3 **Abstract**
4
5
6

7 Monitoring minimal residual disease (MRD) in patients with acute lymphoblastic
8 leukemia (ALL) is a useful way for assessing treatment response and relapse.
9

10
11
12 We studied the value of MRD and showed a correlation with relapse for 34 adult
13 patients with ALL. MRD was evaluated by real-time quantitative polymerase chain
14 reaction (RQ-PCR) with probes derived from fusion chimeric genes (BCR/ABL) (n=12)
15
16 or PCR-based detection of clonal immunoglobulin and T-cell receptor gene
17 rearrangements (n=16), or both (n=6). We analyzed 27 of the 34 patients who could be
18
19 examined for MRD on day 100 after induction therapy. The overall survival (OS) rate
20 (45.0%) and relapse-free survival (RFS) rate (40.0%) at 2 years in CR patients with
21
22 MRD level $\geq 10^{-3}$ (n=12) were significantly lower than those in CR patients with MRD
23 level $< 10^{-3}$ (n=15) (OS rate: 79.0%, RFS rate: 79.4%) (log-rank test, $P=0.017$ and
24
25 0.0007). We also applied multicolor flow cytometry for comparison with MRD results
26
27 analyzed by PCR methods. The comparison of results obtained in 27 follow-up samples
28
29 showed consistency in 17 samples (63.0%) ($P=0.057$). MRD analysis on day 100 is
30
31 important for treatment decision in adult ALL.

3 **Introduction**
4
5
6
7

8 The prognosis of adult patients with acute lymphoblastic leukemia (ALL) is dismal.
9

10 Although most adult patients with ALL enter complete remission (CR), only 30% to
11
12 40% of patients survive 5 or more years (1). The major cause of treatment failure is
13
14 relapse, affecting approximately half of the patients who have achieved CR (2). Survival
15
16 depends on risk factors such as age, white blood cell (WBC) count, time to CR, disease
17
18 immunophenotype, cytogenetics, and molecular abnormalities (1), and several studies
19
20 have shown that detection of minimal residual disease (MRD) in childhood and adult
21
22 ALL is an independent risk parameter of high clinical relevance (3). Early indicators of
23
24 disease outcome would be particularly useful for the design of new treatments.
25
26
27
28
29
30
31
32
33
34
35

36 The rationale of MRD analysis is to improve estimation of treatment response, to
37
38 provide independent prognostic information, and to optimize therapeutic strategies.
39
40
41

42 Established methods for detecting MRD are polymerase chain reaction (PCR)
43
44 amplification of antigen receptor genes and of fusion transcripts and flow cytometric
45
46 detection of ectopic or aberrant immunophenotypes (4).
47
48
49
50

51 Flow cytometric detection of MRD is based on the identification of immunophenotypic
52
53 combinations expressed on leukemic cells but not on normal hematopoietic cells (4).
54
55
56
57

58 Abnormal antigen expression or leukemia-specific gene rearrangements or fusion
59
60
61

1
2
3 transcripts are suitable for MRD detection; however, they cannot be identified in all
4
5
6 patients. Therefore, the complementary use of both methods might allow monitoring of
7
8
9 virtually all patients for MRD.
10

11
12 We previously reported that molecular MRD status by PCR amplification of antigen
13
14 receptor genes is a strong predictor of outcome in adult ALL (5). In this study, we
15
16 accumulated more patients and reevaluated the significance of MRD. We also compared
17
18
19 the two methods of MRD detection: PCR amplification and flow cytometry.

