murray, 1973; Jannasch et al., 1974) and they open up new routes to an understanding of basic biological-chemical interactions in the sea.

Biochemical processes often involve electron transfers (Lehninger, 1965). The terminal electron acceptor under oxic conditions is oxygen and the end product is water. As oxygen is depleted, some organisms may use nitrate, sulfate and eventually carbon dioxide in succession as alternate terminal electron acceptors (Richards, 1965). Consequently,

-123-

reduced forms of nitrogen, sulfur and carbon such as nitrite, molecular nitrogen, ammonia, thiosulfate, sulfide and methane may be formed. Since the pE of the open oceans is presumably poised by the oxygen-water couple at 12.5 (Sillen, 1961) according to the equation

$$O_2(g) + 4H^+ + 4e^- = 2H_2O \qquad \log K = 83.1 \qquad (III-2-1)$$

the removal of oxygen causes a drastic drop in pE. Thorstenson (1970) and Brewer and Murray (1973) estimated that in anoxic basins, the sulfate-sulfide couple has the largest redox buffer capacity. Thus, the pE will be poised at -4 by this couple in the absence of oxygen according to the equation

$$SO_4^= + 9H^+ + 8e^- = HS^- + 4H_2O \quad \log K = 33.0 \quad (III-2-2)$$
This large, biologically induced change in redox potential brings about accompanying changes in the speciation and distribution of multi-oxidation-state elements such as iron and manganese (Spencer and Brewer, 1971). The presence of sulfide also causes a re-partition of many trace elements (for example, zinc and copper) between the dissolved and particulate phases as most sulfides are highly insoluble (Spencer et al., 1972).

Anoxic basins are also well known nutrient traps (Fanning and Pilson, 1972; Brewer and Murray, 1973). Nutrients are transported into the deep anoxic layer by biogenic particles and re-mineralization may occur within the water column or in the sediments. Physical removal of the re-gen-

erated dissolved nutrients is prevented by the weak mixing processes. However, some microbes live close to the oxic-anoxic interface. They derive their energy by chemosynthesis (Sorokin, 1964; Tuttle, private communication). Consequently, they may remove some of the nutrients at such depths (Brewer and Murray, 1973).

In this section, I shall report the distribution of dissolved iodine in two anoxic basins, the Black Sea and the Cariaco Trench, and in the oxic Venezuela Basin which serves as a comparison for normal oceanic conditions. The distribution of iodine in anoxic basins is heretofore unknown. However, since iodine is bioactive and since the iodate-iodide transition occurs at a pE between the oxygen-water and the sulfate-sulfide couples, iodine may exhibit a combination of the behaviors described above. Moreover, if iodide is indeed diffusing into the bottom waters from the sediments as suggested by Tsunogai (1971b), this process should be most conspicuous in the anoxic basins where the residence time of the deep water is long and the sediments are rich in organic material and strongly reducing.

The Black Sea

The Black Sea is the world's largest anoxic basin.
It is connected only to the Mediterranean Sea via the Bos-
porus, the Sea of Marmara and the Dardanelles. The maximum
sill depth in the Bosporus is 34 m (Gunnerson and Ozturgut,
1974). A number of rivers including the Danube and the
Dnepr, which have average flows of 6200 and 1700 m^3/sec
(Leopold, 1960), flow into the Black Sea and create a light,
less saline surface layer on a subsurface outflow. The
deep inflow of saline Mediterranean water is sporadic (Bog-
danova, 1961) with estimates of the annual flow ranging
from 328 km^3/yr (Merz and Moller, 1928) to negligible (
Ulloyot and Ilgaz, 1946). The average flow is often quoted
as about 190 km^3/yr (Spencer and Brewer, 1971; Brewer and
Murray, 1973; Ostlund, 1974). Thus, whereas the surface
salinity of the Black Sea may vary from 17.2 ‰ to 18.3 ‰
depending on the proximity to terrestrial runoffs, in the
deep water the salinity is relatively constant at 22.4 ‰
(Brewer, 1971). The potential temperature is also quite
variable at the surface and in winter the surface waters
are cooler than the deep waters, though vertical mixing is
inhibited by the strong salinity gradient. The strong verti-
cal stratification is thus maintained solely by the salin-
ity difference between the surface and the deep waters. The
absolute level of the salinity of the Black Sea is much
lower than that of the open oceans, consequently, it should

not be classified as a typical marine basin. Profiles of
the salinity and potential temperature of the Black Sea are
shown in figure III-2-1.

The maximum depth of the Black Sea is about 2200 m
(Ross et al., 1974) and the oxygen-sulfide boundary occurs
at about 150 to 250 m (Brewer, 1971). The anoxic zone can
be further subdivided according to the radiocarbon ages.
The formal C-14 age of the water between 300 and 1700 m is
about 1000 years, whereas, below 1700 m, the age may well
exceed 2000 years old and the water is probably renewed
only by eddy diffusion (Ostlund, 1974). The deep inflow of
Mediterranean water may occur at various depths, although,
based on the formal radiocarbon ages and the temperature-
salinity relationship, it has to occur above 1700 m (Ost-
lund, 1974; Brewer and Murray, 1973). The vertical advective
velocity and eddy diffusion coefficient in the mixing zone
between about 100 m and 300 m have been estimated to be
0.5 m/yr and 0.014 cm^2/sec respectively (Spencer and Brewer,
1971).

The Cariaco Trench

The Cariaco Trench, the second largest known
anoxic basin of the world, is a depression situated on the
northern Venezuelan continental margin at roughly $10^\circ 30'$N
and $65^\circ 31'$W. It is approximately 100 miles long and 40 miles
wide and has a maximum depth of about 1400 m. It is separ-
Fig. III-2-1 Salinity and θ profiles in the Black Sea at
station CHAIN-120-1355 (42°50'N, 33°00'E). • repre-
sents salinity. + represents θ.

ated from the Caribbean Sea by a sill at a depth of about 150 m. Above this sill depth, the waters of the Cariaco Trench mix freely with the surface waters of the open sea. The Trench is subdivided into two deep basins (eastern and western) with a saddle at about 900 m below sea level in between (Maloney, 1966). The salinity decreases from about 36.8 ‰ at the surface to 36.185 ‰ in the deep water and the potential temperature decreases from about $26^{\circ}C$ to $16.75^{\circ}C$. Thus, unlike the Black Sea, the Cariaco Trench is a true marine basin and its vertical stratification is maintained solely by the strong thermal gradient instead of by a salinity gradient. Profiles of salinity and potential temperature are shown in figure III-2-2.

The deep water of the Cariaco Trench is renewed by slow flushing. Estimates of the residence time of the anoxic water vary widely. Fanning and Pilson (1972) subdivided the anoxic zone into two layers and suggested that advective renewal only occurs from 300 m to 1000 m. Below 1000 m, eddy diffusion is the only means for mixing. They suggested the residence time of the water in the upper layer to be 800 years on the basis of a silicate balance. Richards and Vaccaro (1956) and Richards (1975) reported a residence time of 70 years by using phosphate as the tracer. Deuser (1973) estimated a range of 22 years to 570 years with a geometric mean of 112 years based upon estimates of the rate of oxidation of organic matter; Presley (1974) sug-

-129-
Fig. III-2-2 Profiles of salinity and θ in the Cariaco Trench. + Western Basin;
• Eastern Basin.

gested a range of 50 to 100 years from the sulfur accumulation rate in the sediments. Radiocarbon dating gives a residence time of about 100 years (Ostlund, private communication).

The shorter residence time of the anoxic waters in the Cariaco Trench, relative to the Black Sea, suggests that it may be a less stable system. The potential density (σ_θ) of the deep water is about 26.50. At the oxygen-sulfide boundary at about 300 m, σ_θ is 26.46 and at the sill depth at 150 m, σ_θ is 26.35. Thus, the overall density gradient of the Cariaco Trench is only 0.15 in σ_θ whereas in the Black Sea it is about 1.0 in σ_θ.

III.2.2 Sampling and analytical methods

Samples were obtained from one station in each of the two basins of the Cariaco Trench, one station in the Venezuela Basin and one station in the Black Sea during cruises AII-79 and CHAIN-120. The locations of the stations are shown in figure III-2-3. Samples were either analyzed on board for iodate or frozen at $-5^{\circ}C$ in polyethylene bottles immediately after collection and transferred back to Woods Hole for analysis. This method for the storage of samples has been shown to be reliable (Wong, 1973). All samples were analyzed for iodate by photometric micro-titration with a precision of better than 1% (Wong and Brewer, 1974). Iodide profiles were obtained from the eastern basin of the Cariaco Trench, the Venezuela Basin and the Black Sea. The samples were analyzed by neutron activation analysis as described in section II.4 with a precision of $\pm 5\%$ and a reagent blank of about 0.005 uM. The data from these cruises are compiled in Appendices B and C.

III.2.3 Results and discussion

Iodine in oxic and anoxic basins

The distributions of iodate and iodide in the oxic Venezuela Basin (figure III-2-4) are similar to previous observations from other parts of the open oceans (Tsunogai, 1971b; Tsunogai and Henmi, 1971; Wong and Brewer, 1974). The iodate concentration is lowest at the surface (0.3 uM) and it increases with depth to about 0.5 uM. A mid-depth maximum is also observed. It corresponds with a phosphate maximum and a oxygen minimum and may be the result of the re-mineralization of organisms (Wong and Brewer, 1974). In constrast, the iodide concentration is highest in the surface waters and decreases rapidly with depth to below the detection limit (0.005 uM) below the euphotic zone. A thin sub-surface iodide maximum is observed at 100 m with a concentration of about 0.38 uM, corresponding with a sub-surface salinity maximum. A sub-surface iodide maximum of such magnitude has not been documented before and the present data are insufficient for a detailed discussion of its origin.

In the anoxic basins, as a result of the drastic drop in pE, iodine exhibits markedly different behavior below the oxic zone. The profiles are shown in figures III-2-5 to III-2-7. The oxygen-sulfide boundaries occur at 150 m in the Black Sea and 265 m in the Cariaco Trench. In the

oxic zone, an iodate minimum (0.88 uM in the Black Sea;
0.340 and 0.369 uM in the eastern and western basins of
the Cariaco Trench) is again present at the surface, and
the concentration increases with depth to 0.146 uM in the
Black Sea, and 0.431 uM and 0.469 uM in the two basins of
the Cariaco Trench. However, at about 100 m in the Black
Sea and 180 m in the Cariaco Trench, the concentration
starts to drop sharply and reaches zero at approximately
the oxygen-sulfide boundary. In constrast, the concentra-
tions of iodide are high at the surface (0.047 uM in the
Black Sea; 0.086 uM in the Cariaco Trench) and they de-
crease to minimum concentrations at 75 m (0.011 uM) and
160 m (0.019 uM) in the Black Sea and the Cariaco Trench
respectively. Below these depths, the concentrations in-
crease rapidly. Below the oxygen-sulfide boundary, the
iodide concentration remains approximately constant at
about 0.44 uM in the Cariaco Trench. In the Black Sea,
there is a clear general increasing trend towards the bot-
tom from 0.22 uM to 0.43 uM.

