# ON GEOMETRICAL PROPERTIES OF PRECONDITIONERS IN IPMS FOR CLASSES OF BLOCK-ANGULAR PROBLEMS* 

JORDI CASTRO $\dagger$ AND STEFANO NASINI $\ddagger$

#### Abstract

One of the most efficient interior-point methods for some classes of block-angular structured problems solves the normal equations by a combination of Cholesky factorizations and preconditioned conjugate gradient for, respectively, the block and linking constraints. In this work we show that the choice of a good preconditioner depends on geometrical properties of the constraints structure. In particular, it is seen that the principal angles between the subspaces generated by the diagonal blocks and the linking constraints can be used to estimate ex-ante the efficiency of the preconditioner. Numerical validation is provided with some generated optimization problems. An application to the solution of multicommodity network flow problems with nodal capacities and equal flows of up to 127 million of variables and up to 7.5 million of constraints is also presented.

Key words. interior-point methods, structured problems, preconditioned conjugate gradient, principal angles, large-scale optimization

AMS subject classifications. 90C06, 90C08, 90C51

1. Introduction. Many real-world optimization problems exhibit a primal block-angular structure, where decision variables and constraints can be grouped in different blocks which are dependent due to some linking constraints Applications of this class of problems can be found, for instance, in multicommodity telecommunications networks, statistical data protection, multistage control and planning, and complex networks.

Solution strategies to deal with this class of problems can be broadly classified into simplex-based methods [14, 22], decomposition methods [16, 1, 2, 26], approximation methods [5], and interiorpoint methods [10, 20] One of the most efficient interior-point methods (IPMs) for some classes of block-angular problems solves normal equations by a combination of Cholesky factorizations for the block constraints and preconditioned conjugate gradient (PCG) iterations for the linking constraints $[10,11]$. The spectral radius of a certain matrix in the preconditioner, which is always in $[0,1)$ plays an important role in the efficiency of this approach. It was observed that for separable convex problems with nonzero Hessians this spectral radius is reduced, and the PCG becomes more efficient [13]. When the spectral radius approaches 1 , switching to a suitable preconditioner may be an efficient alternative [7]. It is worth noting that computing approximate Newton directions by PCG does not destroy the good convergence properties of IPMs, as shown in [19]. There is an extensive literature on the use of PCG within IPMs for other types of problems (e.g., [3, 4, 9, 17, 24, 27] to mention a few).

However, it is not yet clear why for some classes of block-angular problems the above approach may be very efficient (see, for instance, the results of [13, 12]), while it may need a large number of PCG iterations in others. The spectral radius may be used to monitor the good or bad behaviour, but an ex-ante explanation has to be found in the structural information of the block-angular constraints matrix. The purpose of this paper is to provide such a explanation by considering geometrical properties of the primal block-angular matrix structure which, in addition, may be used to improve the preconditioning in some instances. It will be shown that the principal angles between the subspaces generated by the diagonal blocks and the ones generated by the linking constraints play an important role, explaining the efficiency of the approach and providing a proper choice of the preconditioner.

This paper is organized as follows. Section 2 outlines the specialized IPM for primal blockangular problems. Section 3 analyses the quality of preconditioning techniques based on geometrical and spectral properties. This analysis is used to obtain new complementary preconditioners to deal with orthogonality and collinearity of the subspaces generated by the diagonal blocks and the ones generated by the linking constraints. Section 4 provides a numerical validation of the analysis in previous section. This is based on both a simulation analysis of the effect of geometrical relations on PCG iterations-Subsection 4.1-and a real world application to multicommodity network flow problems with nodal capacities-Subsection 4.2 -, where the analyzed geometrical properties can be fully exploited.

[^0]2. Outline of the IPM for primal block-angular problems. The primal block-angular formulation dealt with by the algorithm is
\[

$$
\begin{align*}
& \min \sum_{i=0}^{k}\left(c^{i}\right)^{\top} x^{i}  \tag{2.1a}\\
& \text { subject to } {\left[\begin{array}{ccccc}
N_{1} & & & \\
& N_{2} & & & \\
& & \ddots & & \\
& & & N_{k} & \\
L_{1} & L_{2} & \ldots & L_{k} & I
\end{array}\right]\left[\begin{array}{c}
x^{1} \\
x^{2} \\
\vdots \\
x^{k} \\
x^{0}
\end{array}\right]=\left[\begin{array}{c}
b^{1} \\
b^{2} \\
\vdots \\
b^{k} \\
b^{0}
\end{array}\right] }  \tag{2.1b}\\
& 0 \leq x^{i} \leq u^{i}  \tag{2.1c}\\
& i=0, \ldots, k .
\end{align*}
$$
\]

Matrices $N_{i} \in \mathbb{R}^{m_{i} \times n_{i}}$ and $L_{i} \in \mathbb{R}^{l \times n_{i}}, i=1, \ldots, k$, respectively define the block-diagonal and linking constraints, $k$ being the number of blocks. Vectors $x^{i} \in \mathbb{R}^{n_{i}}, i=1, \ldots, k$, are the variables for each block. $x^{0} \in \mathbb{R}^{l}$ are the slacks of the linking constraints. $b^{i} \in \mathbb{R}^{m_{i}}, i=1, \ldots, k$, is the right-hand side vector for each block of constraints, whereas $b^{0} \in \mathbb{R}^{l}$ is for the linking constraints. The upper bounds for each group of variables are defined by $u^{i} \in \mathbb{R}^{n_{i}}, i=0, \ldots, k$. Problems with equality linking constraints can be formulated by setting $u^{0}=0$. The total number of constraints and variables of (2.1) is thus, respectively, $\widetilde{m}=l+\sum_{i=1}^{k} m_{i}$ and $\widetilde{n}=l+\sum_{i=1}^{k} n_{i}$. Formulation (2.1) is a very general model which accommodates to several block-angular problems.

In this work we consider the specialized IPM of $[10,11]$. Briefly, this approach requires the solution at each interior-point iteration of the normal equations system $A \Theta A^{\top} \Delta y=g$, where $A \in \mathbb{R}^{\widetilde{m} \times \tilde{n}}$ is the constraints matrix of $(2.1 \mathrm{~b}) ; \Theta=\left(W(U-X)^{-1}+Z X^{-1}\right)^{-1} \in \mathbb{R}^{\tilde{n}}$ is a diagonal matrix computed from the values $(x, w, z) \in \mathbb{R}^{3 \widetilde{n}}$ of the current primal-dual point-w and $z$ being the Lagrange multipliers associated to, respectively, upper and lower bounds; $\Delta y \in \mathbb{R}^{\widetilde{m}}$ is the direction of movement for the Lagrange multipliers of equality constraints $y$; and $g \in \mathbb{R}^{\widetilde{m}}$ is some right-hand-side. A derivation of the normal equations can be found in [28].