3 **Patients and methods**
4
5
6

7
8 *Patient characteristics*
9

10
11 A total of 46 adult ALL patients were included in the study during the period from May
12
13
14 2001 to December 2007 at Hokkaido University Hospital and hospitals associated with
15
16
17 the Hokkaido Leukemia Study Group. They were registered with the study when the
18
19
20 diagnoses of ALL were made. Twelve of the 46 patients who entered the study were
21
22
23 excluded (patients with no IGH, TCR δ , or TCR γ clonal marker or fusion transcripts at
24
25
26 diagnosis (n=5), patients who died before or during induction chemotherapy (n=5), and
27
28
29 patients who did not achieve CR (n=2)). In total, MRD could be monitored in 34 of the
30
31
32
33 46 initial patients.
34
35

36
37 The characteristics of the 34 patients are summarized in Table 1. Seventeen (50.0%) of
38
39
40 the patients were male and 17 (50.0%) were female. Their median age was 48.5 years
41
42
43 (range, 15-79 years) and median duration of follow-up was 567.5 days (range, 49-2040
44
45
46 days). The median WBC count was $10.9 \times 10^9 /L$ (range, $1.7-3272.5 \times 10^9 /L$). Thirty
47
48
49 patients had B-precursor ALL and 4 had T-ALL. Eighteen patients were Philadelphia
50
51
52 (Ph) chromosome-positive: 13 patients (55.6%) had p190^{BCR/ABL} transcripts, 3 patients
53
54
55 (16.7%) had p210^{BCR/ABL} transcripts, and the other 2 (11.1%) had both transcripts. One
56
57
58 patient was positive for SIL/TAL1 and another patient was positive for E2A/PBX1, but
59
60
61
62
63
64
65

1
2
3 these fusion transcripts were not used to detect MRD. Eighteen (52.9%) of the 34
4
5
6 patients received chemotherapy only, and the remaining 16 (47.1%) received allogeneic
7
8
9 stem cell transplantation after chemotherapy. Eight patients had related donors and 8
10
11
12 patients had unrelated donors. Clinical characteristics of the patients are shown in Table
13
14
15
16 2.

17
18
19 Twenty-six patients were treated with intravenous cyclophosphamide, vincristine,
20
21
22 daunorubicin or doxorubicin, etoposide, cytosine arabinoside, steroid, l-asparaginase,
23
24
25 with or without imatinib, and intrathecal methotrexate for induction therapy. One patient
26
27
28 received only imatinib, another patient received etoposide and imatinib, and another
29
30
31 patient was treated with idarubicin and cytosine arabinoside because the diagnosis of
32
33
34 acute myelogenous leukemia was made at the first time. The induction therapies for
35
36
37 other five patients were not known. The conditioning regimen for allogeneic
38
39
40 transplantation consisted of total body irradiation in combination with
41
42
43 cyclophosphamide and etoposide for 13 patients or fludarabine for 1 patient. The
44
45
46 conditioning regimen was unknown for the other three patients.

47
48
49
50
51 Clinical decisions concerning treatment of the patients were made by their physicians
52
53
54 regardless of MRD results. Enrollment in the study was contingent upon informed
55
56
57 consent of the patient. The study was approved by the Institutional Review Board of
58
59
60

1
2
3 Hokkaido University Graduate School of Medicine.
4
5

6 *Remission and relapse*
7

8
9 Morphologic CR was defined as less than 5% blast cells in a regenerated bone marrow
10
11 (BM) aspirate, absence of extramedullary leukemia, and peripheral blood (PB)
12
13 neutrophil and platelet counts of $> 1.5 \times 10^9 /L$ and $> 100 \times 10^9 /L$, respectively. Clinical
14
15
16 relapse was defined as detection of at least 5% blast cells in BM or detection of
17
18
19 leukemic cells extramedullary.
20
21
22

23
24
25 *Sample processing*
26

27
28 BM or PB was collected at the time of initial diagnosis and at several clinical points
29
30 (day 30 and day 100 after diagnosis, before the conditioning regimen, after
31
32 transplantation and any points at the end of each chemotherapy). Some samples were
33
34
35 collected after completion of the treatment. The samples were used for PCR study of
36
37
38 IGH/TCR rearrangements and BCR/ABL fusion gene transcripts. Some of the samples
39
40
41 were also used for flow cytometry study. A total of 231 samples (220 BM and 11 PB
42
43
44 samples) were analyzed; the median number of samples analyzed per patient was 6
45
46
47 (range, 2-22) (Table 3). For a total of 27 BM samples from five patients MRD was
48
49
50 analyzed by both PCR amplification and flow cytometry. We did not evaluate the
51
52
53
54 difference in values of MRD between BM and PB samples.
55
56
57
58
59
60
61