The interconversion of iodide and iodate is
represented by the equation

$$IO_3^- + 6H^+ + 6e^- = I^- + 3H_2O \quad \log K = 110.1 \quad (III-2-3)$$
The change in the speciation of iodine in the anoxic zone
can be predicted from the thermodynamic properties of this
reaction. A concentration diagram of the iodine system at

a pH of 8.1 and a total iodine concentration of 0.5 uM is shown in figure III-2-8. In the oxic layer where the pE is 12.5 (Sillen, 1961) iodate will be the dominant form. By constrast, the pE in the anoxic zone is -4 (Spencer and Brewer, 1971) and iodide will be the predominating species.

The conversion of iodate to iodide occurs between 100 m and 150 m in the Black Sea and 160 m and 265 m in the Cariaco Trench. Between these depths, oxygen and sulfide co-exist at low concentrations and their combined redox buffer capacity at most depths is between +1 meq/kg and -1 meq/kg as shown in table III-2-1. In comparison with the redox buffer capacities in truly oxic or anoxic waters, this is remarkably low (<20%) and suggests a chemical instability in this zone where the redox potential may fluctuate with the degree of mixing between oxic and anoxic waters. The pE of a body of natural water is calculated from the couple having the highest redox buffer capacity to poise the system. In this mixing zone, the picture seems unclear. If iodide and iodate are at chemical equilibrium so that they may be used as indicators, the pE will be between 10.0 and 10.7 and suggest that neither the oxygen-water couple nor the sulfate-sulfide couple is poising the pE.

The profiles of specific total iodine, which is defined as the ratio of total iodine to salinity, of the three basins are shown in figure III-2-9. In all cases, there is a slight depletion in the surface waters with

Fig. III-2-9 Profiles of specific total iodine in the Venezuela Basin, the Cariaco Trench and the Black Sea.

value of 7.3 nmoles/g and 11.6 nmoles/g in the Black Sea and the Cariaco Trench respectively. This depletion may be caused by the uptake of iodine by organisms.

In the anoxic zone of the Cariaco Trench, within the noise of the data, specific total iodine may be considered constant at 12.3 nmoles/g. However, in the Black Sea there is an increasing trend with depth from 10.0 to 19.4 nmoles/g. This may be caused either by the advection of water of high iodine content into the Black Sea, or a diffusion of iodine into the bottom water from the underlying sediments. The specific total iodine in the deep Venezuela Basin is only about 14 nmoles/g and there is no a priori reason to suppose that the inflowing Mediterranean water should be much different from other oceans. Thus, an advective source for this increased iodine seems unlikely although it cannot yet be completely ruled out. There is however ample evidence suggesting a flux of iodide out of the sediments. In addition to Tsunogai's observation (1971) of excess iodide in the deep Pacific, Price and co-workers (Price et al., 1970; Price and Calvert, 1973) have reported an enrichment of iodine in surface sediments. The concentrations correlated linearly with the organic carbon content and decreased exponentially with depth. Iodine is also enriched in interstitial waters and concentrations up to 150 uM have been reported (Bojanowski and Paslawska, 1970). Pavlova and Shiskina (1973) further showed that the concen-

tration increases with depth. These observations suggest a possible post-depositional diagenetic remobilization of iodine from organic-rich sediments in reducing environments. Thus, diffusion of iodine into the bottom water appears to be a plausible explanation for the high specific total iodine in the Black Sea. The difference between the Cariaco Trench and the Black Sea in this respect may be due to the longer residence time of the water in the latter. Other factors, such as the iodine concentration gradient in the interstitial waters and the composition of the sediments will certainly affect the distribution too, however, there are no available data at the present time for a more detailed assessment.

The distributions of iodide, iodate and total iodine in the mixing zones of the Black Sea and the Cariaco Trench are shown in figures III-2-10 and III-2-11. These data are compared with the profiles expected from simple mixing between two boundary conditions by vertical advection and diffusion as described in Spencer and Brewer (1971). This steady state one dimensional model is formulated as

$$\frac{dc}{dt} = K \frac{d^2c}{dz^2} - w \frac{dc}{dz} = 0 \qquad \text{(III-2-4)}$$

where K is the vertical eddy diffusivity and w is the vertical advective velocity. The solution of this equation is
Fig. III-2-10 The distribution of iodide, iodate and total iodine in the mixing zone of the Black Sea.
Fig. III-2-11 The distribution of iodide, iodate and total iodine in the mixing zone of the Cariaco Trench.

$$(C - C_o) = (C_m - C_o) \frac{(e^{z/z^*} - 1)}{(e^{z_m/z^*} - 1)} \qquad \text{(III-2-5)}$$

where C_o is the concentration at the lower boundary z_o, C_m is the concentration at the upper boundary z_m, and z^* is the ratio of K/w (Craig, 1969). The model is applicable only over linear regions of the θ-S diagram where horizontal velocities and concentration gradients may be neglected. The assumption of a true steady state in the Cariaco Trench is questionable. It may however closely approach a steady state in short time intervals. z^* can be estimated from the profiles of salinity or potential temperature. The values used here are 0.23 km and 0.09 km for the Cariaco Trench and the Black Sea respectively. Iodate appears to be consumed over the entire depth interval of the mixing zone in both basins, reflecting the chemical reduction of iodate to iodide. Iodide is produced in the same intervals, which may be the result of the combined effects of the reduction of iodate and the re-mineralization of particles. In the Black Sea, there is some consumption below 200 m which may possibly be attributed to biological activity (Brewer and Murray, 1973). For total iodine, there is production above the interface and slight consumption below it. Spencer and co-workers (Spencer and Brewer, 1971; Spencer et al., 1972) have observed similar features in dissolved manganese and iron. They suggested the localized dissolution of the mineral oxides in a strong pycnocline

as an explanation. A similar mechanism may also be operating in the iodine system, whereby iodine-rich biogenic particles may preferentially re-mineralize in the pycnocline. In the lower mixed layer, the consumption may again be explained by chemosynthesis. The interconversion of iodine between iodate and iodide will not affect the distribution of total iodine. A more rigorous model is inappropriate at the present time because it calls for a priori knowledge of the functionality of the production and consumption term with depth as in Spencer and Brewer (1971). Since the distribution of iodine in the mixed layer is controlled by a host of processes as described earlier, quantification of such a term will be difficult. Moreover, the growing complexity of this term may prohibit an analytical solution of the advection-diffusion equation with the limited known boundary conditions.

In general, the profiles of iodate, iodide and total iodine in the mixed layer of the Cariaco Trench show features similar to the Black Sea, however, they are usually more subdued. This may reflect the fact that the Black Sea is a more stable system with longer residence time and a stronger pycnocline.

The redox potential of the oceans

The common oxidation states of iodine are: (1) -1 as hydroiodic acid and iodides; (2) 0 as elemental iodine; (3) +1 as hypoiodous acid and hypoiodites; and (4) +5 as iodic acid and iodates. The distribution of iodine among these species as a function of pE at a pH of 8.1 and a total iodine concentration of 0.5 uM is shown in figure III-2-8. A more detailed discussion on the thermodynamics of the iodine system is given in section IV.2.

In oxic waters, if the pE is poised by the O_2/H_2O couple, its value will be 12.5 (Sillen, 1961) and iodate will be the only measurable species. Brewer and Murray (1973) suggested that the pE is poised by the $SO_4^=/HS^-$ couple in anoxic waters so that the pE will be -4. At such a pE, iodide will be the only detectable iodine species. The present analytical capability has a detection limit for iodate or iodide of about 0.005 uM. My observations from the anoxic and oxic basins confirm these predictions except in the surface waters where the disequilibrium is attributed to biological perturbation (Tsunogai and Sase, 1969).

Breck (1974) has recently suggested that the pE of the oceans is poised by the O_2/H_2O_2 couple. He calculated the lower limit of the pE of the ocean to be 8.5 and proceeded to use this value for the prediction of chemical speciations in the oceans. However, this pE value is inconsistent with the observed distribution of the iodine

species. Figure III-2-8 shows that at a pE of 8.5, the con-
centrations of iodate and iodide will be 10^{-17} M and $10^{-6.3}$
M respectively. This implies that iodate should not be
detectable with the presently available analytical methods
and this is contrary to the fact that iodate is ubiquitous
in the open oceans and it is the predominant species. In
oxic deep waters where biological perturbations of chemical
equilibria may be minimal, the iodide concentration is
indistinguishable from the blank of 0.005 uM and iodate
constitutes all the measurable iodine (figure III-2-4).
This observation is more consistent with a pE of 12.5 as
calculated from the O_2/H_2O couple. If one takes the upper
limit of the iodide concentration in the deep waters as
0.005 uM, one can calculate the lower limit of the pE of
the oceans to be 10.7.

Liss et al. (1973) suggested that the iodate-
iodide couple may act as a sensor for the effective pE
level in the oceans. The interconversion between iodide
and iodate involves the transfer of six electrons. Conse-
quently, the concentration ratio of these two species will
be extremely sensitive to pE changes. Given the detection
limits of iodate and iodide to be both at about 0.005 uM
($10^{-8.3}$ M), one can calculate the usable range of this
sensor to be 10.0 to 10.7 as shown in figure III-2-8. Thus,
it is apparent that at least at the present time, the
iodate-iodide couple is not a desirable tool for measuring

pE in the oceans which may have a range of 12.5 to -4.

III.3 The distribution of iodine in a coastal basin, the

    Gulf of Maine

III.3.1 Introduction

       If the distribution of the dissolved iodine
species in the surface waters of the oceans is controlled
by biological activity (Tsunogai and Sase, 1969; Tsunogai
and Henmi, 1971; Tsunogai, 1971b; Wong and Brewer, 1974),
seasonal effects may indirectly induce changes in this
distribution. These seasonal effects are probably more
prominent in the coastal waters of the temperate zone where
seasonal changes in productivity are more pronounced. In
this section, I shall present data on the distribution of
iodine in the winter of 1974-1975 in a coastal basin, the
Gulf of Maine.