Exploiting the block structure of $A$ and $\Theta$ we have

$$
\begin{align*}
A \Theta A^{\top} \Delta y & =\left[\begin{array}{ccc|c}
N_{1} \Theta_{1} N_{1}^{\top} & & & N_{1} \Theta_{1} L_{1}^{\top} \\
& \ddots & & \vdots \\
& & N_{k} \Theta_{k} N_{k}^{\top} & N_{k} \Theta_{k} L_{k}^{\top} \\
\hline & & & \\
L_{1} \Theta_{1} N_{1}^{\top} & \ldots & L_{k} \Theta_{k} N_{k}^{\top} & \Theta_{0}+\sum_{i=1}^{k} L_{i} \Theta_{i} L_{i}^{\top}
\end{array}\right] \Delta y  \tag{2.2}\\
& =\left[\begin{array}{cc}
B & C \\
C^{\top} & D
\end{array}\right]\left[\begin{array}{c}
\Delta y_{1} \\
\Delta y_{2}
\end{array}\right]=g,
\end{align*}
$$

where $\Delta y_{1}$ and $\Delta y_{2}$ are the components of $\Delta y$ associated to, respectively, block and linking constraints; and $\Theta_{i}=\left(W_{i}\left(U_{i}-X_{i}\right)^{-1}+Z_{i} X_{i}^{-1}\right)^{-1}, i=0, \ldots, k$, are the blocks of $\Theta$. By eliminating $\Delta y_{1}$ from the first group of equations of (2.2), we obtain

$$
\begin{align*}
\left(D-C^{\top} B^{-1} C\right) \Delta y_{2} & =g_{1}  \tag{2.3a}\\
B \Delta y_{1} & =g_{2}, \tag{2.3b}
\end{align*}
$$

for a proper partition of the right-hand side into $g_{1}$ and $g_{2}$. The specialized IPM for this class of problems solves (2.3) by a combination of $k$ Cholesky factorizations, for the systems involving $B$ and PCG for (2.3a). Indeed, matrix $D-C^{\top} B^{-1} C \in \mathbb{R}^{l \times l}$ of (2.3a), whose dimension is the number of linking constraints, is symmetric and positive definite, since it is the Schur complement of the normal equations (2.2), which are symmetric and positive definite. System (2.3a) can thus be solved by PCG. A good preconditioner is instrumental. $D-C^{\top} B^{-1} C$ is a $P$-regular splitting, i.e., it is symmetric and positive definite, $D$ is nonsingular and $D+C^{\top} B^{-1} C$ is positive definite. Therefore the $P$-regular splitting theorem [25] guarantees that

$$
\begin{equation*}
0<\rho\left(D^{-1}\left(C^{\top} B^{-1} C\right)\right)<1 \tag{2.4}
\end{equation*}
$$

where $\rho(\cdot)$ denotes the spectral radius of a matrix (i.e., the maximum absolute eigenvalue). This allows us to compute the inverse of $D-C^{\top} B^{-1} C$ as the following infinite power series (see [10, Prop.

4] for a proof).

$$
\begin{equation*}
\left(D-C^{\top} B^{-1} C\right)^{-1}=\left(\sum_{i=0}^{\infty}\left(D^{-1}\left(C^{\top} B^{-1} C\right)\right)^{i}\right) D^{-1} \tag{2.5}
\end{equation*}
$$

A preconditioner is thus obtained by truncating the infinite power series (2.5) at some term. The more the terms included, the better the preconditioner will be, at the expense of increasing the execution time of each PCG iteration. If we only include the first term, or the first and second terms, of the infinite power series (2.5) the resulting preconditioners will be, respectively, $D^{-1}$ or $\left(I+D^{-1}\left(C^{\top} B^{-1} C\right)\right) D^{-1}$. As shown in [12], in most test problems $D^{-1}$ was the best option for the tradeoff between being a good and an efficient preconditioner. Thus, in this work we will focus on the first term preconditioner $D^{-1}$. Although the expected performance for a general primal blockangular matrix is problem dependent, the effectiveness of the preconditioner obtained by truncating the infinite power series (2.5) is governed by the spectral radius $\rho\left(D^{-1}\left(C^{\top} B^{-1} C\right)\right)$-the farther from 1 , the better [13] - and the structure of $D$, as each PCG iteration requires the solution of a system with this matrix.

The spectral radius tends to approach 1 when the IPM is close to the optimal solution. For this reason a hybrid preconditioner was introduced in [7]: the power series preconditioner (either $D^{-1}$ or $\left.\left(I+D^{-1}\left(C^{\top} B^{-1} C\right)\right) D^{-1}\right)$ is used in the initial IPM iterations, switching to the splitting preconditioner [24] when the former becomes inefficient. The above hybrid scheme is supported by the known good behaviour of the splitting preconditioner near the solution of the linear optimization problem. Briefly, given the normal equations matrix $A \Theta A^{\top}$, the splitting preconditioner is based on a partition of the columns of $A$ into basic and nonbasic columns, forming the nonsingular basic matrix $A_{B} \in \mathbb{R}^{\widetilde{m} \times \widetilde{m}}$ and the nonbasic one $A_{N} \in \mathbb{R}^{\widetilde{m} \times(\widetilde{n}-\widetilde{m})}$, respectively. Applying the same partition to $\Theta$, the normal equations matrix can be rewritten as

$$
\begin{equation*}
A \Theta A^{\top}=A_{B} \Theta_{B} A_{B}^{\top}+A_{N} \Theta_{N} A_{N}^{\top} \tag{2.6}
\end{equation*}
$$

The splitting preconditioner is thus $\Theta_{B}^{-1 / 2} A_{B}^{-1}$. The symmetric application of this preconditioner to $A \Theta A^{\top}$ gives:

$$
\begin{align*}
\left(\Theta_{B}^{-1 / 2} A_{B}^{-1}\right)\left(A \Theta A^{\top}\right)\left(\Theta_{B}^{-1 / 2} A_{B}^{-1}\right)^{\top} & =\Theta_{B}^{-1 / 2} A_{B}^{-1}\left(A_{B} \Theta_{B} A_{B}^{\top}+A_{N} \Theta_{N} A_{N}^{\top}\right) A_{B}^{-T} \Theta_{B}^{-1 / 2} \\
& =I+\left(\Theta_{B}^{-1 / 2} A_{B}^{-1} A_{N} \Theta_{N}^{1 / 2}\right)\left(\Theta_{B}^{-1 / 2} A_{B}^{-1} A_{N} \Theta_{N}^{1 / 2}\right)^{\top} \tag{2.7}
\end{align*}
$$

Sufficiently close to an optimal solution, with a suitable choice of the columns of $A_{B}$, the diagonal entries of $\Theta_{B}^{-1}$ and $\Theta_{N}$ are very small and $\left(\Theta_{B}^{-1 / 2} A_{B}^{-1} A_{N} \Theta_{N}^{-1 / 2}\right)$ approaches the zero matrix. Some strategies for identifying a suitable matrix $A_{B}$ are discussed in [24, 7].