1
2
3 *Quantitative real-time PCR analysis of BCR/ABL*
4
5

6 Samples were analyzed for BCR/ABL, TEL/AML1, MLL/AF4, MLL/AF9, MLL/AF6,
7
8
9 MLL/ENL, E2A/PBX1, and SIL/TAL1 chimeric genes. Samples were amplified by
10
11
12 real-time quantitative polymerase chain reaction (RQ-PCR) and quantified by parallel
13
14
15 amplification of serial dilutions of transcript-containing plasmids. A 10^{-5} sensitivity for
16
17
18
19 MRD detection could be obtained.
20
21

22 *PCR analysis of IGH/TCR gene rearrangements*
23
24

25 When a BCR/ABL chimeric fusion gene was not present, leukemia-specific probes were
26
27
28 generated by genomic amplification and sequencing of VDJ regions of the
29
30
31 immunoglobulin heavy chain (IGH) and T-cell receptor δ and γ (TCR δ and TCR γ)
32
33
34 genes. The method of PCR analysis of IGH/TCR gene rearrangements has been
35
36
37 described previously (5). The sensitivity was 10^{-3} . When two MRD probes gave
38
39
40
41 different results in the same patient, the higher MRD level was considered valid for the
42
43
44 purpose of the study.
45
46

47 *Flow cytometry*
48
49

50
51 Leukemia-associated immunophenotypes were identified by flow cytometry with
52
53
54 four-color combinations of monoclonal antibodies. The flow cytometric method used
55
56
57 has been described previously (6). For each case, one or more marker combinations that
58
59
60
61
62
63
64
65

1
2
3 allowed the identification of one leukemic cell in 10^3 - 10^4 normal nucleated cells were
4
5
6 selected at diagnosis and used to study MRD during therapy. This approach reached
7
8
9 sensitivities up to 10^{-4} .
10

11 *Statistical analysis*

12
13 Survival curves were plotted according to the method of Kaplan and Meier, and
14
15
16 comparison of the curves was made using log-rank tests. Overall survival (OS) was
17
18
19 measured from the date of induction therapy until death. Relapse-free survival (RFS)
20
21
22 was measured from the date of induction therapy until the date of relapse or death,
23
24
25
26 whichever occurred first. Univariate and multivariate analyses were performed to
27
28
29
30
31 evaluate the independent prognostic factors for OS and RFS by a Cox regression model.
32
33

1
2
3 **Results**
4
5
6
7
8

9
10 *Identification of MRD-PCR targets*
11

12 Eighteen patients were Ph chromosome-positive and their MRD was detected by
13
14 BCR/ABL fusion transcripts. Thirty IGH/TCR gene rearrangements were found at
15
16 diagnosis in the 22 ALL patients: 19 IGH (two different kinds in five patients), 6 TCR δ ,
17
18 and 5 TCR γ gene rearrangements. Eight patients had two targets and 14 patients had one
19
20 target (Table 3). MRD was analyzed by both BCR/ABL fusion transcripts and
21
22 IGH/TCR gene rearrangements in 6 patients. The results obtained by the two methods
23
24 were concordant. In 5 patients, MRD was also detected by flow cytometry (BCR/ABL,
25
26 4; IGH gene rearrangement, 1).
27
28

29 Patients achieved first CR after a median period of 35 days (range, 15–105 days).
30
31

32 Sixteen patients (47.1%) received allogeneic stem cell transplantation following
33
34 induction and consolidation chemotherapy. Seventeen patients relapsed and 17 patients
35
36 remained in CR.
37
38

39 We analyzed 27 of the 34 patients who could be examined for MRD on day 100. The
40
41 overall survival (OS) rate (45.0%) and relapse-free survival (RFS) rate (40.0%) at 2
42
43 years in CR patients with MRD level $\geq 10^{-3}$ (n=12) were significantly lower than those
44
45
46
47
48
49
50
51
52
53
54
55
56
57
58
59
60
61
62
63
64
65

