## Abstract

This paper describes the leaching behavior and release mechanisms of arsenic (As), boron (B) and selenium (Se) from excavated rocks using sequential extraction for solid-phase fractionation, batch experiments with pH variation, and consecutive batch experiments with changes in the solid-liquid mixing ratios. Arsenic in the excavated rock was mostly found with the sulfides/organic matter fraction while majority of the leachable B and Se were associated with the exchangeable phases. The leaching of As was strongly pH dependent, Se was pH dependent only around the acidic region, and B was pH independent. Consecutive washing technique with deionized water effectively lowered the B and Se concentrations in the leachate below the drinking water standards of Japan, but was inefficient in the removal of As. Arsenic exhibited non-conservative leaching behavior and its movement was affected by processes like dissolution, precipitation and pyrite oxidation. In contrast, B and Se behaved more conservatively, resulting in their easy removal from the excavated rock by simple washing and dilution.

## 1. INTRODUCTION

Recent tunnel projects in Japan for roads, railways and other purposes have excavated rocks containing significant amounts of arsenic (As), boron (B), selenium (Se) and heavy metals. These hazardous excavated rocks generally fall into two categories: altered and sedimentary rocks. Excavated rocks that have undergone hydrothermal alteration are usually enriched with As and heavy metals. On the other hand, unaltered sedimentary rocks generally contain significant amounts of As, B and Se that originate from the sea during the diagenesis of the rock. Arsenic is toxic even in minute amounts and can cause serious health problems like arsenicosis, keratosis and certain types of cancer (O'Day *et al.* 2004; Sengupta 2002). Boron and Se are essential micronutrients but toxic at high concentrations. Large doses of the former could cause reproductive and developmental problems (Fail *et al.* 1998) while the latter could cause selenosis in humans and animals (Tinggi 2003). Disposing such hazardous construction wastes into the environment, without any proper treatment to reduce their risks, would pollute the surrounding areas as well as harm all living organisms through the food chain. Special landfills are currently used for the disposal of these rocks, but this approach is very expensive and not viable in the long term due to the huge amount of excavated rocks produced annually. Thus, a more cost-effective disposal method that can adequately detoxify the waste material needs to be developed.

Published works regarding the distribution and mobilization of As, B and Se in the environment especially in aquifer and soil systems are numerous (Acharyya *et al.* 2000; Akai *et al.* 2004; Brannon and Patrick 1987; Das *et al.* 1996; Dowling *et al.* 2002; Fishbein 1983; Levinson and Ludwick 1966; Parks and Edwards 2009; Peters and Blum 2003; Savage *et al.* 2000; Zawislanski *et al.* 2003). In addition, hydrothermally altered rocks have been extensively covered in the literature particularly in the context of ore formation and characterization (Aiuppa

*et al.* 2006; Allen and Hahn 1994; Halbach *et al.* 1993; Horton *et al.* 2001; Huston *et al.* 1995; Ostwald and England 1977). However, very few have tackled the problem associated with toxic element release from excavated rocks. Our previously published works have explained the importance of pH, redox potential (Eh) and dissolved oxygen (DO) in the leaching behaviors of As and Pb from altered rocks and the strong influence of minor or trace minerals like pyrite and calcite on the mechanisms controlling their release (Tabelin and Igarashi 2009; Tabelin *et al.* 2010; Tabelin *et al.* 2012a). Furthermore, results of long-term column experiments by the authors showed that a considerable amount of As in altered rocks was released during the early stages via the dissolution of soluble secondary minerals, which were mostly products of pyrite oxidation (Tabelin *et al.* 2012b). Based on these previous results, it seems that the removal of these soluble secondary phases may potentially solve the problem of toxic elements release from excavated rocks.

This study was conducted to examine the effectiveness of “washing” as a mitigation approach for excavated rocks containing toxic elements. The hazardous elements of concern in this research include As, B and Se. Consecutive batch leaching experiments were conducted to simulate the washing process. The effects of solid-liquid ratio on the leaching behaviors of these hazardous elements were also elucidated. Furthermore, the effects of pH and coexisting ions on the leaching behaviors of B and Se were investigated because these elements were not included in our previous papers. Finally, sequential extraction was conducted to identify the functional solid phases of the excavated rocks that incorporate these elements. If successful, washing could be an effective and economical mitigation approach for these types of rocks. Findings of this study may to some extent address the current environmental pollution problems related to the leaching of toxic elements, particularly As, from sedimentary and hydrothermally altered rocks excavated during tunnel construction.