This specialized IPM has been recently implemented in a software package called BlockIP [12], that will be used for the computational results of this paper.
3. Analysis of preconditioning techniques for block-angular problems. The main source of difficulty in solving a primal block-angular problem of the form (2.1) is the presence of linearly independent linking constraints, $L_{1} x_{1}+L_{2} x_{2}+\ldots+L_{k} x_{k} \leq b_{0}$. Consider the lucky-and unlikelycase where $A$ is such that for every $i=1 \ldots k$ each row vector of $L_{i}$ belongs to the column space of $N_{i}^{\top}$ (linearly dependent linking constraints). By the definition of $B, C$ and $D$ in (2.2), we may write

$$
\begin{align*}
C^{\top} B^{-1} C & =\sum_{i=1}^{k} L_{i} \Theta_{i} N_{i}^{\top}\left(N_{i} \Theta_{i} N_{i}^{\top}\right)^{-1} N_{i} \Theta_{i} L_{i}^{\top}  \tag{3.1}\\
& =\sum_{i=1}^{k} L_{i} \Theta_{i}^{1 / 2} P_{i} \Theta_{i}^{1 / 2} L_{i}^{\top}
\end{align*}
$$

where

$$
\begin{equation*}
P_{i}=\Theta_{i}^{1 / 2} N_{i}^{\top}\left(N_{i} \Theta_{i} N_{i}^{\top}\right)^{-1} N_{i} \Theta_{i}^{1 / 2} \quad i=1, \ldots, k \tag{3.2}
\end{equation*}
$$

is the projection operator onto $\mathcal{R}\left(\Theta_{i}^{1 / 2} N_{i}^{\top}\right)$, the range or column space of $\Theta_{i}^{1 / 2} N_{i}^{\top}$. If each column vector of $\Theta_{i}^{1 / 2} L_{i}^{\top}$ belongs to $\mathcal{R}\left(\Theta_{i}^{1 / 2} N_{i}^{\top}\right)$ (which is equivalent to say that the row vectors of $L_{i}$ might be written as a linear combination of the row vectors of $N_{i}$ ) then $P_{i} \Theta_{i}^{1 / 2} L_{i}^{\top}=\Theta_{i}^{1 / 2} L_{i}^{\top}$, as $P_{i}$ is the
identity operator of the subspace generated by the columns of $\Theta_{i}^{1 / 2} N_{i}^{\top}$, and

$$
\begin{align*}
D-C^{\top} B^{-1} C & =D-\sum_{i=1}^{k} L_{i} \Theta_{i}^{1 / 2} P_{i} \Theta_{i}^{1 / 2} L_{i}^{\top}  \tag{3.3}\\
& =D-\sum_{i=1}^{k} L_{i} \Theta_{i} L_{i}^{\top}=\Theta_{0}
\end{align*}
$$

On the contrary, if each column vector of $\Theta_{i}^{1 / 2} L_{i}^{\top}$ belongs to $\mathcal{N}\left(N_{i} \Theta_{i}^{1 / 2}\right)$, the null space of $N_{i} \Theta_{i}^{1 / 2}$, then $P_{i} \Theta_{i}^{1 / 2} L_{i}^{\top}=0$ and

$$
\begin{equation*}
D-C^{\top} B^{-1} C=D-\sum_{i=1}^{k} L_{i} \Theta_{i}^{1 / 2} P_{i} \Theta_{i}^{1 / 2} L_{i}^{\top}=D \tag{3.4}
\end{equation*}
$$

Thus $\Theta_{0}^{-1}$ and $D^{-1}$ would be the inverse (i.e., the exact preconditioners) of $D-C^{\top} B^{-1} C$ when, for $i=1 \ldots k$, each column vector of $\Theta_{i}^{1 / 2} L_{i}^{\top}$ belongs to either $\mathcal{R}\left(\Theta_{i}^{1 / 2} N_{i}^{\top}\right)$ or $\mathcal{N}\left(N_{i} \Theta_{i}^{1 / 2}\right)$, respectively. Needless to say, these two extreme cases will rarely appear in a real problem; for instance, when $\Theta_{i}^{1 / 2} L_{i}^{\top}$ belongs to $\mathcal{R}\left(\Theta_{i}^{1 / 2} N_{i}^{\top}\right)$ the linking constraints are redundant and can be removed, obtaining a block-separable problem. However, as seen in next subsection, they allow to decide whether $D$ or $\Theta_{0}$ will be a good preconditioner for (2.3a), and which of them will theoretically behave better.
3.1. Geometrical and spectral properties. According to previous discussion, the goodness of the approximation of $\Theta_{0}^{-1}$ and $D^{-1}$ to $\left(D-C^{\top} B^{-1} C\right)^{-1}$ might be measured by the principal angles between the range spaces of $\Theta_{i}^{1 / 2} N_{i}^{\top}$ and $\Theta_{i}^{1 / 2} L_{i}^{\top}$, for $i=1, \ldots, k$. The principal angles provide information about the relative position of two subspaces of an inner product space. Consider two subspaces $\mathcal{L}_{\Theta}$ and $\mathcal{N}_{\Theta}$ of $\mathbb{R}^{n}$, with $\operatorname{dim} \mathcal{L}_{\Theta}=l$, $\operatorname{dim} \mathcal{N}_{\Theta}=m$, and $q=\min \{l, m\}$. The principal angles between $\mathcal{L}_{\Theta}$ and $\mathcal{N}_{\Theta}$, denoted as $0 \leq \gamma_{1} \leq \ldots \leq \gamma_{q} \leq \pi / 2$, are obtained by solving for $j=1, \ldots, q$ this sequence of optimization problems [6][18, Chapter 12]:

$$
\begin{align*}
& \cos \left(\gamma_{j}\right)=\max _{u, v} u^{\top} v  \tag{3.5}\\
& \text { subject to }\|u\|=1,\|v\|=1  \tag{3.6}\\
&  \tag{3.7}\\
& \quad u \in \mathcal{L}_{\Theta}, v \in \mathcal{N}_{\Theta}  \tag{3.8}\\
& \\
& u^{\top} v_{k}=0, u^{\top} u_{k}=0, k=1 \ldots j-1,
\end{align*}
$$

$u_{j} \in \mathbb{R}^{n}$ and $v_{j} \in \mathbb{R}^{n}$ being the optimal vectors. In other words, for $j=1$ the procedure finds the unit vectors $u_{1} \in \mathcal{L}_{\Theta}$ and $v_{1} \in \mathcal{N}_{\Theta}$ which minimize the angle between them-named $\gamma_{1}$. For $j>1$, the procedure considers the orthogonal complements of $\operatorname{span}\left\{u_{1}, \ldots, u_{j-1}\right\}$ in $\mathcal{L}_{\Theta}$ and of $\operatorname{span}\left\{v_{1}, \ldots, v_{j-1}\right\}$ in $\mathcal{N}_{\Theta}$, and computes a new pair of vectors $u_{j}, v_{j}$ in the above subspaces minimizing the angle $\gamma_{j}$. In our case, we have that $\mathcal{L}_{\Theta}=\mathcal{R}\left(\Theta_{i}^{1 / 2} L_{i}^{\top}\right)$ and $\mathcal{N}_{\Theta}=\mathcal{R}\left(\Theta_{i}^{1 / 2} N_{i}^{\top}\right)$. The vectors $\left\{u_{1}, \ldots, u_{q}\right\}$ and $\left\{v_{1}, \ldots, v_{q}\right\}$ are called principal vectors, associated to principal angles $\left\{\gamma_{1}, \ldots, \gamma_{q}\right\}$. The principal angles between subspaces can be graphically depicted as in Figure 1. If $q=m=l$, the distance between the equidimensional subspaces $\mathcal{L}_{\Theta}$ and $\mathcal{N}_{\Theta}$ is defined as $\sin \gamma_{q}=\sqrt{1-\cos ^{2} \gamma_{q}}[18$, Chapter 2].