1
2
3 in CR patients with MRD level $<10^{-3}$ (n=15) (OS rate: 79.0%, RFS rate: 79.4%)
4
5
6 (log-rank test, $P=0.017$ and 0.0007). A lower MRD value on day 100 after induction
7
8
9 therapy was associated significantly with longer survival (Fig. 1a and b). Two patients
10
11
12 were excluded from the study because of relapse before day 100 after induction therapy.
13
14

15
16 Monitoring of MRD enabled prediction of relapse in 10 of the 14 relapsed patients
17
18
19 whose results of MRD analyses were available before relapse. The median time from
20
21
22 molecular to clinical relapse was 65 days (range, 12-305 days).
23
24

25 *Comparison of the results obtained by flow cytometry and PCR analysis*

26
27
28 We compared MRD levels determined by both flow cytometry and PCR analysis in 27
29
30
31 follow-up BM samples from 5 patients (Table 4). Four of them had Ph-positive ALL
32
33
34 and MRD was analyzed by BCR/ABL fusion transcripts. The other patient was
35
36
37
38 analyzed by IGH gene rearrangement.
39
40

41
42 Concordance between the flow cytometric and PCR results was obtained in 17 (63.0%)
43
44
45 of the 27 samples ($P=0.057$). No significant changes regarding immunophenotype were
46
47
48 observed when MRD phenotypes at relapse were compared to the original phenotypes
49
50
51 at diagnosis.
52

53
54 Of the 10 samples that were MRD-positive by flow cytometry but MRD-negative by
55
56
57 PCR, very low levels (below 10^{-4}) could be detected by flow cytometry in 5 samples
58
59
60
61

1
2
3 from 2 patients. The other 5 samples from 3 patients were MRD-positive by flow
4
5
6 cytometry (0.18%, 0.16%, 0.39%, 0.42%, and 2.53%) but MRD-negative by PCR.
7
8

9
10 *Other prognostic factors*

11
12 In addition, we examined factors correlated with OS and RFS by the log-rank test. In
13
14
15 the log-lank test, a lower MRD value on day 100 was associated significantly with
16
17
18 longer survival (Table 5). However, we could not determine other factors, such as age,
19
20
21 WBC count at diagnosis, Ph chromosome, immunophenotype, sex, days to achieve CR,
22
23
24 and type of treatment (chemotherapy or transplantation). Therefore, our data provide
25
26
27 evidence that molecular MRD status on day 100 is a strong predictor of outcome in
28
29
30 adult ALL.
31
32

33
34
35 *Relative risk of relapse*

36
37
38 Looking for informative predictors of the achievement of molecular CR on day 100, we
39
40
41 used univariate and multivariate analyses to investigate the role of conventional clinical
42
43
44 findings such as age younger than 55 years or not, WBC count at diagnosis, Ph
45
46
47 chromosome, immunophenotype, sex, days to achieve CR, and MRD levels on day 30.
48
49
50 Univariate analysis showed that MRD positivity on day 100 was associated with age
51
52
53 older than 55 years and MRD positivity on day 30, but there were no significant
54
55
56 associations in multivariate analysis.
57
58
59
60
61
62
63
64
65

1
2
3 **Discussion**
4
5
6
7
8
9

10 There is increasing evidence that MRD has strong prognostic significance in adult
11 patients with ALL. Mortuza et al. found that MRD positivity detected especially at 3 to
12 6 months after induction therapy in adults with B-ALL was associated with an increased
13 risk of relapse (7). Holowiecki et al. reported that MRD equal or greater than 0.1% of
14 bone marrow cells after induction was a strong and independent predictor for relapse in
15 both standard and high-risk groups (2).
16
17
18
19
20
21
22
23
24
25
26