## 2. MATERIALS AND METHODS

### 2.1 Sample collection, preparation and characterization

Four rock samples were collected from different tunnel construction projects in the island of Hokkaido, Japan. Rock samples collected from Nakakoshi (N sample), Teine (T sample) and Sensyo (S sample) are hydrothermally altered rocks while that from Horonobe (H sample) is an unaltered sedimentary rock. The N sample is mostly composed of slate that underwent hydrothermal alteration characterized by silicification, pyritization and argillic alteration of kaolinite resulting in high As abundances in the rock (up to 510 mg/kg) (Tabelin *et al.* 2012b). The T sample was collected from a closed mine site with epithermal Au-Ag-Cu deposit and is mostly composed of altered tuff and andesite (Tabelin *et al.* 2012a). The rock sample collected from the S site is composed mainly of partly altered mudstone and sandstone formed during the Cretaceous period (Tabelin *et al.* 2012a). The sedimentary rock sample from the H site is composed predominantly of mudstone rich in diatoms. During the construction of these tunnels, excavated rocks were temporarily stored at interim sites prior to their final disposal. Sampling was done at random points at these sites using a shovel. Sizes of the rocks collected ranged from big (ca. 20 cm in diameter) to fine (< 2mm in diameter). These rock samples were brought back to the laboratory, air dried, crushed, sieved through a 2 mm aperture screen and stored in air tight containers to minimize exposure to moisture. The effect of sample variability was kept to a minimum by crushing all rocks collected from each site to < 2 mm, mixing them thoroughly and storing them in one container. Moreover, mixing of the crushed rock was always done in these containers before sampling for the subsequent experiments. Samples used for both the leaching and sequential extraction experiments were taken from these “stock” crushed rocks. For the chemical and mineralogical analyses, samples taken from the “stock” containers were further

crushed to less than 50  $\mu\text{m}$  and then analyzed using an X-ray fluorescence spectrometer (Spectro Xepos, Rigaku Corporation, Japan) and an X-ray diffractometer (MultiFlex, Rigaku Corporation, Japan), respectively. Boron and Se contents of the excavated rock samples were determined using the wet method, which was done by total dissolution of the sample with strong acids and subsequent analysis of the leachate.

### *2.2 Sequential extraction experiments*

The sequential extraction procedure used in this study was developed by Marumo *et al.* (2003) for the determination of the leachabilities of trace elements including As from soils and sediments. This method was a modification of the procedures of Tessier *et al.* (1979) and Clevenger (1990). A summary of the extraction procedure used is outlined in Table 1. For this procedure, one gram of the < 2 mm crushed rock fraction was utilized. After each extraction step, the residue was washed with 8 – 10 ml deionized (DI) water (18  $\Omega\cdot\text{cm}$ ) and diluted to 50 ml prior to the chemical analysis. The residual fraction was calculated from the difference between the total amount of As and the total As extracted from the sample.

### *2.3 Batch leaching experiments with pH variations*

Batch leaching experiments were conducted by mixing 15 grams of crushed rock sample with 150 ml of prepared leachant with known concentrations of acid or base for 24 hours at 120 rpm. The desired suspension pH values were achieved by adding reagent grade hydrochloric acid (HCl) or sodium hydroxide (NaOH) solutions (Wako Pure Chemical Industries Ltd., Japan). After 24 hours, the pH and Eh of the suspensions were measured and the leachates collected by filtration through 0.45  $\mu\text{m}$  sterile membrane filters (Millipore Corporation, USA). The leachate samples were then stored at 6<sup>0</sup>C prior to the chemical analyses.