Principal angles between two subspaces can be computed by the singular value decomposition, as shown by next theorem from [6] (procedure also described in [18, Chapter 12]):

Theorem 3.1. Let the columns of matrices $Q_{L} \in \mathbb{R}^{n \times l}$ and $Q_{N} \in \mathbb{R}^{n \times m}$ form orthonormal bases for the subspaces $\mathcal{L}$ and $\mathcal{N}$, correspondingly. Principal vectors $u \in \mathbb{R}^{n}$ and $v \in \mathbb{R}^{n}$ must verify $u=Q_{L} \widetilde{u}$ and $v=Q_{N} \widetilde{v}$, where $\widetilde{u} \in \mathbb{R}^{l}$ and $\widetilde{v} \in \mathbb{R}^{m}$ are left and right singular vectors of $Q_{L}^{\top} Q_{N}$, associated to the singular value $\cos (\gamma(u, v))$, that is to say, $\left(Q_{L}^{\top} Q_{N}\right) \widetilde{v}=\cos (\gamma(u, v)) \widetilde{u}$.

The algorithm of Figure 2 outlines how to compute the principal angles of column spaces of matrices $L^{\top} \in \mathbb{R}^{n \times l}$ and $N^{\top} \in \mathbb{R}^{n \times m}$. The algorithm is just provided for completeness; as it will be shown later, it does not need to be used in practice. Indeed, its use would be prohibitive since the required singular value decomposition may be computationally very expensive for large optimization problems.