27
28 We also showed that OS and RFS at 2 years in CR patients positive for MRD by
29 PCR-based detection of BCR/ABL transcripts or IGH/TCR gene rearrangements were
30 significantly lower than those in CR patients negative for MRD.
31
32
33
34
35
36
37

38 Three highly specific and sensitive methodologies for MRD detection are available:
39 multiparameter flow cytometric immunophenotyping, RQ-PCR-based detection of
40 fusion gene transcripts or breakpoints, and PCR-based detection of clonal
41 immunoglobulin and T-cell receptor gene rearrangements (8).
42
43
44
45
46
47
48
49

50 PCR-based detection of rearranged IGH/TCR genes is currently the most broadly
51 applied MRD technique owing to its high level of standardization, its well-defined
52 quantitative range and good sensitivity, as well as applicability in the majority of ALL
53
54
55
56
57
58
59
60
61
62
63
64
65

1
2
3 patients (3). To reach a higher level of sensitivity, DNA sequencing of the junctional
4
5
6 regions is required in order to design tumor-specific primers and/or probes.
7

8
9 A major drawback of using rearranged immune genes as MRD-PCR targets is the
10
11 possible occurrence of continuing rearrangements during the course of therapy and
12
13 during follow-up, which can lead to false-negative PCR results (9).
14
15
16

17
18 Relapse could not be predicted in 4 of the 14 relapsed patients in this study. In two of
19
20 them, TCR δ or IGH gene rearrangement was not detected even at the time of relapse.
21
22

23
24 Clonal TCR δ rearrangement in particular can be lost during the follow-up period
25
26 preceding relapse (10), and continuing rearrangements during the disease course occur
27
28 in 10-40% of cases depending on the target used (11).
29
30
31

32
33 One specific advantage of flow cytometry over PCR-based assays is that it allows direct
34
35 quantification of MRD, rather than extrapolating it from amounts of PCR product (9).
36
37
38

39
40 However, the immunophenotype of leukemic cells may change during progression of
41
42 the disease, and if these changes affect markers used for monitoring MRD, a
43
44 false-negative finding may result (12, 13).
45
46
47

48
49 In this study, concordance between the flow cytometric and PCR results was obtained in
50
51 17 (63.0%) of the 27 samples. Comparative analyses showed that more concordant
52
53 results could be obtained for both methods at the level of 10^{-3} and 10^{-4} (14, 15). In three
54
55
56
57
58
59
60
61

1
2
3 cases, some samples showed discordant results. In these cases, MRD might be
4
5
6 overestimated by flow cytometry because normal cells cannot be easily distinguished
7
8
9 from leukemic cells in studies of MRD (6).
10

11
12 The combination use of the two methods may offset the possibility of false-negative and
13
14
15
16 false-positive MRD results due to these events (16).
17

18
19 We did not find a significant prognostic value of MRD in patients who received
20
21
22 allogeneic transplantation. It has been shown that MRD detected before transplantation
23
24
25 was a significant predictor of failure after transplantation (17, 18). However, Patel et al.
26
27
28 suggested that molecularly determined MRD pre-transplant was not a risk factor for
29
30
31 relapse in patients receiving allogeneic stem cell transplantation in the first CR (19). It
32
33
34
35 has also been shown that MRD status after allogeneic transplantation was an important
36
37
38 predictor of outcome in adults with ALL (7, 18). The MRD status before and after
39
40
41 transplantation was not correlated with survival in this study, which may be explained
42
43
44 by the small number of patients who received transplantation.
45

46
47 Results of log-rank tests showed that age, WBC count at diagnosis, sex, Ph-positivity,
48
49
50
51 and immunophenotype were not associated with prognosis or relapse. Generally,
52
53
54 advanced age of the patient and high WBC count at diagnosis with acute leukemia are
55
56
57 related to poor prognosis. In this study, we did not intervene in clinical decisions
58
59
60
61

1
2
3 concerning treatment of the patients, but MRD level on day 100 after induction
4
5
6 chemotherapy was only a good prognostic factor to monitor relapse and classify the
7
8
9 groups as good or poor prognosis.
10