#### *2.4 Consecutive leaching experiments*

Consecutive batch leaching experiments were conducted with different solid-liquid ratios. Rock samples with mass of 10, 20 and 50 g were mixed separately with 100 ml of DI water, which is equivalent to solid-liquid ratio of 1:10, 1:5 and 1:2, respectively. The rock-DI water suspensions were shaken at 120 rpm for 24 hours. After shaking, the pH, Eh and electrical conductivity (EC) were measured followed by centrifugation of the suspension using Sigma 3K 30 laboratory centrifuge (Sigma, Germany) for 30 minutes at a speed of 3,000 rpm. The supernatant was then filtered using vacuum filtration with 0.45  $\mu\text{m}$  sterile membrane filters. The residue was collected and re-used for the next washing. One hundred milliliters of DI water was again mixed with the residue and shaken for 24 hours at 120 rpm. These series of mixing and filtration steps were repeated six times for each solid-liquid ratio. All filtrates collected were acidified ( $\text{pH} < 2$ ) and stored at  $6^{\circ}\text{C}$  prior to the chemical analyses.

#### *2.5 Chemical analysis*

Concentrations of As, B, Se and coexisting ions greater than 0.1 mg/L were analyzed using the standard method of an inductively coupled plasma atomic emission spectrometer (ICP-AES) (ICPE-9000, Shimadzu Corporation, Japan). Leachates with low concentrations of As and Se ( $< 0.1$  mg/L) were pre-treated prior to the analysis using the hydride generator attached to the ICP-AES. For the pre-treatment of As, 30 ml of sample leachate was mixed with 15 ml of 12 M HCl, 2 ml of 20% potassium iodide (KI) solution, 1 ml of 10% ascorbic acid solution and diluted with DI water to 50 ml. On the other hand, pre-treatment procedure for Se is as follows:

- i. One milliliter of 6 M  $\text{HNO}_3$  and 0.25 ml of 8 M  $\text{H}_2\text{SO}_4$  were mixed with 50 ml of sample in a beaker.

- ii. The mixture was heated at 250<sup>0</sup>C until the residual volume of solution left was only a few milliliters. Around this time, white fumes were seen coming out of the beaker.
- iii. As soon as these white fumes were observed, the beaker was removed from the hotplate and allowed to cool at room temperature for ca. 1 hour.
- iv. After cooling, 10 ml of 6 M HCl was added and the solution was heated at 100<sup>0</sup>C for 5 minutes.
- v. The solution was removed from the hotplate, allowed to cool at room temperature and diluted to 50 ml.

Concentrations of B and coexisting ions less than 0.1 mg/L were analyzed using the ultrasonic aerosol generator attached to the ICP-AES. Sulfur in the leachate was predominantly in the form of sulfate (SO<sub>4</sub><sup>2-</sup>) based on the results of anion chromatography (ICS – 1000, Dionex Corporation, USA), so for faster and easier determination of SO<sub>4</sub><sup>2-</sup>, the ICP-AES was used. The standard ICP-AES method has a margin of error of ca. 2 – 3% while analyses using more sensitive hydride and ultrasonic aerosol generators have uncertainties of ca. 5%. Concentrations of cations like Ca<sup>2+</sup>, Na<sup>+</sup> and Mg<sup>2+</sup> were analyzed using a cation chromatograph, ICS – 90 (Dionex Corporation, USA).

### **3. RESULTS**

#### *3.1 Chemical and mineralogical properties of the excavated rocks*

The chemical and mineralogical properties of the excavated rock samples are summarized in Tables 2 and 3, respectively. The rock sample from the T site has the highest As content amounting to 150 mg/kg while that from the S site contains the least at 6.9 mg/kg. The As content of the H sample, which is mostly composed of mudstone, is similar to the average As

content of sedimentary rocks (5 – 10 mg/kg) (Webster 1999). In contrast, altered rocks except the S sample have higher than the average As content. Arsenic in the T sample is more than 100 times higher than the average As content of igneous rocks (1.5 mg/kg) (Ure and Berrow 1982) while that in the N sample is ca. 2 times higher than the average As content of sedimentary rocks. Boron is found in significant amounts only in samples of sedimentary origin (*i.e.*, S, N and H samples). The unaltered H sample has the highest B content amounting to 209 mg/kg. In addition, only the S sample contains Se at 0.59 mg/kg. All the rock samples are predominantly composed of quartz and/or plagioclase and minor or trace amounts of pyrite (Table 3). Both S and N samples have calcite as a minor mineral consistent with the significant CaO in Table 2. Kokoite, which is an ammonium-calcium sulfate mineral, was detected in the H sample in trace amounts.