III.3.2 Sampling and analytical methods

I have occupied three stations in the Gulf of Maine, two in the Wilkinson Basin (AII-86-2122 and AII-86-2138) and one in the Murray Basin (AII-86-2151) during cruise AII-86 within the period of January 4 - 11, 1975. The locations of the stations are shown in figure III-3-1. Samples were frozen immediately after collection and were shipped back to Woods Hole for analysis. Samples from station 2122 were analyzed for both iodate and iodide while samples from stations 2138 and 2151 were analyzed for iodate only. Iodate was analyzed by photometric micro-titration with a precision of better than ±1% (Wong and Brewer, 1974) while iodide was analyzed by instrumental neutron activation analysis with a precision of ±5% (Wong and Brewer, 1976). The reagent blank of the activation analysis is about 0.005 uM and the data reported here have not been blank corrected. The complete data set is shown in Appendix D.
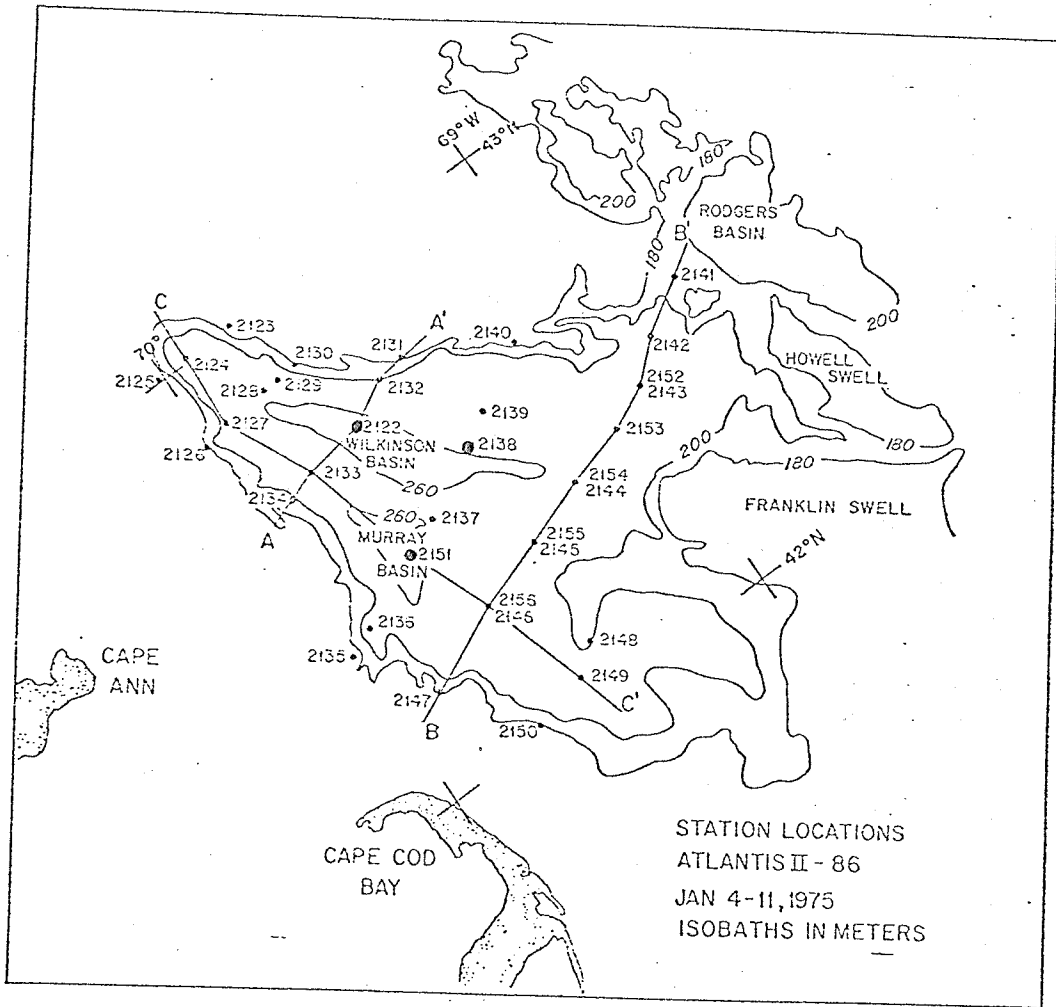

Fig. III-3-1 The cruise track and station locations of
        cruise AII-86.

III.3.3 The Gulf of Maine and the Murray-Wilkinson Basin

The Gulf of Maine is a semi-enclosed basin bounded by Maine to the north, Massachusetts to the west, Georges Bank to the south, and Browns Bank and Nova Scotia to the east. The Murray-Wilkinson Basin is one of the depressions in the Gulf and it is situated between $42°N$ and $43°N$, and $69°W$ and $70°W$. It is elongated (NNW-SSE) and is about 80 miles long. It has a maximum depth of about 285 meters and is surrounded by a sill at about 150 meters depth. It is connected to the Rogers Basin to the east, the Franklin Basin to the southeast and the Platts Basin to the north by passages at depths of about 185 m, 185 m and 170 m respectively. The deep part of the Murray-Wilkinson Basin is subdivided by the Wilkinson Divide at about 250 m into the Wilkinson Basin and the Murray Basin.

The surface layers of the Gulf mix freely with coastal waters and their properties are probably significantly influenced by local events. Among all the basins in the Gulf, the Murray-Wilkinson Basin has the most stable deep water and it is renewed by slope and coastal waters of Labrador origin (Colton, 1968). A more detailed description of the hydrography of the Basin has been prepared by Spencer and Brewer (1975).

III.3.4 Results and discussion

Although the winter of 1974 to 1975 was not a particularly severe one, the effect of overturn in the water column is clearly evident. There is only a weak thermocline between 140 m and 200 m where the potential temperature drops about $1^\circ C$ and the σ_θ of the bottom water is only about 0.8 σ_θ units higher than that of the surface water. The sill is also situated at about 150 m. Above 140 m, the water is well mixed and none of the properties (salinity, potential temperature, σ_θ , oxygen, silicate and phosphate) measured show any significant gradient (figure III-3-3 to III-3-8) although sometimes there are differences in the absolute values between one station and another. The stations were occupied in the order of 2122, 2138 and 2151. Between stations 2122 and 2138, there was a severe winter storm with snow and freezing rain and its effects on the properties of the surface waters are difficult to assess quantitatively. However, most of the properties (salinity, θ , σ_θ , and oxygen) in the top 70 m of station 2138 do exhibit noticeable deviations from the other stations.

Productivity at this time of the year is probably low. Although no C-14 uptake measurements were made, the nutrient values in the surface waters seem to be consistent with this interpretation. Phosphate and silicate in the surface waters are about 0.9 uM and 9 uM respectively. Such values are exceedingly high. In typical open ocean surface

waters with a moderate productivity, phosphate and silicate are usually only about 0.1 uM in both cases (GEOSECS preliminary reports). The high nutrient levels observed here imply low surface productivity.

The profiles of iodate and iodide are shown in figures III-3-2, III-3-6 and III-3-8 for stations 2122, 2138 and 2151 respectively. The iodate concentrations in the top 100 m of stations 2122 and 2151 are rather uniform with minor variations between 0.40 and 0.44 uM. This uniformity is common to all properties and reflects vigorous winter mixing. Station 2138 seems to be anomalous and considerably larger variations in the concentrations of iodate in the surface layers can be observed. A much lower concentration is found in the top 50 m with a minimum concentration of 0.35 uM at 25 m. Between 50 m and 100 m, the concentration is similar to the other stations. Salinity, θ and phosphate also exhibit deviations from uniformity in the top 50 m of the same station. Actually, the salinity and θ of the surface waters of this station are the lowest and give rise to a distinct surface minimum. This anomaly may be caused by dilution of the surface waters by rain and snow during the storm.

Below 100 m, considerable variation can be observed in all properties within each station and from station to station. A sharp break can be observed in the profiles of all properties between 120 m and 150 m where

the sill situates. This break in the iodate profiles seems to occur at slightly shallower depths than the other properties. Iodate increases smoothly with depth from about 150 to 200 m at stations 2122 and 2138. At station 2151, the profile exhibits complex fine structures between 130 and 200 m. Similar features are found in profiles of phosphate, silicate, oxygen, salinity and θ, and may represent mixing between different water types.

Below 200 m, all the other properties show only subtle variations. However, a distinct iodate minimum is observed at all three stations at about 225 m. In the profiles of the other properties, there is no or occasionally a weak suggestion of an inflexion at this depth. The present data are insufficient for making a more detailed assessment of the cause of this minimum.

The most striking, although not unexpected, observation is the absence of the marked depletion of iodate (up to 50%) in the surface waters which has frequently been reported (Tsunogai and Henmi, 1971; Tsunogai, 1971b; Wong and Brewer, 1974). In this winter, in the Gulf of Maine, any depletion of iodate (if one is present at all) is hidden within the variations, real or experimental, of the profiles. This behavior of iodate seems to support the proposal that iodate is removed by its reduction to iodide through biological agents (Tsunogai and Sase, 1969). Consequently, during winters, when productivity is low, the depletion of

iodate will be least pronounced.

The profile of iodide from station 2122 (figure III-1-2) is consistent with this interpretation of the distribution of iodate. Iodide is also rather uniform in the top 150 m as a result of vigorous vertical mixing. However, its absolute concentration of 0.04 uM is only about 40% of the nearby Woods Hole surface water (0.123 uM, Wong and Brewer, 1975) and <50% of the moderately productive Equatorial Atlantic waters (0.10 uM, Wong, 1976; see also section III.1) probably as a result of a lower biological activity in the winter time.

The iodide concentration decreases noticeably below 150 m to a minimum of about 0.02 uM. However, its concentration even below the thermocline is always significantly above the blank of 0.005 uM. There are three possible sources for this iodide which is thermodynamically unstable and is probably produced only in surface waters or reducing environments: (1) the sinking and subsequent advection of iodide rich surface waters along isopycnals; (2) the downward diffusion of iodide from the surface waters through the thermocline; and (3) the diffusion of iodide from the underlying sediments. All three mechanisms seem to be possible here. The first mechanism implies that the deep water is young so that the iodide has not been completely removed by oxidation. The deep water of this Basin is probably young as it originates from the nearby Labrador slope water (Colton, 1968). The

-165-

thermocline is also weak as a result of winter mixing with a $\widetilde{\sigma_\theta}$ difference between the surface and deep water of only 0.6 to 0.7 $\widetilde{\sigma_\theta}$ unit. Thus, diffusion through the thermocline cannot be ruled out. Moreover, below 200 m, there is also a general trend of increasing iodide concentration towards the bottom. Although this increase in concentration is small and is within the analytical uncertainty, it points to the possibility of a flux of iodide from the sediments as suggested by Tsunogai (1971b).

III.4 The distribution of iodine in marine suspended matter

III.4.1 Introduction

      The present status of our knowledge on the geo-
chemistry of the marine iodine system has been briefly re-
viewed in section I.2. This evidence suggests that particu-
late iodine is likely to be important in the cycling of
iodine in the ocean. In this section, I shall report mea-
surements of particulate iodine in samples obtained from
the Atlantic during the GEOSECS (Geochemical Ocean Sections
Study) expedition.