As $\Theta_{i}, i=1, \ldots, k$, are different at each interior-point iteration, the principal angles between the subspaces $\mathcal{L}_{\Theta_{i}}$ and $\mathcal{N}_{\Theta_{i}}$ also change. Accordingly, the goodness of the approximation of $\Theta_{0}^{-1}$ and $D^{-1}$ to $\left(D-C^{\top} B^{-1} C\right)^{-1}$ dynamically changes along the interior-point iterations. Proposition 3.2

```

Fig. 2. Algorithm to compute principal angles between column spaces of $L^{\top}$ and $N^{\top}$.
below provides a lower bound of the cosine of principal angles of $\mathcal{L}_{\Theta}$ and $\mathcal{N}_{\Theta}$ as a function of the principal angles of $\mathcal{L}$ and $\mathcal{N}$.

Proposition 3.2. Consider the subspaces $\mathcal{L}=\mathcal{R}\left(L^{\top}\right) \subseteq \mathbb{R}^{n}$ and $\mathcal{N}=\mathcal{R}\left(N^{\top}\right) \subseteq \mathbb{R}^{n}$ and their image sets $\mathcal{L}_{\Theta}=\mathcal{R}\left(\Theta^{1 / 2} L^{\top}\right) \subseteq \mathbb{R}^{n}$ and $\mathcal{N}_{\Theta}=\mathcal{R}\left(\Theta^{1 / 2} N^{\top}\right) \subseteq \mathbb{R}^{n}$ under the linear transformation $\Theta^{1 / 2}$, where $\Theta$ is a positive diagonal matrix. Let $\gamma(u, v)$ be the first principal angle between $\mathcal{L}$ and $\mathcal{N}$, associated to principal vectors $u$ and $v$; and $\gamma_{\Theta}$ the first principal angle between $\mathcal{L}_{\Theta}$ and $\mathcal{N}_{\Theta}$. If $\mathcal{L}$ and $\mathcal{N}$ are not orthogonal, then

$$
\begin{equation*}
\cos \left(\gamma_{\Theta}\right) \geq \max \left\{0, \frac{\Theta_{c}}{\Theta_{\max }} \cos (\gamma(u, v))\right\} \tag{3.9}
\end{equation*}
$$

where $\Theta_{\min }$ and $\Theta_{\max }$ are the smallest and largest diagonal components of $\Theta$, and $\Theta_{c} \in\left[-\Theta_{\max }, \Theta_{\max }\right]$. If in addition $u_{i} v_{i} \geq 0$ for all $i=1, \ldots, n$ then we have

$$
\begin{equation*}
\cos \left(\gamma_{\Theta}\right) \geq \frac{\Theta_{\min }}{\Theta_{\max }} \cos (\gamma(u, v))>0 \tag{3.10}
\end{equation*}
$$

Proof. Let $\gamma\left(\frac{\Theta^{1 / 2} u}{\left\|\Theta^{1 / 2} u\right\|}, \frac{\Theta^{1 / 2} v}{\left\|\Theta^{1 / 2} v\right\|}\right)$ be the angle between the unitary transformed vectors $\frac{\Theta^{1 / 2} u}{\left\|\Theta^{1 / 2} u\right\|} \in$ $\mathcal{L}_{\Theta}$ and $\frac{\Theta^{1 / 2} v}{\left\|\Theta^{1 / 2} v\right\|} \in \mathcal{N}_{\Theta}$. From the definition of principal angles as resulting from the maximization problem (3.5)-(3.8), and since vectors $\frac{\Theta^{1 / 2} u}{\left\|\Theta^{1 / 2} u\right\|}$ and $\frac{\Theta^{1 / 2} v}{\left\|\Theta^{1 / 2} v\right\|}$ are feasible for this problem, we have

$$
\begin{equation*}
\cos \left(\gamma_{\Theta}\right) \geq \cos \left(\gamma\left(\frac{\Theta^{1 / 2} u}{\left\|\Theta^{1 / 2} u\right\|}, \frac{\Theta^{1 / 2} v}{\left\|\Theta^{1 / 2} v\right\|}\right)\right) \tag{3.11}
\end{equation*}
$$

Since $u, v$ are principal vectors, by (3.6) $\|u\|=\|v\|=1$. Moreover, since principal angles are always in $[0, \pi / 2]$, and we are assuming $\mathcal{L}$ and $\mathcal{N}$ are not orthogonal, we have

$$
\begin{equation*}
0<u^{\top} v=\|u\|\|v\| \cos (\gamma(u, v))=\cos (\gamma(u, v)) \leq 1 \tag{3.12}
\end{equation*}
$$

By definition of inner product, by (3.12), using that for any square matrix $M$ and vector $w\|M w\| \leq$ $\|M\|\|w\|$, and that $\sqrt{\Theta_{\max }} \geq\left\|\Theta^{1 / 2}\right\|$,

$$
\begin{align*}
\cos \left(\gamma\left(\frac{\Theta^{1 / 2} u}{\left\|\Theta^{1 / 2} u\right\|}, \frac{\Theta^{1 / 2} v}{\left\|\Theta^{1 / 2} v\right\|}\right)\right) & =\frac{u^{\top} \Theta v}{\left\|\Theta^{1 / 2} u\right\|\left\|\Theta^{1 / 2} v\right\|} \geq \frac{u^{\top} \Theta v}{\left\|\Theta^{1 / 2}\right\|^{2}\|u\|\|v\|} \geq  \tag{3.13}\\
& \geq \frac{1}{\Theta_{\max }} \frac{u^{\top} \Theta v}{u^{\top} v} \cos (\gamma(u, v)) \geq \frac{u^{\top} \Theta v}{\Theta_{\max }} \cos (\gamma(u, v))
\end{align*}
$$

Defining the set $\mathcal{P}=\left\{i \in\{1, \ldots, n\}: u_{i} v_{i} \geq 0\right\}$, since $\|u\|=\|v\|=1$ and $u^{\top} v \leq 1$, we have that

$$
\begin{equation*}
0 \leq \sum_{i \in \mathcal{P}} u_{i} v_{i} \leq 1 \quad \text { and } \quad-1 \leq \sum_{i \notin \mathcal{P}} u_{i} v_{i} \leq 0 \tag{3.14}
\end{equation*}
$$

Then, by (3.14),

$$
u^{\top} \Theta v=\sum_{i \in \mathcal{P}} \Theta_{i} u_{i} v_{i}+\sum_{i \notin \mathcal{P}} \Theta_{i} u_{i} v_{i} \geq \Theta_{\max } \sum_{i \notin \mathcal{P}} u_{i} v_{i} \geq-\Theta_{\max }
$$

and similarly,

$$
u^{\top} \Theta v=\sum_{i \in \mathcal{P}} \Theta_{i} u_{i} v_{i}+\sum_{i \notin \mathcal{P}} \Theta_{i} u_{i} v_{i} \leq \Theta_{\max } \sum_{i \in \mathcal{P}} u_{i} v_{i} \leq \Theta_{\max }
$$

Then, there is a $\Theta_{c} \in\left[-\Theta_{\max }, \Theta_{\max }\right]$ such that

$$
\begin{equation*}
\Theta_{c}=u^{\top} \Theta v \tag{3.15}
\end{equation*}
$$

Applying (3.15) in (3.13), and since, by definition, $\cos \left(\gamma_{\Theta}\right) \geq 0$, inequality (3.9) is proved.
If $u_{i} v_{i} \geq 0$ for all $i=1, \ldots, n$, we have

$$
\begin{equation*}
\frac{u^{\top} \Theta v}{u^{\top} v} \geq \frac{\Theta_{\min } u^{\top} v}{u^{\top} v}=\Theta_{\min } . \tag{3.16}
\end{equation*}
$$

Applying (3.16) to the penultimate term of (3.13) we get (3.10). $\square$
An important consequence of Proposition 3.2 is that we have no information about the principal angles in the final iterations, as $\Theta_{\min } / \Theta_{\max }$ can approach 0 and $\Theta_{c} / \Theta_{\max }$ can be any number in $[-1,1]$ when the iterative process gets close to the optimal solution. In the worst case, it may even happen that almost-collinear subspaces $\mathcal{L}$ and $\mathcal{N}$ become almost-orthogonal for some $\Theta$.

It is worth noting that the two extreme cases have opposite behaviour:

- If $\mathcal{L}$ and $\mathcal{N}$ are orthogonal (that is, their principal angles are $\pi / 2$ ), then, for a diagonal $\Theta$ matrix such that some component $\Theta_{i, i}$ is very large, and for other components $j \neq i \Theta_{j j} \approx 0$, the principal angles of $\mathcal{L}_{\Theta}$ and $\mathcal{N}_{\Theta}$ will become close to 0 . This is a limit case of (3.10).
- If $\mathcal{L} \subseteq \mathcal{N}$, then the principal angles are 0 . This means that, for some matrix $Y \in \mathbb{R}^{m \times l}$, $L^{\top}=N^{\top} Y$, thus $\left(\Theta^{1 / 2} L^{\top}\right)=\left(\Theta^{1 / 2} N^{\top}\right) Y$ and the principal angles of $\mathcal{L}_{\Theta}$ and $\mathcal{N}_{\Theta}$ will also be 0 . However this case is not of practical interest, since if $\mathcal{L} \subseteq \mathcal{N}$ then the linking constraints are redundant and can be removed.
A downside of the use of principal angles between subspaces for this purpose appears when $\mathcal{R}\left(L_{i}^{\top}\right)=\mathbb{R}^{n_{i}}$, for $i=1, \ldots, k$, such that $\mathcal{N}_{i} \subseteq \mathcal{L}_{i}$. In such case the principal angles are always zero, regardless of what $\mathcal{R}\left(N_{i}^{\top}\right)$ is. This happens, for instance, in multicommodity network flow problems [10] and edge-colored network problems [15], where $L_{i}=I$, for $i=1, \ldots, k$. Since our interest is on whether linking constraints belong to $\mathcal{R}\left(N_{i}^{\top}\right)$, and not the opposite, a more sensible approach would be to provide the average of the principal angles between the $l$ constraints of $L_{i}$ and $\mathcal{R}\left(N_{i}^{\top}\right)$. This procedure has the added benefit that the computation of each single principal angle through (3.5)(3.8) is highly simplified. In particular, denoting by $L_{i, j}$ the vector associated to the $j$-th constraint of $L_{i},(3.5)-(3.8)$ reduces to

$$