The sequential extraction procedure used in this study grouped As and B into five fractions/phases. Four of these fractions/phases are unstable under various geochemical conditions encountered in the environment. The exchangeable fraction is easily mobilized with changes in the concentrations of coexisting ions that can affect sorption. Hazardous contaminants associated with carbonates are unstable under mildly acidic conditions, those found in the Fe-Mn fraction are released under reducing conditions, and those incorporated with sulfides/organic matter dissolve under oxidizing conditions. The crystalline/residual phase is stable under normal geochemical conditions found in the environment, and hazardous elements associated in this fraction/phase are generally regarded as immobile. Majority of As found in the altered excavated rock samples (*i.e.*, S, T and N samples) were associated with sulfides/organic matter and exchangeable phases/fractions amounting to at least 47% of the total As content (Figure 1). However, As in the carbonate phase of the T sample was significantly lower than those of the S and N samples. In contrast, ca. 73% of the total As content of the unaltered rock sample (*i.e.*, H

sample) was found together with the exchangeable, carbonates and sulfides/organic matter fractions. These results suggest that As in the rock, whether altered or unaltered, is mostly associated with the “mobile” phase susceptible to mobilization under normal geochemical conditions encountered in the environment. In contrast, B in the excavated rocks was mostly incorporated in the crystalline/residual fraction (39 – 56%) (Figure 2). In the mobile fraction, B is found mostly with the exchangeable phase (23 – 30%) and with sulfides/organic matter fraction (10 – 14%). In all rock samples, amounts of As and B associated with Fe-Mn oxides were also significant except for the T sample (Figures 1 and 2).

### *3.2 Effects of pH on As, B and Se leaching*

Figure 3 illustrates the leaching behaviors of As, B and Se from the S sample as a function of pH. The leaching of As was highly pH dependent and was enhanced under both acidic and alkaline conditions. This As leaching trend with pH is identical to the previous results of the authors using altered rocks from different tunnel projects (Tabelin and Igarashi 2009). In contrast, Se leaching slightly increased at acidic pH but not in the alkaline region while the leaching behavior of B appeared to be independent of pH. For the S sample, Se and B concentrations in the entire pH range were higher than the drinking water standards of Japan (Se: 10 µg/L; B: 1 mg/L) while As release was only a problem at acidic and alkaline conditions.

### *3.3 Effects of consecutive washing on leachate concentrations of As, B, Se and coexisting ions*

#### *3.3.1 S sample*

Properties of the leachates from the S sample are shown in Figure 4. The pH of this sample was slightly alkaline when in contact with water independent of the number of extractions and the solid-liquid ratio (Figure 4a). The leaching of As had a slight decreasing trend in all solid-liquid

ratios used (Figure 4b), but As concentration was successfully lowered below 10 µg/L only at the lowest solid-liquid ratio of 1:10. Concentration of B had a decreasing trend as a function of the number of extraction, but the decrease was more dramatic compared to As regardless of the solid-liquid ratio (Figure 4c). Initially, B concentrations were 3.15, 2.05 and 1.35 mg/L for solid-liquid ratios of 1:2, 1:5 and 1:10, respectively. After the sixth extraction, these values were lowered below ca. 0.5 mg/L. It was also observed that B concentrations in the leachate were lower than the drinking water standard after several extractions depending on the solid-liquid ratio. The leaching curves of Se had a generally decreasing trend similar to those of As and B (Figure 4d). Selenium concentrations during the first extraction were significant in all the solid-liquid ratios used and a maximum concentration of 117 µg/L was measured in the 1:2 solid-liquid ratio. However, the concentration of Se in the leachate was lowered below 10 µg/L after only 2 extractions for the 1:5 and 1:10 solid-liquid ratios while one more additional extraction was necessary for the 1:2 ratio to achieve a similar result. Concentrations of Fe, Cl<sup>-</sup> and SO<sub>4</sub><sup>2-</sup> in the leachate decreased with the number of extraction and were lower in cases with lower solid-liquid ratios (Figures 4e, g and h). At higher solid-liquid ratios (*i.e.*, 1:2 and 1:5), Ca<sup>2+</sup> concentration decreased as the number of extraction increased, but was not observed in the lowest solid-liquid ratio of 1:10 (Figure 4f). The concentrations of As, B and Se had strong correlations with that of SO<sub>4</sub><sup>2-</sup> (Table 4). Additionally, moderate positive correlations were found between the concentrations of B and Se with that of Cl<sup>-</sup>, but only a weak positive correlation existed between As and Cl<sup>-</sup> (Table 4). Regardless of the solid-liquid ratio, the S sample continued to have significant Ca<sup>2+</sup> and SO<sub>4</sub><sup>2-</sup> concentrations in the leachate even after the 6<sup>th</sup> extraction most likely due to the continued dissolution of calcite and oxidation of pyrite found in the rock (Figures 4f and h).