III.4.2 Sampling and analytical method

       Samples were obtained from 13 stations of the
GEOSECS (Geochemical Ocean Sections Study) expedition. The
cruise track and the positions of the stations are shown
in figure III-4-1. Stations where particulate iodine data
are available are marked as solid triangles. The analyti-
cal method has been described in detail in section II.5.
Briefly, for each sample, about 10 l of sea water is pres-
sure filtered through a 0.6 u (37 mm in diameter) Nuclepore
filter. The sea salts are carefully washed away. The filter
is dried and then pressed into a pellet (4 mm x 1 mm). The
pellets are analyzed by neutron activation analysis using
the facilities at the Rhode Island Nuclear Science Center
at Narragansett, Rhode Island. A listing of the data is
shown in Appendix E.
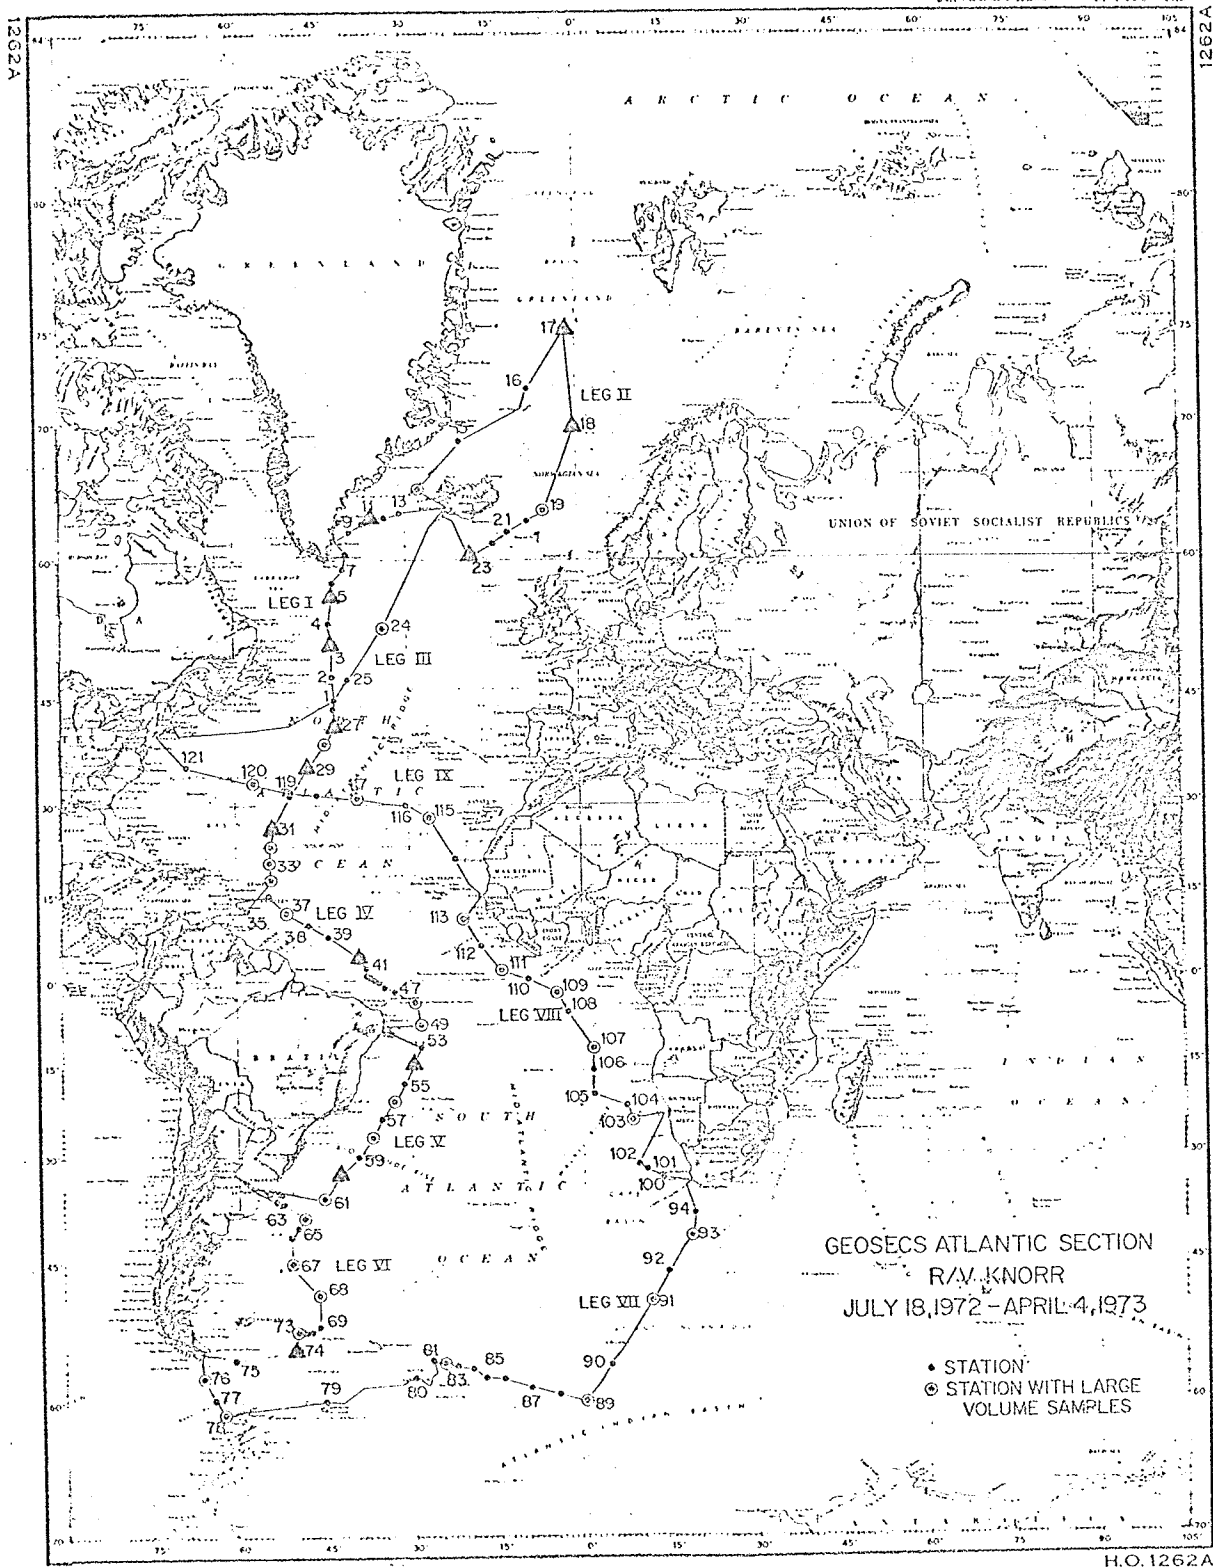

Fig. III-4-1 The cruise track and station positions
of the GEOSECS Atlantic section. Stations where
particulate iodine data are available are marked
as solid triangles.

-169-

III.4.3 Results and discussion

Most of the particles in the surface waters are likely to be biogenic. Consequently, the particulate composition may be close to that of marine organisms. On the other hand, particles close to the bottom of the ocean may have a composition similar to surface sediments. Iodine concentrations usually range between 100 and 300 ppm in marine organisms (Bowen, 1966) and between 60 and 800 ppm in surface sediments (Price et al., 1971; Price and Calvert, 1973). Table III-4-1 shows the iodine content of suspended matter collected closest to the surface and the bottom of the Atlantic at thirteen stations. The concentrations are normalized to the dry weight of the total suspended matter. The ranges of concentrations of iodine in the particulate matter from the surface and the bottom waters are 32 to 1256 ppm and 19 to 225 ppm with mean concentrations of 271 ppm and 112 ppm respectively. These thirteen stations cover a large geographical area (75°N to 55°S). The wide ranges of the concentrations of particulate iodine in the surface and bottom waters probably reflect real geographical variations. However, the means of these values are within the range of iodine content in marine organisms and surface sediments. Thus, although no previous data are available for a direct comparison, the values reported here seem to be reasonable.

* Relative to the dry weight of total suspended matter.

Figure III-4-2 shows   typical profiles of parti-
culate iodine and total particulate matter. The most pro-
minent feature in particulate iodine is the sharp maximum
in the surface waters. The highest concentration observed
is 127 ng/kg (relative to the weight of sea water filtered)
at 18 m in station 18. The maximum may occur at the surface
or at a few tens of meters below the surface. In all cases,
the maximum occurs within the euphotic zone. Below this
zone, the concentration drops sharply to about 1 to 2 ng/kg
and it remains approximately constant with depth until the
nepheloid layer, where an increase in concentration towards
the bottom is frequently observed. Total particulate matter
shows similar features although the increase in concentration
in the nepheloid layer is more marked.

The sharp maximum in the euphotic zone is
probably caused by a high rate of fixation of iodine by
biological activity. The sharp drop of concentration at
about the thermocline implies a rapid cycling of iodine
between its dissolved and particulate phases within the
euphotic zone as a large portion of the biogenic particles
is re-mineralized. The concentration of total suspended
matter also decreases sharply in the same depth interval
and this seems to indicate a dissolution of particulate
material. This distribution of particulate iodine in the
surface layers is similar to particulate organic carbon,
phosphorus and nitrogen (Menzel and Ryther, 1964; Holm-

-172-

Particulate Iodine ng/kg

total particulate matter.

Hansen et al., 1966; Hobson and Menzel, 1969; Holm-Hansen, 1972) and it suggests that they may be controlled by similar processes. Rapid cycling of biological material within the euphotic zone is well known. Williams et al. (1969) estimated that only 0.5% of the photosynthetically fixed carbon enters the deep sea. In the bottom water, the increase in particulate iodine concentration is possibly caused by the resuspension of surface sediments as the total particulate concentration also increases markedly.

Inorganic detrital contribution to particulate iodine is probably insignificant. In marine suspended matter, the iodine content is always a few tens of ppm or higher throughout the entire water column. This is about two orders of magnitude higher than the concentration in rocks. Profiles of particulate iodine in units normalized to the dry weight of total particulate matter are much noisier than those normalized to a unit weight of sea water. This is probably due to the larger uncertainty in the determination of total particulate weight. However, there is still a tendency of higher particulate iodine content in surface waters with an average of about 200 ppm. Below the euphotic zone, the concentration is approximately constant at around 100 ppm even in the nepheloid layer. Table III-4-1 seems to bear out this relationship although considerable variations may occur from station to station. Since clay detrital particles are usually resistant to dissolution, this cannot be

used to explain these variations in concentration with depth.

A profile of the ratio of particulate iodine to particulate scandium (I/Sc) is shown in figure III-4-3. Particulate scandium has a detrital origin and is likely to be related to the clay fraction. The profile shows high I/Sc in the surface waters. It decreases rapidly with depth to a background level which remains low even in the nepheloid layer. In the surface waters, the particles are mostly biogenic. Consequently, iodine concentration is high and the scandium concentration is low and thus I/Sc is high. In deep waters, the degradable biogenic particles have already been decomposed leaving only a residual amount of iodine behind. As a result, I/Sc is low. In the bottom waters, only particles most resistant to degradation remain. A significant or even major portion of them may have a detrital origin. The increase in particulate iodine probably reflects only the increase in total suspended matter. Thus, the accompanying increase in particulate scandium concentration is sufficient to compensate for this effect and the I/Sc therefore remains low.

Figure III-4-4 shows a section of particulate iodine in the Western Atlantic from 75°N to 55°S. The surface waters seem to be characterized by concentrations above 5 ng/kg. The higher concentrations (above 10 ng/kg) are confined to the higher latitudes where biological