11
12 Although limitation of MRD assessment for prediction of extramedullary relapse is
13
14 recognized (19), MRD methods can be used to predict outcome on the basis of early
15
16 response to therapy and to recognize leukemia relapse (20).
17
18
19

20
21
22 Thorn et al. suggested that MRD levels calculated by the quantification of BCR/ABL
23
24 transcripts were higher than levels obtained by flow cytometry and by quantitative PCR
25
26 of rearranged IGH/TCR genes (21). However, whether the results of these methods
27
28 coincide with those of PCR amplification of fusion transcripts is not yet established (22).
29
30
31

32
33
34 Further progress in how to assess MRD and improve the prognosis in adult patients with
35
36 ALL in association with MRD is expected.
37
38
39

40
41 In this study, we investigated the prognostic value of MRD in adult patients with ALL.
42

43
44 We found that ALL patients with MRD level $<10^{-3}$ on day 100 had significantly better
45

46
47 OS and RFS than those of ALL patients with MRD level $\geq 10^{-3}$. Therefore, MRD
48

49
50 analysis is useful for monitoring the prognosis of ALL patients. PCR analysis and flow
51

52
53 cytometry were both useful for the detection of MRD. However, both methods can yield
54

55
56 false-negative and false-positive results, and improvements are needed for further

Figure legends

Figure 1. Comparison of overall survival (OS, a) and relapse-free survival (RFS, b) by MRD detection on day 100 after induction therapy.

Table 1. Characteristics of the patients.

Characteristics	N
Number of patients	34
Gender (%)	
Male	17 (50.0%)
Female	17 (50.0%)
Median age, years (range)	48.5 (15-79)
Age	
< 35 years	14 (41.2%)
≥35 years	20 (58.8%)
< 55 years	21 (61.8%)
≥55 years	13 (38.2%)
Median follow-up period, days (range)	567.5 (49-2040)
Immunophenotype	
B-ALL	30 (88.2%)
T-ALL	4 (11.8%)
Median WBC, $\times 10^9/L$ (range)	10.9 (1.7-3272.5)
WBC $< 30 \times 10^9/L$ (B), $< 100 \times 10^9/L$ (T)	25 (73.5%)
WBC $\geq 30 \times 10^9/L$ (B), $\geq 100 \times 10^9/L$ (T)	5 (14.7%)
unknown	4 (11.8%)
Median hemoglobin, g/dL (range)	10.3 (4.1-14.9)
Median platelet, $\times 10^9/L$ (range)	50.5 (3-302)
Median LDH, IU/L (range)	730 (206-11730)
Philadelphia chromosome	
negative	16 (47.1%)
positive	18 (52.9%)
p190 ^{BCR/ABL}	13 (38.2%)
p210 ^{BCR/ABL}	3 (8.8%)
p190 ^{BCR/ABL} and p210 ^{BCR/ABL}	2 (5.9%)

Treatment	
Chemotherapy	18 (52.9%)
Chemotherapy→Transplantation	16 (47.1%)
Conditioning	
Myeloablative	12 (75.0%)
Reduced intensity	2 (12.5%)
unknown	2 (12.5%)
Stem cell source	
Bone Marrow	6 (37.5%)
Peripheral Blood	7 (43.8%)
Cord Blood	3 (18.8%)
Median time to CR, days (range)	35 (15-105)
Outcome at 2 years	
Overall survival	54.6%
Relapse-free survival	51.8%

Table 2. Clinical characteristics and outcome of the patients.

TCR δ and TCR γ	2
BCR/ABL and IGH/TCR rearrangements	6
p190 ^{BCR/ABL} and IGH	2
p190 ^{BCR/ABL} and 2 clones of IGH	1
p210 ^{BCR/ABL} and IGH	1
p190 ^{BCR/ABL} and TCR δ	1
p190 ^{BCR/ABL} and TCR δ , TCR γ	1
Number of samples	231
Median (range)	6 (2-22)
Bone marrow	220
Peripheral blood	11