\cos (\gamma)=\quad \max _{x \in \mathbb{R}^{m_{i}}} \quad c^{\top} x \quad \begin{gathered}
\text { where } \quad c=N_{i} \frac{L_{i, j}}{\left\|L_{i, j}\right\|}, ~
\end{gathered}
$$

whose solution can be directly computed as

$$
x=\left(N_{i} N_{i}^{\top}\right)^{-1} \frac{c}{2 \lambda} \quad \text { where } \quad \lambda=\frac{1}{2} \sqrt{c^{\top}\left(N_{i} N_{i}^{\top}\right)^{-1} c}
$$

As shown below, the goodness of the dynamical approximation of $\Theta_{0}^{-1}$ and $D^{-1}$ to $(D-$ $\left.C^{\top} B^{-1} C\right)^{-1}$ along the interior-point iterations is related to the changes in the spectral radius of matrix $D^{-1}\left(C^{\top} B^{-1} C\right)$ —which is always in $[0,1)[10$, Theorem 1]. Since $D$ is the first term of the power series (2.5), the farther away from 1 is the spectral radius of $D^{-1}\left(C^{\top} B^{-1} C\right)$ the better is the quality of the approximation of the first few terms of (2.5). Although the particular behavior of the spectral radius value is problem dependent, in general, it comes closer to 1 as we approach the optimal solution, because of the ill-conditioning of the $\Theta$ matrix. Next result provides a clear relationship between the spectral radius of $D^{-1}\left(C^{\top} B^{-1} C\right)$ and the projection operators in the subspaces $\mathcal{L}_{\Theta}$ and $\mathcal{N}_{\Theta}$.

Proposition 3.3. Let $\lambda$ be an arbitrary eigenvalue of $D^{-1}\left(C^{\top} B^{-1} C\right)$. If each column vector of $\Theta_{i}^{1 / 2} L_{i}^{\top}$ belongs to $\mathcal{R}\left(\Theta_{i}^{1 / 2} N_{i}^{\top}\right)$ then

$$
\begin{equation*}
\lambda=\frac{r^{\top}\left(\sum_{i=1}^{k} L_{i} \Theta_{i} L_{i}^{\top}\right) r}{r^{\top} D r} \tag{3.17}
\end{equation*}
$$

where $r$ is the corresponding eigenvector associated to $\lambda$. On the contrary, if each column vector of $\Theta_{i}^{1 / 2} L_{i}^{\top}$ belongs to $\mathcal{N}\left(N_{i} \Theta_{i}^{1 / 2}\right)$, the null space of $N_{i} \Theta_{i}^{1 / 2}$, then

$$
\begin{equation*}
\lambda=0 \tag{3.18}
\end{equation*}
$$

Proof. Eigenvalue $\lambda$ of $D^{-1}\left(C^{\top} B^{-1} C\right)$ satisfies $\left(C^{\top} B^{-1} C\right) r=\lambda D r$ for some eigenvector $r$. From the definition of $C, B, D$ in (2.2) and projection matrices $P_{i}$ in (3.2) we have

$$
\left(\sum_{i=1}^{k} L_{i} \Theta_{i} N_{i}^{\top}\left(N_{i} \Theta_{i} N_{i}^{\top}\right)^{-1} N_{i} \Theta_{i} L_{i}^{\top}\right) r=\lambda D r
$$

is equivalent to

$$
(1-\lambda) D r=\left(\Theta_{0}+\sum_{i=1}^{k} L_{i} \Theta_{i} L_{i}^{\top}\right) r-\left(\sum_{i=1}^{k} L_{i} \Theta_{i} N_{i}^{\top}\left(N_{i} \Theta_{i} N_{i}^{\top}\right)^{-1} N_{i} \Theta_{i} L_{i}^{\top}\right) r
$$

which implies

$$
\begin{equation*}
(1-\lambda)=\frac{r^{\top} \Theta_{0} r+r^{\top}\left(\sum_{i=1}^{k} L_{i} \Theta_{i}^{1 / 2}\left(I-P_{i}\right) \Theta_{i}^{1 / 2} L_{i}^{\top}\right) r}{r^{\top} D r} \tag{3.19}
\end{equation*}
$$

From this expression and applying the definition of $W_{\mathcal{R}}$ and $W_{\mathcal{N}}$

$$
\begin{equation*}
W_{\mathcal{N}}=\sum_{i=1}^{k} L_{i} \Theta_{i}^{1 / 2}\left(I-P_{i}\right) \Theta_{i}^{1 / 2} L_{i}^{\top} \quad \text { and } \quad W_{\mathcal{R}}=\sum_{i=1}^{k} L_{i} \Theta_{i}^{1 / 2} P_{i} \Theta_{i}^{1 / 2} L_{i}^{\top} \tag{3.20}
\end{equation*}
$$

we find the following identities

$$
\begin{equation*}
\lambda=\frac{r^{\top}\left(\sum_{i=1}^{k} L_{i} \Theta_{i} L_{i}^{\top}\right) r-r^{\top} W_{\mathcal{N}} r}{r^{\top} D r}=\frac{r^{\top} W_{\mathcal{R}} r}{r^{\top} D r} . \tag{3.21}
\end{equation*}
$$

It turns out that $r^{\top} W_{\mathcal{N} r}=0$ when each column vector of $\Theta_{i}^{1 / 2} L_{i}^{\top}$ belongs to $\mathcal{R}\left(\Theta_{i}^{1 / 2} N_{i}^{\top}\right)$; and $r^{\top} W_{\mathcal{R}} r=0$ when each column vector of $\Theta_{i}^{1 / 2} L_{i}^{\top}$ belongs to $\mathcal{N}\left(N_{i} \Theta_{i}^{1 / 2}\right)$. The proof is complete.

Note that a clear lesson from Proposition 3.3 is that the spectral radius might be small even in the case of almost collinearity between the row vectors of $L_{i} \Theta_{i}^{1 / 2}$ and their projections into $\mathcal{R}\left(\Theta_{i}^{1 / 2} N_{i}^{\top}\right)$, when $r^{\top} \Theta_{0} r \gg r^{\top}\left(\sum_{i=1}^{k} L_{i} \Theta_{i} L_{i}^{\top}\right) r$. This means that, although $\Theta_{0}$ is in theory a better preconditioner in case of almost collinearity, in practice it can be even outperformed by $D$. This is consistent with

Table 1
CPU time of BlockIP using $D^{-1}$ and $\Theta_{0}^{-1}$ preconditioners. The instances have $l=100$ linking constraints and $k=100$ equal diagonal block matrices $N \in \mathbb{R}^{10 \times 50}$.

some of the computational results of sections 4-4.2, and with Theorem 1 of [13], which stated that the spectral radius $\rho$ of $D^{-1}\left(C^{\top} B^{-1} C\right)$ is bounded by

$$
\begin{equation*}
0 \leq \rho \leq \max _{j \in\{1, \ldots, l\}} \frac{\gamma_{j}}{\left(\frac{u_{j}}{v_{j}}\right)^{2} \Theta_{0 j}+\gamma_{j}}<1 \tag{3.22}
\end{equation*}
$$

where $u$ is the eigenvector (or one of the eigenvectors) of $D^{-1}\left(C^{\top} B^{-1} C\right.$ ) for $\rho ; \gamma_{j}, j=1, \ldots, l$, and $V=\left[V_{1} \ldots V_{l}\right]$, are respectively the eigenvalues and matrix of columnwise eigenvectors of $\sum_{i=1}^{k} L_{i} \Theta_{i} L_{i}{ }^{\top}$; $v=V^{\top} u$ (and, abusing of notation, we assume that for $v_{j}=0,\left(u_{j} / v_{j}\right)^{2}=+\infty$ ). Clearly, from (3.22), the larger $\Theta_{0}$, the closer $\rho$ to 0 , which it is also concluded from (3.17).
4. Numerical validation. The numerical validation of the proposed preconditioning technique is based on two types of computational experiments: i) assessing the effect of the described geometrical relations to the number of PCG iterations; ii) analyzing the global numerical performance of both preconditioning techniques, when applied to classes of multicommodity network flow problems. All the runs were carried out on a Fujitsu Primergy RX300 server with 3.33 GHz Intel Xeon X5680 CPUs (24 cores) and 144 GB of RAM, under a GNU/Linux operating system (Suse 11.4), without exploitation of multithreading capabilities.
4.1. Geometrical relations and PCG iterations. Consider two full rank matrices $N \in$ $\mathbb{R}^{m \times n}, n>m$, and $Y \in \mathbb{R}^{l \times m}, n>l$, and let $L=Y N$. The rows of $L \in \mathbb{R}^{l \times n}$ are linear combinations of the rows of $N$ and the principal angles between the subspaces generated by $L^{\top}$ and $N^{\top}$ are zero. Each vector in $\mathcal{R}\left(L^{\top}\right)$ can be rotated an angle $\alpha$ around the $i^{\text {th }}$ and $j^{\text {th }}$ coordinate axes by pre-multiplying $L^{\top}$ by the $n \times n$ rotation matrix:

$$
R_{i j}(\alpha)=\left[\begin{array}{ccccccccc}
1 & \cdots & 0 & 0 & \cdots & 0 & 0 & \cdots & 0  \tag{4.1}\\
\vdots & \ddots & \vdots & 0 & \cdots & 0 & \vdots & \ddots & \vdots \\
0 & \cdots & \cos (\alpha) & 0 & \cdots & 0 & -\sin (\alpha) & \cdots & 0 \\
0 & \cdots & 0 & 1 & \cdots & 0 & 0 & \cdots & 0 \\
\vdots & \ddots & \vdots & \vdots & \cdots & \vdots & \vdots & \ddots & \vdots \\
0 & \cdots & 0 & 0 & \cdots & 1 & 0 & \cdots & 0 \\
0 & \cdots & -\sin (\alpha) & 0 & \cdots & 0 & \cos (\alpha) & \cdots & 0 \\
\vdots & \ddots & \vdots & \vdots & \cdots & \vdots & \vdots & \ddots & \vdots \\
0 & \cdots & 0 & 0 & \cdots & 0 & 0 & \cdots & 1
\end{array}\right] .
$$

If we consider $\mathcal{H}=\{(i, j): 1 \leq i \leq n-1, i<j \leq n\}$, the set of all possible pairs of coordinate axes, the $n(n-1) / 2$ distinct $R_{i j}(\alpha)$ rotation matrices may be concatenated in some order to produce a new rotation matrix such as $\prod_{(i, j) \in \mathcal{S}} R_{i j}(\alpha)$, where $\mathcal{S} \subseteq \mathcal{H}$. (Rotations in three dimensions and higher do not commute, so that different orderings give different rotations.)