-176-
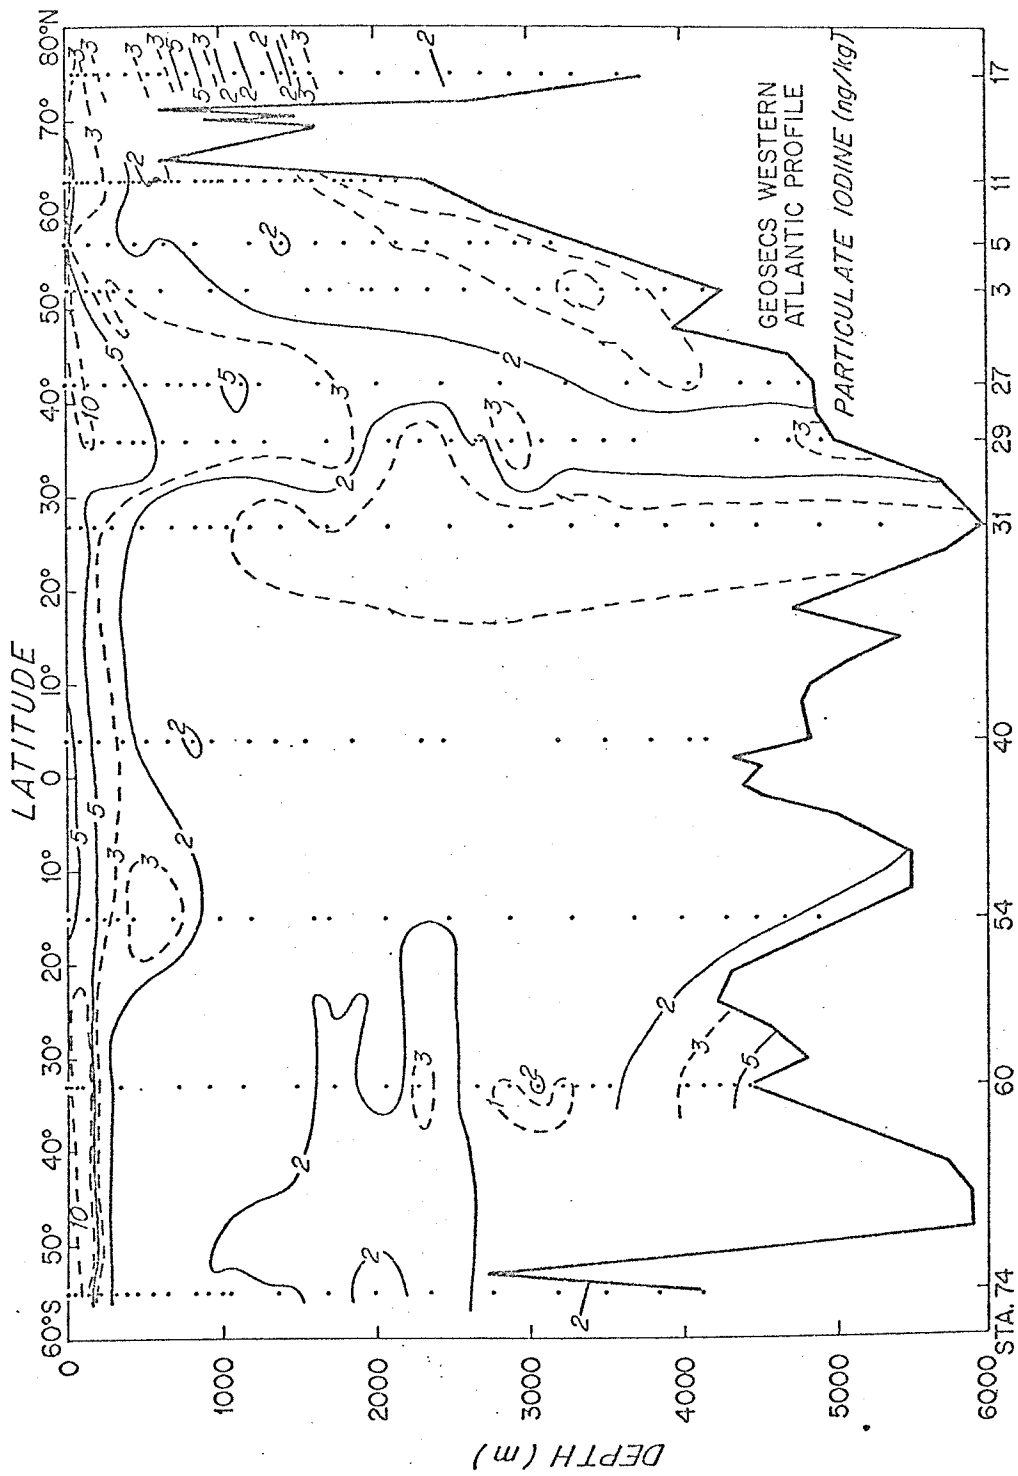

Fig. III-4-4 A section of particulate iodine in the Western Atlantic from 75°N to 55°S.

activity is highest. In the deep waters, the concentrations are generally below 2 ng/kg.

There is evidence suggesting the transport of particles with the water masses along isopycnals. At station 17, at 75°N, the thermocline is weak. The $\widetilde{\sigma}_\theta$ surfaces are almost vertical. As a result, particulate iodine is uniformly high down to about 2300 m. This distribution suggests downward mixing. There is also a tongue of water with high particulate iodine concentration that extends down to about 2000 m between 30°N and 50°N and this may represent the sinking of the Labrador Sea Water. The $\widetilde{\sigma}_\theta$ surfaces also show an accompanying sharp dip in this region. Station 31 at 27°N is in the middle of the North Atlantic gyre. The productivity of this region is low (Koblentz-Mishke et al., 1970) and this is reflected in the low particulate iodine concentrations throughout the entire water column. In this station, below 900 m, the concentration never exceeds 1 ng/kg. the lowest level observed in the entire Atlantic. Higher particulate iodine concentrations are observed in the nepheloid layer at stations 3, 29, 54, 60 and 74.

The standing crop of particulate iodine in the top 200 m of the water column of each station has been estimated and tabulated in table III-4-2. The map of the distribution of primary productivity compiled by Koblentz-Mishke et al. (1970) is shown in figure III-4-5 and the approximate positions of the stations are marked on the map. Al-

+ - Station with standing crop of >2.0 mg I/m^2.

⊙ - Station with standing crop of 1.5 to 2.0 mg I/m^2.

△ - Station with standing crop of <1.5 mg I/m^2.

though this map of productivity is rather crude, a qualitative correlation between the standing crops of particulate iodine and productivity is still apparent. Standing crops above 2 mg-I/m^2 in stations 3, 11, 18, 27 and 60 are all associated with high productivity whereas in the middle of the gyre, stations 29, 31 and 54, the standing crops are below 1.5 mg-I/m^2. Finer details can be observed with the help of more refined maps of productivity. The marked difference in the standing crops between stations 17 and 18 probably reflects the large difference in productivity between the Norwegian Sea and the Greenland Sea as shown by the more detailed map by Berge (1958). Zones of high productivity also hug the coasts of the southern tip of Greenland and the north-eastern coasts of Canada, whereas, in between these zones in the Labrador Sea, the productivity is lower (Steeman Nielsen, 1958). The distribution of the standing crop of particulate iodine in this area is consistent with this pattern with higher concentrations at station 11, 3 and 27 and lower concentration at station 5.

CHAPTER IV. THE INTERCONVERSION OF THE DISSOLVED IODINE SPECIES IN THE OCEAN

IV.1 Introduction

In this section, our present understanding on the effects of thermodynamics, chemical kinetics and biological activity on the interconversion of dissolved iodine species will be reviewed. Based on this information and data from further laboratory studies, the relative stability and the fate of the various species of dissolved iodine will be assessed. The plausibility of invoking these species as agents in geochemical processes will be examined.

IV.2   The thermodynamic properties of the aqueous iodine
        system

        Iodine shows five principal oxidation states:
(1) -1 as hydroiodic acid and iodides; (2) 0 as elemental
iodine; (3) +1 as hypoiodous acid and hypoiodites; (4) +5
as iodic acid and iodates; and (5) +7 as periodic acid and
periodates. Other oxidation states (+4 and +3) have been
reported but they are treated merely as chemical curiosi-
ties (Latimer, 1952). Some thermodynamic properties of the
iodine system are summarized in tables IV-2-1 and IV-2-2.

        The relative abundances of the various species
at equilibrium, at a total iodine concentration of 5×10^{-7}M,
as a function of pE and the detection limits of our present
analytical capability are shown in figure IV-2-1. Above a
pE of 10.7, iodate is the dominant form, while, below a
pE of 10.0, iodide will be dominant. Iodate and iodide co-
exist in measurable quantities only within the pE range of
10.0 to 10.7. All the other species are presently undetect-
able. The concentration diagram does not show the relative
stabilities of all the species. It only presents the compo-
sition of the mixture at equilibrium. The relative stabili-
ties of the different species of a single element may be
better shown by an oxidation state diagram (Johnson,
1968) which has not yet been used by oceanographers. It
is a plot of the electrode potential for the conversion

of an element from a certain oxidation state to its standard
state against the oxidation state. It shows the stability
of a certain oxidation state towards oxidation, reduction
and disproportionation. It also points out the possibility
of the existence of metastable species. Oxidation potentials
are usually given in two sets in standard textbooks, with
one set determined in 1 N acid and the other in 1 N base
(Douglas and McDaniel, 1965). The reference state used by
chemists is the hydrogen-hydronium ion couple. In natural
waters, hydrogen does not occur in significant quantities.
The oxygen-water or the oxygen-hydroxide ion couple seems
to be the more appropriate reference state. Thus, in acid,
the reference couple will be

$$O_2 + 4H^+ + 4e^- = 2H_2O \qquad \log K = 83.1 \qquad (IV-2-1)$$

and, in base, the reference couple will be

$$O_2 + 2H_2O + 4e^- = 4OH^- \qquad \log K = 13.56 \qquad (IV-2-2)$$

The oxidation state diagram of the iodine system is shown
in figure IV-2-2 and the thermodynamic parameters used
in the construction of the diagram are shown in table IV-
2-3.

In an acidic solution, iodate is the most stable
form. Iodide will be oxidized to elemental iodine which is
metastable. Hypoiodite will disproportionate to form iodate
and elemental iodine whereas periodate will be reduced to
iodate. Although elemental iodine is less stable than
iodate, it is a metastable form and it will not be oxidized

to iodate unless it is first oxidized to hypoiodite and this step is thermodynamically unfavorable. Thus, a solution of iodide in an acidic medium will be oxidized to elemental iodine which will persist in such an oxidation state.

In a basic solution, iodate is still the most stable form. However, iodide is now the metastable species. Both elemental iodine and hypoiodite are subject to disproportionation giving iodide and iodate as the final products. Periodate will again be reduced to iodate. Thus, iodide will persist in a basic solution and its oxidation to iodate may be initiated only if it is first oxidized to elemental iodine. Although the ocean is neither 1 N in acid nor 1 N in base, one may expect iodine to exhibit behaviors more similar to those in a basic solution since sea water has a pH of 8.1 (Sillen, 1961).

The stability of the iodine system relative to the other more common redox couples in the ocean is shown in the electron free energy level diagram in figure IV-2-3. The data are compiled in tables IV-2-1 and IV-2-4. In this diagram, the oxidized species of a couple lower down in the energy scale will oxidize the reduced member of a couple higher up when all species are in their standard states. Thus, in an acidic solution, oxygen will oxidize iodide to iodine according to the equation

$$4I^- + 4H^+ + O_2 = 2I_2 + 2H_2O \qquad (IV-2-3)$$
whereas, in a basic solution, the corresponding reaction
Fig. IV-2-3   The electron free energy level diagram of the

$$4I^- + O_2 + 2H_2O = 2I_2 + 4OH^-$$ (IV-2-4)
will not occur.

The other redox couples presented in the figure are frequently involved in biochemical reactions. Reduced species such as sulfide, nitrite, ammonia, methane and methanol, which may be produced as metabolic byproducts, all have the potential of changing the oxidation state of iodine. A particularly interesting redox couple is the NADPH (reduced nicotinamide-adenine-dinucleotide phosphate) and the $NADP^+$ couple. The interconversion between these two species is a well known route for electron transfer in biochemical processes (Lehninger, 1965). The electron free energy level of this couple is high and it implies that biological processes involving the interconversion between NADPH and $NADP^+$ may induce the interconversion between iodide and iodate if these two reactions can be coupled together.

IV.3   The complexation of iodide in sea water

Since sea water is a complex mixture of ions, the association of ions to form complexes and ion-pairs such as $MgSO_4^0$(Garrels and Thompson, 1962) is well recognized. The formation of complexes will change the chemical behavior of an element. Thus, in considering the physical chemistry of iodide, the possibility of complexation must be examined.