### 3.3.2 T sample

Figure 5 shows the leachate chemistry of the T sample as functions of the solid-liquid ratio and the number of extraction. The leachate pH of this sample was acidic independent of the solid-liquid ratio and the number of extraction (Figure 5a). Concentrations of As in the leachate were very high especially during the first extraction in the highest solid-liquid ratio of 1:2 (5,040 µg/L). Lowering the solid-liquid ratios to 1:5 and 1:10 dramatically decreased the concentrations of As to 1,540 and 262 µg/L, respectively. In addition, As concentration also decreased substantially with increasing number of extraction dropping below 10 µg/L after the second extraction. After the sixth extraction, As concentrations in the leachate were ca. 1 µg/L in all cases. The concentration curves of coexisting ions like Al, Fe, Ca<sup>2+</sup>, Mg<sup>2+</sup>, Cl<sup>-</sup> and SO<sub>4</sub><sup>2-</sup> had similar flushing-out trends, that is, their concentrations were high at the start followed by significant concentration decrease with increasing number of extraction (Figures 5c, d, e, f, g and h). Among these above mentioned coexisting ions, Al, Fe and SO<sub>4</sub><sup>2-</sup> concentrations were relatively high especially during the first two extractions regardless of the solid-liquid ratio used (Al: 3 – 221 mg/L; Fe: 29 – 1980 mg/L; SO<sub>4</sub><sup>2-</sup>: 82 – 4260 mg/L). In addition, SO<sub>4</sub><sup>2-</sup> concentrations approached 10 mg/L similar to that observed in the S sample. Strong positive correlation between As and SO<sub>4</sub><sup>2-</sup> was also observed in this sample regardless of the solid-liquid ratio (Table 5). Concentrations of Ca<sup>2+</sup>, Mg<sup>2+</sup> and Cl<sup>-</sup> were relatively low (Ca<sup>2+</sup>: 0.01 – 10.1 mg/L; Cl<sup>-</sup>: 1.36 – 3.02 mg/L; Mg<sup>2+</sup>: 0.004 – 2.24 mg/L) in the leachate independent of the number of extraction. Regardless of these differences, lowering the solid-liquid ratio generally decreased the concentrations of these coexisting ions. These results indicate that the dissolution of soluble mineral phases and dilution have strong effects on the relative concentrations of coexisting ions in this sample.

### 3.3.3 N sample

The pH values of the leachates from the N sample were slightly alkaline (8.11 – 8.37) as illustrated in Figure 6a. In this sample, the leaching curve of As slightly decreased with increasing number of extraction and at lower solid-liquid ratio, but the concentrations were all above 10 µg/L (Figure 6b). In contrast, B curves resembled flushing-out trends similar to those observed with B and Se from the S sample (Figure 6c; Figures 4c and d). Concentrations of Al and Fe were relatively low in this sample (Al: 1.29 – 1.72 mg/L; Fe: 0.04 – 0.175 mg/L), and both ions showed slight concentration variations with the number of extraction and solid-liquid ratio (Figures 6d and e). On the other hand, the other coexisting ions like  $\text{Ca}^{2+}$ ,  $\text{Cl}^-$  and  $\text{SO}_4^{2-}$  had flushing-out leaching trends as a function of the number of extraction, and the concentrations of these ions decreased in accordance with as the solid-liquid ratio (Figures 6f, g and h). The concentrations of As and B in this sample also had strong positive correlations with that of  $\text{SO}_4^{2-}$  while moderate positive correlation was found between B and  $\text{Cl}^-$  (Table 6).