We are interested in showing the performance of the PCG method at each interior-point iteration when changing the geometrical relations between the diagonal block and the linking constraint
small instances

matrices, in accordance with specified rotations. To do so we randomly draw $N_{i} \in \mathbb{R}^{m \times n}$ and $Y_{i} \in \mathbb{R}^{l \times m}, i=1, \ldots, k$, from a uniform probability distribution. Then $\mathcal{S} \subseteq \mathcal{H}$ is also randomly selected to compute the rotation matrix $\prod_{(i, j) \in \mathcal{S}} R_{i j}(\alpha)$. Finally, we obtain the linking constraint matrices $L_{i}=Y_{i} N_{i}\left(\prod_{(i, j) \in \mathcal{S}} R_{i j}(\alpha)\right)$, for $i=1, \ldots, k$. This procedure relies on the number $\bar{r}=|\mathcal{S}|$ of concatenated rotation matrices and the angle of rotation $\alpha$ to evaluate the associated changes in the PCG iterations using $\Theta_{0}^{-1}$ and $D^{-1}$ as preconditioners.

The BlockIP package [12] implementing the specialized interior-point method has been extended with the $\Theta_{0}^{-1}$ preconditioner introduced in this work. Tables 1 and 2 show the computational results obtained with BlockIP using $D^{-1}$ and $\Theta_{0}^{-1}$ preconditioners. Instances of Table 1 are "small", with $l=100$ linking constraints, and $k=100$ equal diagonal block matrices $N \in \mathbb{R}^{10 \times 50}$. For the "big" instances of Table 2 these dimensions are $l=200, k=1000$, and $N \in \mathbb{R}^{20 \times 200}$. The first column of these tables show the angle $\alpha$ of each rotation, whereas the second column reports the number $\bar{r}$ of rotation matrices considered. The remaining columns give the CPU time, number of IPM iterations, and average number of PCG iterations per IPM iteration, for both preconditioners.

It is observed that the performance of the specialized IPM strongly relies on those angles for both the small and big instances. Indeed, the average number of PCG iterations appears to increase or decrease depending on the angles and the particular preconditioner. For $\Theta_{0}^{-1}$, the smaller the angle, the better the preconditioner, whereas the opposite holds for the small instances and $D$ (this is not so clearly observed for the big instances). This numerical evidence supports the previous discussion on the effect of the geometrical relations between the diagonal blocks and the linking constraint matrices on the quality of the preconditioner.

The plots of figures 3, 4, 5 and 6 illustrate the evolution of the number of PCG iterations (vertical axis) at each IPM iteration (horizontal axis) for both preconditioners. Small and large instances of

Fig. 5. PCG iterations along the IPM iterations for $\alpha=\pi / 8, \bar{r}=2$, with preconditioners $\Theta_{0}^{-1}$ and $D^{-1}$. Plots have to be read from right to left.
small instances

big instances

the same dimensions as in tables 1 and 2 have been used, but with different angles and always with $\bar{r}=2$ rotations matrices. The horizontal axis shows the value of $\log \mu$ (the natural logarithm of the barrier parameter), such that the plots have to be read from right to left (the first and last IPM iterations correspond respectively to the rightmost and leftmost points). The blue and green dots are related to $\Theta_{0}^{-1}$ and $D^{-1}$ respectively. The corresponding lines show polynomial curves of degree four which have been fitted to the observed number of PCG iterations. It is observed that for small angles (figures 3 and 4), as expected by the theory, the preconditioner $D^{-1}$ usually requires more PCG iterations than $\Theta_{0}^{-1}$; this difference increases as we approach the optimal solution, for the small instances. However, for the "larger" angles of figures 5 and 6 , again in accordance with theory, preconditioner $D^{-1}$ becomes more efficient than $\Theta_{0}^{-1}$ after some IPM iteration. The message should then be that, for problems with small angles, $\Theta_{0}^{-1}$ should be preferred in general, and $D^{-1}$ otherwise. It is worth noting that a benefit of $\Theta_{0}^{-1}$ is that it is always a diagonal preconditioner, independently of the problem, unlike $D^{-1}$, which may require a Cholesky factorization.
4.2. Multicommodity network flow problem with nodal capacities and equal flows. Let $\mathcal{G}=(\mathcal{V}, \mathcal{A})$ be a directed graph, where $\mathcal{V}$ is a set of $n$ vertices or nodes and $\mathcal{A}$ is a set of $n^{\prime} \operatorname{arcs}$, and let $\mathcal{K}$ be a set of $k$ commodities. The multicommodity network flow problem with nodal capacities (MNFPNC from now on) looks for the minimum cost routing of the flows for all the commodities from some source to some destination nodes, imposing capacities on the total outflow at some nodes $h \in \mathcal{C} \subseteq \mathcal{V}$. This problem differs from the standard multicommodity flow problem in that capacities are imposed at nodes, instead of at arcs. The node capacities constraints are

$$
\begin{equation*}
\sum_{i \in \mathcal{K}} \sum_{j \in \mathcal{V}} x_{h j}^{i} \leq b_{0}^{h}, \quad h \in \mathcal{C}, \tag{4.2}
\end{equation*}
$$

where $b_{0}^{h}$ denotes the capacity of node $h \in \mathcal{C}$. MNFPNC matches the standard formulation (2.1) of primal block-angular problems, by considering $m_{i}=n, n_{i}=n^{\prime}, N_{i}=N \in \mathbb{R}^{(n-1) \times n^{\prime}}$ for all $i=1, \ldots, k$, where $N$ is the node-arc incidence matrix associated to $\mathcal{G}$; and $l=|\mathcal{C}|, L_{i}=L \in \mathbb{R}^{l \times n^{\prime}}$ for all $i=1, \ldots, k$, are derived from $N$ by considering only positive coefficients to obtain (4.2).

Tables 3 and 4 report two computational experiments associated to MNFPNCs of different sizes. The eight instances of Table 3 correspond to problems where $l=0.2 n$ (i.e., only $20 \%$ of nodes are constrained to have an outflow capacity), whereas the eight instances of Table 4 correspond to problems where $l=n$ (all the nodes have capacities). For each instance, the tables provide the number of nodes $n$, number of commodities $k$, the total number of variables ("n.var"), total number of constraints ("n.con."), and the CPU time and (within parentheses) total number of iterations for all the solvers considered: primal simplex, dual simplex and barrier for CPLEX; and BlockIP with both $\Theta_{0}^{-1}$ and $D^{-1}$ preconditioners. A time limit of 3600 seconds was considered.

It can be seen from tables 3 and 4 that the CPU time associated to the primal simplex is always far greater than the ones of the other solvers. The dual simplex is quite competitive and in some instances outperforms CPLEX barrier method and BlockIP. BlockIP with both preconditioners is in general more efficient than CPLEX barrier, although it requires more IPM iterations because - since it uses PCG-it computes Newton directions instead of second or higher order ones. The network size $n$ does not seem to have a substantial effect on the comparative efficiency of the five solvers. Instead the increase in the number of linking constraints (either $l=0.2 n$, in Table 3 or $l=n$, in Table 4) almost double the CPU time of the CPLEX barrier method, whereas slightly affects the specialized IPM.