I have studied the complexation of iodide by potentiometric titrations of solutions with standard iodide solutions using an iodide specific electrode as a detector. The electrode potential is given by the Nernstian equation

$$E = E^0 - 59.16 \log C_I \qquad \qquad \text{(IV-3-1)}$$

at 25^0C where E is the observed electrode potential in mV, E^0 is a characteristic empirical constant and C_I is the activity of the iodide ions. If C_T is the total concentration of iodide and C_c is the concentration that has undergone complexation, then

$$C_I = C_T - C_c \qquad \qquad \text{(IV-3-2)}$$

and $E = E^0 - 59.16 \log (C_T - C_c)$.   (IV-3-3)

If no complexation occurs, $C_c = 0$ and $\log C_T$ will be a linear function of E. On the other hand, in the presence of complexing agents, a plot of E against $\log C_T$ will no longer be linear unless C_c is a linear function of C_T so that $C_c = k\, C_T$ where k is a constant. However, as such a titration proceeds, the complexing capacity of the solution is reduced and may finally be exhausted. Consequently, C_c will probably

be more dependent on the complexing capacity than on the amount of iodide added to the solution.

Figure IV-3-1 shows the potentiometric titration of 2 l of a 0.01 M $Na_2B_4O_7 \cdot 10H_2O$ and 0.5 M NaCl solution with standard iodide solutions at $25^{\circ}C$. The borate acts as a pH buffer, poising the pH of the solution at about 9. The sodium chloride sets the ionic strength of the solution which will be about 0.53 molal. The iodide concentration in the solution after each addition of the standard iodide solution is calculated from the concentration and the volume of the titrant added. The electrode potential is linearly related to the log of the concentrations above 10^{-5}M with a slope of -54 mV per concentration decade. Figure IV-3-1 also shows the results of a similar titration of 2 l of Woods Hole surface water (salinity ~34 to 35‰) which has a comparable ionic strength of 0.67 molal (Kester and Pytkowicz, 1969). The electrode potential is again linearly related to the log of the concentrations above 10^{-5}M with a slope of -52 mV per concentration decade.

The linear relationships and similar slopes suggest that iodide behaves identically in sea water and in sodium chloride solution. Rechnitz et al. (1966) reported a range of the slope of -53 to -59 mV per concentration decade for the calibration of an iodide electrode in carefully prepared standard iodide solutions using sodium nitrate as the ionic strength adjuster and under meticu-
Fig. IV-3-1 Potentiometric titrations of sea water and a 0.5 M sodium chloride solution with standard iodide solutions.

lously controlled experimental conditions. The agreement between the reported slopes and those determined in this study also suggests that the complexation of iodide in sea water is unlikely. This interpretation also agrees with the calculation in table I-2-4 which shows that the percent of contact ion-pairs of iodide estimated from partial molal volumes is negligible within the uncertainty of the calculation.

IV.4 Chemical kinetics in the interconversion of aqueous

iodine species

The oxidation of iodide to iodate has not been studied previously. A study of the literature showed that experiments were designed mainly to observe the oxidation to adjacent oxidation states. Past efforts were focused on three reactions:

$$6I^- + O_2 + 4H^+ = 2I_3^- + 2H_2O \qquad (IV-4-1)$$

$$I_2 + OH^- = HIO + I^- \qquad (IV-4-2)$$

$$3HIO + 3OH^- = IO_3^- + 2I^- + 3H_2O \qquad (IV-4-3)$$
Studies on reaction (IV-4-1) were always done in strongly acidic medium. The results of earlier investigators (Plotnikov, 1907, 1908; Winther, 1924, 1926; Berthoud and Nicolet, 1927, 1928) contradict each other. More recently, careful investigations from two different groups (Abel, 1952, 1954, 1958a, 1958b; Sigalla and Herbo, 1957, 1958) finally yielded consistent results. They suggested the rate law

$$d(I_3^-)/dt = k\ (O_2)\ (I^-)\ (H^+) \qquad (IV-4-4)$$

Sigalla and Herbo (1957) reported k at 25°C to be 8×10^{-3} M^{-2} min^{-1} and Abel also reported k of similar magnitude (1952, 1958a). A summary of the available data is shown in table IV-4-1. However, while Abel favored a mechanism involving a series of reactions with one electron transfers, the formation of free radicals and chain reactions, Sigalla and Herbo proposed a series of reactions with two electron

Table IV-4-1   The dark auto-oxidation of iodide

Rate Law	Rate Constant	Reference
$d(I_3^-)/dt = k(O_2)(I^-)^{3/2}(H^+)^{4/3}$	---	Plotnikov (1907)
$d(I_3^-)/dt = k(O_2)(I^-)^{2/3}(H^+)^{2/3}$	---	Plotnikov (1908)
$d(I_3^-)/dt = k.10^a(O_2)^{3/2}(I^-)^2(H^+)$ $a = -1.51(I^-)^{1/3}$	---	Winther (1924, 1926)
$-d(I_3^-)/dt = k(O_2)(H^+)^{\frac{1}{2}}(I^-)^x$ $0.55 \leq x \leq 1.55$	---	Berthoud and Nicolet (1927, 1928)
$d(I_3^-)/dt = k(O_2)(I^-)(H^+)$	25°C: 8.0x10^{-3} M^{-2}min^{-1}	Sigalla and Herbo (1951)
$d(I_3^-)/dt = k(O_2)(I^-)(H^+)$ $= k'p_{O_2}(I^-)(H^+)$	25°C: 7.8x10^{-3}M^{-2}min^{-1} 9.6x10^{-6}atm^{-1}M^{-1}min^{-1} 40°C: 1.3x10^{-2}M^{-2}min^{-1} 1.3x10^{-5}atm^{-1}M^{-1}min^{-1}	Abel (1958a)
$d(I_3^-)/dt = k(O_2)(I^-)(H^+)$	---	Alridge (1966)

transfers and without the production of free radicals or the initiation of a chain reaction. Alridge (1966) studied the reaction again and arrived at the same rate law but he failed to further clarify the mechanisms. However, all the proposed mechanisms involve intermediates such as IO^-, HIO or atomic iodine although their stability in aqueous solutions has not been thoroughly investigated.

Appropriate precautions should be taken in extrapolating these observations to natural conditions as these experiments were all performed in artificial medium with an acid concentration of no less than 0.1 N, iodide concentration of no lower than 0.06 M and plentiful supply of oxygen. Catalysis by trace constituents has been carefully and intentionally removed. In the ocean, the pH is 8, the iodide concentration is less than 0.5 uM and the oxygen concentration is usually less than 225 uM. Moreover, sea water contains numerous trace constituents and some of them may catalyze the reaction. Some of the known catalysts are cupric ion (Sigalla and Herbo, 1958) and iron (Alridge, 1966). If indeed the rate law can be extrapolated to the ocean, the rate of formation of elemental iodine from iodide at $25^{\circ}C$ will be 9×10^{-21} M min^{-1} or 1.3×10^{-11} uM day^{-1}, an undetectable rate indeed.

The hydrolysis of elemental iodine in basic solution is extremely fast. Earlier chemists "assumed that the speed with which equilibrium is established precludes

any adequate investigation" (Morgan, 1954). Most of the reactions involved in the hydrolysis of the halogens, with the exception of chlorine, occur in about 10^{-3} second or less. Eigen and Kustin (1962) were able to study these reactions by using a T-jump relaxation technique. For the overall reaction (IV-4-2), they determined the rate constant k to be 3 sec^{-1} with (H^+) of $10^{-5}M$, (I_2) of $10^{-3}M$ and an ionic strength (u) of 0.1 molal. Thus, the rate law is

$$d(HIO)/dt = (3 \ sec^{-1}) \ (I_2) \tag{IV-4-5}$$

and the half life of elemental iodine will be less than 0.5 second. Again, the experimental conditions are appreciably different from the oceanic conditions. However, if their study can be used as an indication of what is happening in nature, it implies that the life time of elemental iodine in the ocean will be extremely short. This seems to corroborate the field observations since elemental iodine has never been detected although its formation has been proposed (Shaw, 1959; Miyake and Tsunogai, 1963). The mechanism for the hydrolysis of elemental iodine is complicated and Eigen and Kustin suggested the following scheme

$$
\begin{array}{c}
I_2 + H_2O \\
\updownarrow \qquad \searrow \\
\qquad \qquad \qquad \qquad I_2OH^- + H^+ \rightleftharpoons HIO + H^+ + I^- \\
\nearrow \\
I_2 + OH^- + H^+
\end{array}
$$
However, this mechanism has not yet been verified by other investigators.

The disproportionation of hypoiodite to form

iodate in a basic solution has been studied by a number of chemists since the turn of the century. Forster (1903) proposed the first rate law and Skrabal and coworkers (1907, 1908, 1911, 1914, 1916, 1934) followed with a series of reports. The historical development has been reviewed by Morgan (1954) and the proposed rate laws are summarized in table IV-4-2. The most recent report by Li and White (1943) gave the rate law as

$$-d(IO^-)/dt = k_1(IO^-)^2 + k_2(IO^-)^2(I^-)/(OH^-) \quad (IV-4-6)$$

where $k_1 = 2.9$ M^{-1} min^{-1} and $k_2 = 104$ M^{-1} min^{-1}. This rate law was obtained from strongly alkaline solution. The hydroxide ion concentration varied from 0.923 M to 0.177 M and the iodide concentration varied from 0.085 M to 0.015 M. In the ocean, (OH^-) is about 10^{-6}M and (I^-) is less than 0.1 uM. (IO^-) must be less than the total iodine concentration of 0.5 uM. If this rate law is assumed to be applicable to sea water, then, as an upper limit, $-d(IO^-)/dt$ is 3.3 x 10^{-12} M min^{-1} or 5 x 10^{-9} M day^{-1}. This rate is slow and may not be measurable in the laboratory easily.

Table IV-4-2 The disproportionation of hypoiodite

Rate Law	Rate Constant	Reference
$-d(IO^-)/dt = k(I^-)(IO^-)(HIO)$	---	Forster (1903)

IV.5 Biologically mediated interconversion of the iodine

    species

        That iodine is concentrated in some marine organ-
isms has been known for a long time. Bowen (1966) gave
concentration factors of 1200 and 6200 for mixed plankton
and brown algae respectively. Enrichment factors as high as
10^4 have been reported for some brown algae (Mauchline and
Templeton, 1964). A summary of the existing data is shown
in section I.2.4. Early studies (Bailey and Kelly, 1955;
Tong and Chaikoff, 1955; Klemperer, 1957) focused on the
mechanism for attaining and sustaining such high concentra-
tion gradients between the cell and its surrounding medium.
A common conclusion of these studies is that only iodide
is removed from sea water into the cell. Inside the cell,
iodine occurs mainly as iodide, although a fraction of it
may occur in organic forms. However, upon hydrolysis, only
a trace of the organic iodine is left. The major portion of
it is converted into inorganic iodide. Shaw (1959, 1960)
investigated the possibility of accompanying changes in the
speciation of iodine during iodide accumulation by the brown
sea weed Laminaria digitata. He reported that, in agreement
with some earlier studies (Dangeard, 1928a, 1928b, 1930;
Kylin, 1930; Roche et al., 1949), iodide can be oxidized
to iodine by marine algae and the oxidation can proceed in
the dark. The elemental iodine then quickly undergoes hydro-
lysis to form hypoiodous acid, which, being a neutral mole-

cule at the pH of sea water, can easily diffuse into the tissues. Inside the tissues, hypoiodous acid may either be reduced back to iodide or be converted into organic iodine. Since the tissues have a lower permeability to ions than to neutral molecules, iodide is retained inside the tissues. He presented a scheme as shown in figure IV-5-1 (Shaw, 1959, 1962). More recently, Gozlan (1968) also reported the occurrence of iodine-producing bacteria.

Sugawara and Terada (1967) studied the assimilation of iodine by a species of the marine alga, Navicula. They reported that the alga preferentially assimilated iodide ions. Little or no uptake of iodate ions occurred. In fact, excessive amounts of iodate can hamper the growth of the algae. There is evidence indicating the conversion of iodide to iodate and vice versa during the growth of the algae.

The reduction of iodate to iodide by bacteria has been reported by Tsunogai and Sase (1969). They concluded that bacteria that are capable of reducing nitrate to nitrite, using nitrate reductase as the enzyme, can also reduce iodate to iodide. They also claimed the detection of the formation of elemental iodine in the process.

These studies indicate that biological activity is important in the interconversion of the iodine species. Both the oxidation of iodide and the reduction of iodate can be induced by such processes. However, since these studies
Fig. IV-5-1   A possible mechanism of iodide absorption
   by brown algae proposed by Shaw (1959).

are limited to a few species of algae and bacteria, it is as yet unclear whether these processes are quantitatively important in affecting the oceanic distributions.

IV.6 Previous laboratory studies

Sugawara and Terada (1958) were the earliest investigators to study the stability of various species of iodine in sea water. They added in excess of 50 mg of elemental iodine to a liter of sea water and observed a gradual decrease in the elemental iodine concentration and a corresponding increase in the iodate concentration. Less than 40% of the elemental iodine added was left after 25 days. This rate is substantially slower than those determined in artificial media (see section IV.4). Nonetheless, this experiment shows that elemental iodine is unstable in sea water and Sugawara and Terada favored the hydrolysis of elemental iodine to hypoiodite and its subsequent disproportionation to iodate and iodide as an explanation for their observations according to the reactions

$$I_2 + OH^- = I^- + IO^- + H^+ \qquad\qquad (IV-6-1)$$

$$\text{and} \quad 3IO^- = 2I^- + IO_3^- \qquad\qquad (IV-6-2)$$
They also suggested that the direct oxidation of iodide to a higher oxidation state, such as hypoiodite, is difficult.

Recently, Truesdale (1974) has re-examined this problem. He suggested that elemental iodine in sea water may behave differently at trace concentrations. He limited the addition of elemental iodine to less than 1400 ug I_2-I/l. He also observed a rapid disappearance of elemental iodine in sea water. Less than 15% of the added elemental iodine is left after 24 hours. In low iodine concentration (260

ug I_2-I/l), all the elemental iodine disappears after 30 minutes. The rate of the reaction decreases with time. However, in the first half an hour, the rate is always about 240 uM/day. He suggested that the elemental iodine initially reacts with organic compounds either by reduction to form iodide or by iodination to form iodinated derivatives. At low elemental iodine concentrations, the organic compounds in sea water may be able to consume all the elemental iodine. At higher elemental iodine concentrations, after these organic compounds are exhausted, the slower reactions, the hydrolysis and subsequent disproportionation of elemental iodine to form iodate, may then proceed. Thus, according to Truesdale (1974), the fate of elemental iodine in sea water will mainly be

$$I_2 + 2R = 2RI \qquad\qquad (IV-6-3)$$

and $\quad I_2 + 2R = 2I^- + 2R^+ \qquad\qquad (IV-6-4)$

where R is an unknown organic compound. There are some doubts about the reliability of these results. Truesdale purged all the oxygen from his reaction mixture with nitrogen before initiating his experiments because oxygen is an interferent in his analytical method. The effect of the absence of oxygen on the reaction pathways is not known. An inert nitrogen atmosphere instead of the natural oxidizing atmosphere may suppress oxidation and thus favor the reduction of iodine. Consequently, his conclusions should be treated with caution.

IV.7 Laboratory studies

IV.7.1 The oxidation of iodide in an aqueous solution

IV.7.1.1 Experimental

Potassium iodide is added to solutions with known
pH and ionic strengths so that the final concentration is
about 1 mM in iodide. The medium may be filtered Woods Hole
surface water or an artificial solution. Two liters of the
solution are quickly transferred into a reaction vessel in
a constant temperature water bath. Air or oxygen is bubbled
through the solution. The pH, temperature and iodide con-
centration inside the reaction vessel are monitored by a
combination pH electrode, a thermometer and an iodide ion
specific electrode. The temperature bath is covered with
styrofoam sheets to minimize heat loss and direct light.
A sketch of the apparatus is shown in figure IV-7-1.

IV.7.1.2 Results and discussion

Figures IV-7-2 and IV-7-3 show the results from
five experiments in various solutions at different pH
values. In the first three experiments (figure IV-7-2), a
medium which is 0.1 M in potassium nitrate and 1 mM in
potassium iodide was used. The pH was buffered at 9, 12 and
6.7 respectively and the temperature was maintained at $49^{\circ}C$.
A decrease in electrode potential will indicate an increase
in the iodide concentration. Thus, as the oxidation of
iodide proceeds, the electrode potential should increase in
Fig. IV-7-1 An apparatus for studying the interconversion of
iodine species. 1 reference electrode; 2 iodide electrode;

ated with $Ca(OH)_2$. Exp. 3: pH 6.7; 49°C; 0.025M $Na_2HPO_4 \cdot$
$7H_2O$ and 0.025M KH_2PO_4.
Fig. IV-7-3 Dark auto-oxidation of iodide. Exp. 4; pH 1; 25°C; 0.1M HCl. Exp. 5; pH 0.9; 25°C.

the positive direction. No consistent trend was observed.
At pH 9, there was in fact a decrease in electrode poten-
tial of 6 mV in $6\frac{1}{2}$ hours. No electrode potential changes
could be detected at pH 12 in 6 hours, while at pH 6.7, it
increased in a haphazard manner for about 9 mV in 23 hours.
(The sharp change in electrode potential in the initial 30
to 60 minutes was caused by the temperature equilibration
between the reaction mixture and the temperature bath.)

In the fourth experiment (figure IV-7-3), a 0.5 M
sodium chloride and 0.1 M hydrochloric acid solution was
used. The iodide concentration was 0.5 mM and the pH was 1.
The bath temperature was maintained at $25^{o}C$. The variations
in electrode potential were only about 1 to 2 mV in 53 hours
and should be considered constant within the experimental
uncertainties. No change could be observed even when oxygen
instead of air was bubbled through the solution. A similar
experiment was done using sea water which had been titrated
to a pH of 0.9 with hydrochloric acid (figure IV-7-3). The
electrode potential dropped 2.5 mV in the first 3 hours. It
then drifted downwards slowly for the next 95 hours. The
total drop in electrode potential in the entire experiment
of 98 hours was only 4 mV.

These experiments did not provide any conclusive
information. In retrospect, the use of an electrode as a
sensor for the disappearance of iodide in this study is
actually a poor choice. The change in electrode potential

(ΔE) is a logarithmic function of the change in iodide concentration since

$$\Delta E = 59.16 \log (a_{It}/a_{I0}) \qquad \text{(IV-7-1)}$$

where a_{It} is the activity of iodide at time t, a_{I0} is the initial iodide activity and ΔE is in mV. Thus, with slow reactions which do not go to completion, observations will be made in a region where the electrode response is least sensitive to concentration changes. In this series of experiments, the maximum change in electrode potential was an increase of 9 mV in 13 hours in experiment 3. This ΔE corresponds to a 30% decrease in the initial concentration. In the other experiments, ΔE was less than 2 mV but it may still represent a 9% decrease in concentration. However, over such a long time span for the experiments (7 to 97 hours), other factors, such as electrode drift, may be sufficient to account for these changes in electrode potentials too. Moreover, there is no systematic change in the rate of disappearance of iodide with varying pH. Even within an experiment at constant pH, the change in electrode potential with time is often haphazard. In one of the experiments, the change in electrode potential would actually suggest an increase in the iodide concentration. This is physically impossible. The only generalization that may be derived from these data is perhaps that iodide is not easily oxidized in aqueous solutions. The rate of the reaction is too slow to be observed with the techniques used here.

IV.7.2 The change in iodate concentration in sea water

   with time

IV.7.2.1 Experimental

   Woods Hole surface water is collected and filtered
through Whatman 40 filter papers. The filtered sea water is
divided into sub-samples which are stored in 250 ml poly-
ethylene bottles at room temperature (about $25^{\circ}C$). A sample
is transferred to the freezer after each preset time inter-
val. All the samples are analyzed for iodate at the end of
the experiment by the colorimetric method as described in
section II.3. The initial sea water frozen immediately
after collection is used for the construction of a calibra-
tion curve.

IV.7.2.2 Results and discussion

   Figure IV-7-4 shows the results from an experi-
ment for a duration of 52 days. The sea water has been
analyzed before the experiment was started and it was found
to contain 22.3 ug/l of iodate-iodine and 15.7 ug/l of
iodide-iodine. Within the error bar ($\pm$ 5%), no change in
iodate concentration could be observed after 52 days of
storage at room temperature. The best fit by the linear
least square method gives

   $(IO_3^-) = 0.002 \ t + 22.34$ (IV-7-2)

where t is time in days. The correlation coefficient is
0.05 and the standard deviation of the slope is ± 0.547.
Fig. IV-7-4 Rate of production of iodate in sea water at 25°C.

Thus, if indeed iodate has been produced by the oxidation of iodide within the period of 52 days, it is undetectable with this method and the change is less than the experimental uncertainty of ± 1 ug-I/l.

IV.7.3 The stability of elemental iodine in an aqueous
        solution

IV.7.3.1 Experimental

Standard iodine solution (3% w/v in potassium iodide)

        10 g of distilled water and 7.5 g of potassium
iodide are transferred into a stoppered weighing bottle.
0.0317 g of elemental iodine ($\frac{1}{4}$ mmole I_2-I) is added to the
solution. The mixture is gently swirled until the elemental
iodine is completely dissolved. The solution is transferred
into a 250 ml volumetric flask. The weighing bottle is
washed three times with small amounts of distilled water and
the washings are also added to the volumetric flask. The
solution is then diluted to volume. The concentration of
iodine is determined by titrating 25 ml of this iodine solu-
tion with a standard sodium thiosulfate solution (4.0356
mM) using the starch-iodine color for the detection of the
end-point. The amount of iodate present in the iodine solu-
tion as an impurity is determined from the difference in
the amount of thiosulfate consumed between an unacidified
and an acidified sample of the iodine solution. The concen-
trations of iodine and iodate in the standard iodine solu-
tion are 0.9243 mM I_2-I and 0.02588 mM IO_3^--I from the
average of two determinations.

Procedure

Two liters of an artificial solution or sea water are transferred into a reaction vessel in a constant temperature bath. The solution is stirred at a constant rate. The pH of the solution is monitored with a combination pH electrode. After the reaction mixture has thermally equilibrated with the water bath, 5 ml of the standard iodine solution is added. Forty ml of this mixture is pipetted into each of two 50 ml volumetric flasks at fixed time intervals. In one flask, the solution is diluted to volume and its absorbance is measured as quickly as possible in a 10 cm cell at 353 nm. To the other flask, which contains 1 ml of 0.1 M sulfuric acid before the addition of the sample, 2 ml of a 5% (w/v) potassium iodide solution is added and the mixture is diluted to volume. After allowing the mixture to stand for 5 minutes with occasional shaking, its absorbance at 353 nm is measured.