Let us consider a slight modification of the MNFPNCs, obtained by introducing to each commodity a set of equal flow constraints, i.e. constraints requiring that each arc in a specified set $\mathcal{R}_{r}$ must carry the same amount of flow, for every group of arcs $r \in R$; that is, $x_{a_{j}}^{i}=x_{a_{h}}^{i}$, for $i=1 \ldots k$, $a_{j}, a_{h} \in \mathcal{R}_{r}, r=1 \ldots R$ (where $a_{j}, a_{h}$ denote two particular arcs in the network). These constraints arose while modeling some real-life problems, such as water resource system management [21]. We call this problem multicommodity equal flow problem with nodal capacities (MEFPNC from now on). Here we are considering MEFPNCs of different sizes with $R=\mathrm{EF} \cdot n$ groups of arcs having the same flows per each commodity and $\left|\mathcal{R}_{r}\right|=\mathrm{EF} \cdot 100$ number of arcs in each group $r=1 \ldots R$, where EF is a given parameter to control the number of equal flow constraints.

Tables 5 and 6 report two computational experiments associated to these MEFPNCs. As before, the eight instances of Table 5 correspond to problems with $l=0.2 n$, whereas $l=n$ in Table 6 . The parameter EF was set to 0.1 in these instances. The meaning of the columns is the same as in tables

Table 5
CPU time and iterations (within parenthesis) of BlockIP (using $D^{-1}$ and $\Theta_{0}^{-1}$ preconditioner) and CPLEX available LP methods (Primal Simplex, Dual Simplex, Barrier Method) when solving MEFPNCs. Only 20\% of nodes are constrained to have an outflow capacity, i.e., $l=0.2 n$.

3 and 4. It is worth to mention that, for every set $\mathcal{R}_{r}=\left\{a_{1}, a_{2}, \ldots, a_{\left|\mathcal{R}_{r}\right|}\right\}$, and $i \in \mathcal{K}$, the equal flow constraints are formulated as $x_{a_{j}}^{i}=x_{a_{j+1}}^{i}, j=1, \ldots,\left|\mathcal{R}_{r}\right|-1$, instead of $x_{a_{1}}^{i}=x_{a_{j}}^{i}, j=2, \ldots,\left|\mathcal{R}_{r}\right|$. With this formulation we avoid a "dense column" for variables $x_{a_{1}}^{i}$, which makes BlockIP more efficient. CPLEX barrier is not affected by this different reformulation due to its presolving capabilities. The principal angles between linking and block constraints are the same for both formulations, since they span the same subspace (it is easy to show that given the constraints matrices for the two formulations, one can obtain one from the other by simple linear manipulations).

The inclusion of equal flow constraints negatively affects the computational performance of all the considered solvers, though in different proportions. The dual simplex and barrier almost double its CPU times in the largest instances with respect to the MNFPNCs, whereas the ones associated to the specialized IPM slightly increase. In fact, the specialized IPM becomes the most efficient algorithm for this class of problems from $k=400$. Also for the MEFPNCs, as it was for the MNFPNCs, the network size $n$ does not seem to have a substantial effect on the ranking of the five solvers.

As for the two preconditioners of BlockIP, results with $\Theta_{0}^{-1}$ and $D^{-1}$ are very similar in solving MEFPNCs with $l=0.2 n$, as shown in Table 5 . Instead $D^{-1}$ results to be slightly a better preconditioner when $l=n$. In both cases BlockIP outperforms the CPLEX available LP methods. It is worth noting that BlockIP uses an out-of-date sparse linear algebra package for the Cholesky factorization [23], while CPLEX implements highly tuned state-of-the-art factorization routines. Therefore, the performance of BlockIP could be significantly improved by the use of a more recent Cholesky solver.

The information of the average principal angles between the subspaces generated by the columns of $L^{\top}$ and $N^{\top}$ of the instances of tables 3-6 are reported in Table 7, differentiating for the 150 and 300 nodes instances. The first information we obtain from Table 7 is that the average principal angles are generally stable with respect to the number of nodes. We also see that average principal angles are in general far from 0 , which may explain why preconditioner $D^{-1}$ outperforms $\Theta_{0}^{-1}$ in general in tables 3-6.

We finally generated and solved a set of large instances, considering only the CPLEX barrier solver, and BlockIP with the two preconditioners, with a time limit of 3600 seconds. The corresponding results are reported in tables 8 and 9 , for small dense and big sparse networks correspondingly. In these tables columns "density" provide the fraction "number of arcs/maximum number of arcs $(n(n-1))$ "; columns "NC" show the fraction of nodal capacity constraints, i.e., "number of node capacities $/ n$ "; and columns "EF" provide the parameter considered for the equal flow constraints.

Table 7
Average principal angles between the subspaces generated by the columns of $L^{\top}$ and $N^{\top}$, for each instance of multi-commodity network flow problems with nodal capacities in tables 3, 4, 5 and 6.

The rest of columns have the same meaning as in previous tables.
Among the 60 instances of tables 8-9, CPLEX barrier resulted to be the most efficient strategy in 17 instances, whereas BlockIP outperformed CPLEX in the remaining 43. Within these latter instances, $D^{-1}$ was a better preconditioner in 33 , against the 10 corresponding to $\Theta_{0}^{-1}$. However, it must be noted that in all the instances where $D^{-1}$ behaved comparatively poorly, its total CPU time has been significantly high ( $>3600$ ). By contrast, $\Theta_{0}^{-1}$ has been outperformed by a more moderated comparative advantage in the aforementioned 33 instances. Unexpectedly, CPLEX barrier was the most efficient solver for some of the instances with a larger number of equal flow constraints of Table 9 ; this may be explained by its highly efficient factorization and presolving routines-which reduce the number of constraints and variable due to the equal flows. It is also worth to remark that BlockIP with $\Theta_{0}^{-1}$ was the only approach that solved all the instances within the time limit.

It must be noted that instances where CPLEX barrier resulted particularly efficient are associated to the big and sparse networks ( $n=800$, density $\leq 0.04$ ), of Table 9 . Higher density matrices seem to favor BlockIP and to penalize CPLEX barrier, as observed in Table 8. However, the final behaviour is problem dependent, such that if the number of nodes is large enough, BlockIP can outperform CPLEX even for sparse networks. For instance, in a tough instance (not included in the above tables) of $n=4000, k=2000$, density $=0.001, \mathrm{NC}=0.2$, with no equal flow constraints, and without any time limit, CPLEX barrier spent about 37000 seconds (requiring 85 Gigabytes of memory), while BlockIP found a solution in 11000 seconds (using 15 Gigabytes of memory).
5. Conclusions. This work showed that the angles between the subspaces generated by the diagonal blocks and the linking constraints may explain the effectiveness of two complementary pre-

conditioners, namely $\Theta_{0}^{-1}$ and $D^{-1}$, in the specialized IPM for block-angular problems. It was also shown that the evolution of principal angles along the IPM iterations rely on the diagonal $\Theta$ matrix. Algebraical properties of the two complementary preconditioners were supported by numerical results. We also analyzed the performance of the specialized IPM with the two preconditioners in the solution of the multicommodity network flow problem with nodal capacities and equal flows, observing that it outperforms all of the available CPLEX methods in some of the largest instances.
$\Theta_{0}^{-1}$ and $D^{-1}$ have shown to be the exact preconditioners when a linking constraint belongs to respectively the range and null space of the matrix of block constraints. Since any vector defining a linking constraint can be decomposed as the sum of two orthogonal vectors belonging to the range and null space of the matrix of block constraints, it would be worth to exploit this fact to see whether a multipreconditioner based on the two above can be obtained, following for instance [8]. This is part of the further research to be done.