In the first two experiments, the medium was Woods Hole surface water filtered through a Whatman 40 filter paper. The third one was distilled water titrated to a pH of 8.2 with a 0.1 M sodium hydroxide solution. The fourth one was a 0.5 M sodium chloride and 2.25 mM sodium bicarbonate solution. The pH was adjusted to 8.2 by titrating the solution with a 0.1 M sodium hydroxide solution.

IV.7.3.2 Results and discussion

The inorganic iodine species added to the medium
gave the following concentrations: 292.5 ug I_2-I/l, 8.2 ug
IO_3^--I/l and 57 mg I^--I/l. The amount of elemental iodine
added is at the lower end of the concentration range used
by Truesdale (1975) and should not mask his proposed reac-
tions with the organic compounds. The amount of elemental
iodine in the solution was monitored by measuring the absor-
bance of the solution at 353 nm in a 10 cm cell. At this
wavelength, both elemental iodine and the tri-iodide ion
absorb strongly (Awtrey and Connick, 1951) while the other
iodine species do not absorb significantly.

Some of the reactions that may be involved in the
experiments are

$$I_2 + I^- \rightleftharpoons I_3^- \tag{IV-7-3}$$

$$I_2 + H_2O \rightleftharpoons I^- + HIO + H^+ \tag{IV-7-4}$$

$$HIO \rightleftharpoons H^+ + IO^- \tag{IV-7-5}$$

$$2R + I_2 = 2RI \tag{IV-7-6}$$

$$3IO^- = IO_3^- + 2I^- \tag{IV-7-7}$$

$$R + HIO \longrightarrow RI \tag{IV-7-8}$$

$$IO^- + \text{reducing agent} \longrightarrow I^- \tag{IV-7-9}$$

$$IO_3^- + 6H^+ + 5I^- = 3I_2 + 3H_2O \tag{IV-7-10}$$
R represents some unknown organic compounds.

Figure IV-7-5 shows the results from four experi-
ments in various media. If elemental iodine is stable in an
aqueous solution at a pH of around 8, only reaction IV-7-3

absorbance from IO_3^- in sea water

Time minute

Absorbance

will occur and it will yield a constant absorbance with time in both the acidified and the unacidified samples. In reality, in the unacidified samples, the absorbance is only about 0.01 to 0.03. Although it is rather constant with time, it is much lower than the expected value of 0.22. (This value is estimated from the amount of elemental iodine present and a calibration curve obtained by generating known amounts of elemental iodine through the reaction of iodate with excess iodide in an acidic solution.) This consumption of elemental iodine occurs within a minute or two - the shortest time within which an absorbance reading can be made - and supports the previous reports that iodine is unstable in sea water (Sugawara and Terada, 1958; Truesdale, 1974). Since the reaction occurs in both sea water and distilled water, the reaction seems to be only pH dependent and is likely to be the hydrolysis of elemental iodine.

Upon acidification, the absorbance increases sharply. In sea water, part of this absorbance is due to the iodate present as shown by reaction IV-7-10. This background absorbance is denoted as a broken line in figure IV-7-6. The restoration of the absorbance by acidification implies that the reaction that consumes elemental iodine is a reversible one. Thus, reactions such as reaction IV-7-6, which is favored by Truesdale (1974), are not likely to occur since such reactions are usually irreversible.

The absorbance of the acidified samples decreases

slowly long after the initial elemental iodine has been consumed, as suggested by the constant and low absorbances of the unacidified samples. This implies the presence of an intermediate which can be converted back to elemental iodine upon acidification as discussed previously. Moreover, this intermediate has to be reactive and it is this intermediate rather than elemental iodine that is irreversibly consumed with time.

The most likely candidate for this intermediate is hypoiodous acid since earlier studies have shown that the hydrolysis of iodine to form hypoiodous acid is rapid in an alkaline solution and this reaction (reaction IV-7-4) is reversible (see sections IV.2 and IV.4 for a more detailed discussion). It is also a very reactive species and it can undergo reactions such as IV-7-7, IV-7-8 and IV-7-9. The disproportionation of hypoiodite to form iodate (reaction IV-7-7) cannot account for the observed decrease in absorbance with time in the acidified samples since one mole of HIO will produce two moles of I_2-I either through reaction IV-7-4 or through the combination of reactions IV-7-7 and IV-7-10. Since iodate is stable in an aqueous solution, if reaction IV-7-7 is the only reaction occurred, there will be no change in absorbance with time. The other routes for the removal of hypoiodite will be its reduction to iodide by an organic or an inorganic reducing agent (reaction IV-7-9) or the iodination of organic species (reaction IV-7-8).

Neither route can be ruled out at the present time.

In sea water, the absorbance of the acidified samples drops to the background level within 2 hours. This level is slightly higher than the absorbance from the iodate initially present in the sea water and this excess (0.015 absorbance unit) is probably caused by the trace of iodate in the standard iodine solution. For practical purposes, one may probably assume that all the hypoiodite is consumed within 2 hours. Thus, the reaction that consumes hypoiodite seems to occur much faster than the disproportionation of hypoiodite to form iodate (reaction IV-7-7). In the artificial media prepared with distilled water, less than 40% of the initial absorbance is lost in 2 hours and this implies that hypoiodite is consumed at a much slower rate in these solutions. The presence of sodium chloride or changes in ionic strength cannot be the cause since the reaction occurs equally slowly in the 0.5 M sodium chloride solution (figure IV-7-6). A major difference between distilled water and the coastal surface sea water is in their organic contents. It is possible that the much lower concentration of organic compounds in distilled water is limiting reactions IV-7-8 and IV-7-9 which are suggested earlier as the routes for the removal of hypoiodite. Alternatively, one may attribute the difference in reaction rate to the possible absence of catalysts in trace quantities in the artificial media.

The loss of iodine from the solution by volatili-

zation is unimportant in this study. Truesdale (1974) has examined this possibility and found that the volatilization of iodine does not occur at the pH of sea water. I have also avoided the bubbling of gases through the reaction mixture, kept the reaction temperature low (25°C) and finished each experiment within 3 hours in order to further minimize this problem. Thus, no elemental iodine should have been lost during the experiments from the reaction mixture. Loss by volatilization may also occur in the acidified samples in the volumetric flasks. However, I have checked the stability of the absorbance of the tri-iodide ion in acidified samples with time and found that there is no observable change in absorbance in over an hour. In my experiments, the absorbance of each acidified sample was measured within half an hour after the generation of the tri-iodide ions. Thus, the decrease in absorbance with time cannot be explained by this mechanism.

In summary, my experiments have shown that elemental iodine is unstable in sea water. Its major decomposition route is probably not by its direct reaction with organic compounds. Iodine probably undergoes hydrolysis to form hypoiodous acid which further reacts with either reducing agents to form iodide or organic molecules to form iodinated compounds. These reactions seem to occur much faster than the disproportionation of hypoiodite to form iodate.

IV.8 A possible oceanic iodine cycle

A tentative cycle of iodine in the ocean is shown in figure IV-8-1. Only elemental iodine and hypoiodite are included as possible intermediates between iodide and iodate because they are the only remaining iodine species that show significant stability in aqueous solutions. The oxidation of iodide to iodate does not necessarily have to go through these species. However, since my experiments suggest that this reaction occurs with difficulty if it occurs at all, this implies the presence of intermediate species which act as energy barriers. Elemental iodine and hypoiodite are two possibilities.

The oxidation of iodide to elemental iodine is thermodynamically unfavorable in a basic solution (sections IV.2 and IV.4), but there is evidence suggesting that organisms can use enzymes, such as iodide oxidase, to cata-lyze the reaction (Shaw, 1959; section IV.5). If elemental iodine is formed, it may be transformed to iodate chemically via hypoiodite by hydrolysis and disproportionation. However, other molecules may compete for hypoiodite and reduce it to the -1 oxidation state. Thus, two cycles may be involved

$$(1) \quad I^- \longrightarrow I_2 \longrightarrow IO^- \longrightarrow I^- \qquad \text{(IV-8-1)}$$

$$(2) \quad I^- \longrightarrow I_2 \longrightarrow IO^- \longrightarrow IO_3^- \longrightarrow I^- \qquad \text{(IV-8-2)}$$
Apparently, cycle (1) proceeds much faster than cycle (2). However, once iodate is formed through cycle (2), it will remain stable in sea water. The only known way to remove

Fig. IV-8-1 A possible oceanic iodine cycle.

iodate in the open ocean is by bacterial reduction to form iodide (Tsunogai and Sase, 1969). This reduction of iodate is thermodynamically unfavorable and a biological mediation must be invoked.

CHAPTER V. CONCLUDING REMARKS

Reliable analytical methods have been developed for the determination of iodate, iodide and particulate iodine in sea water. These techniques are straightforward and their precisions are sufficient for studying the variations in the marine environments.

In addition to physical processes such as advection and diffusion, the distribution and speciation of dissolved iodine in the ocean seem to be controlled by redox potential changes and biological activity also. The drastic shift in redox potential from oxygenated to sulfide-bearing water in anoxic basins brings about accompanying reduction of iodate to iodide as predicted from thermodynamic considerations. In the open oceans, the occurrence of iodide is confined to the euphotic zone and the iodate concentrations at corresponding depths are low. This distribution is consistent with the suggestion that iodide is produced by the enzymatic reduction of iodate by organisms (Tsunogai and Sase, 1969). In coastal waters, the speciation and distribution of iodine may also be affected by the seasonal changes in productivity. Particulate iodine also plays an important role in the cycling of iodine in the ocean. Relative to rocks and minerals, marine suspended matter has much higher iodine content. The iodine-containing particles seem to be biogenic. The concentration of particulate iodine is highest in the euphotic zone and it drops sharply with depth to a background level. This dis-

tribution is similar to the distributions of bioactive elements such as phosphorus and nitrogen in marine suspended matter. The standing crops of particulate iodine in the top 200 m also seem to correlate with surface productivity. The preferential dissolution of particles in strong pycnocline also affects the distribution of dissolved iodine in the water column. The thermodynamically favorable autoxidation of iodide to iodate in sea water may also be mediated by biological activity. Iodide seems to be quite stable in sea water. I was not able to show the oxidation of iodide to iodate at a measurable rate. On the other hand, elemental iodine is extremely unstable with a life time of seconds to minutes in sea water. Thus, elemental iodine must be produced at a very fast rate if it is the vehicle for the transfer of iodine from the oceans to the atmosphere as suggested by Miyake and Tsunogai (1963). The diffusion of iodine from the sediments into the water column probably occurs in the Black Sea. However, in the open ocean, this process is not clearly evident from the distribution of iodide in the bottom water.

There are still discrepancies in our understanding of the marine geochemistry of iodine. Some of the major gaps in our knowledge are: (1) the form and physiological functions of iodine in marine organisms; (2) the rate and products of the re-mineralization of iodine in organisms; (3) the possible diagensis of iodine in the sediments and

subsequent diffusion of iodine into the bottom water; (4) the agent for the transfer of iodine from the ocean into the atmosphere; and (5) the interconversion among the oxidized and reduced species of iodine via biological and chemical processes. This study has defined the importance of, pointed out the possible answers to and provided some of the necessary tools for future investigations of these questions.