### 3.3.4 H sample

The chemical properties of the leachate from the H sample are displayed in Figure 7. The pH of this rock when in contact with water was also slightly alkaline similar to those of the S and N samples, but the pH values in this sample had slightly higher variations as a function of the number of extraction (Figure 7a). Concentration curves of As also had slightly decreasing trends similar to those of the S and N samples regardless of the solid-liquid ratio (Figure 7b). In this sample, the concentration of As decreased below 10 µg/L after ca. the sixth and fifth extraction for lower solid-liquid ratios of 1:5 and 1:10, respectively, but not in the highest solid-liquid ratio (1:2). In contrast, B concentration curves had typical flushing-out trends in all solid-liquid ratios

utilized (Figure 7c). Initial B concentrations in the leachates were 2.98, 5.2 and 9.33 mg/L for solid-liquid ratios of 1:10, 1:5 and 1:2, respectively, which were higher than the drinking water standard of 1 mg/L. However, these concentrations decreased dramatically with the number of extraction, and finally dropped below 1 mg/L after the sixth extraction even in the highest solid-liquid ratio of 1:2. Coexisting ions like Fe were relatively low in the leachate (Figure 7d). On the other hand, relatively high concentrations of  $\text{Ca}^{2+}$ ,  $\text{Na}^+$ ,  $\text{Cl}^-$  and  $\text{SO}_4^{2-}$  were observed in the leachate especially during the first three extractions and at higher solid-liquid ratios. The leaching curves of  $\text{Ca}^{2+}$ ,  $\text{Na}^+$  and  $\text{Cl}^-$  also had flushing-out trends similar to B (Figures 7c, e, f and g). Similar to the other samples of sedimentary origin (*i.e.*, S and N samples), concentrations of As and B had strong positive correlations with  $\text{SO}_4^{2-}$  while B had moderate positive correlation with  $\text{Cl}^-$  (Table 7).

## 4. Discussion

### 4.1 Dissolution, dilution, oxidation and pH variation

The release of As from excavated rocks is affected by many factors and governed by complex processes. In altered rocks, the leaching of As is highly pH dependent and minor minerals like calcite and pyrite predominantly control the pH of the rock-water system (Tabelin and Igarashi 2009; Tabelin *et al.* 2010; Tabelin *et al.* 2012a; Tabelin *et al.* 2012b). The acidic leachate of the T sample could be attributed to the higher pyrite content of the rock relative to calcite. Oxidation of pyrite produces acidity as explained by the following equations:

In addition, leachates during the first couple of extractions were more acidic because of the partial oxidation of the T sample prior to sampling. Partial oxidation (i.e., atmospheric oxidation) of pyrite results in the formation of sulfuric acid and other soluble phases such as  $\text{Fe}^{2+}$ -sulfates, the former being formed due to the hygroscopic nature of  $\text{Fe}^{2+}$ -sulfates (Jerz and Rimstidt, 2004). Because of the low buffering capacity of the rock in the absence of minerals like calcite, the pH of the rock-water system would remain acidic for a very long time. On the other hand, the S and N samples have higher contents of calcite relative to pyrite. Thus, although pyrite oxidation also occurred in these samples, the abundant calcite in the rock effectively buffered the pH resulting in the slightly alkaline pH of the leachates. In the case of the H sample, kokaite was the source of the  $\text{NH}_4^+$  ions that buffered the acidity produced by pyrite oxidation.

The concentrations of As in the leachate from the rock samples of sedimentary origin (i.e., S, N and H samples) were generally lower compared to the T sample primarily because of the relatively higher As content of this altered volcanic rock (ca. 7 – 20 times higher than the samples of sedimentary origin). In all the rock samples, addition of more water (i.e., lower solid-liquid ratio) diluted the concentration of As resulting in its proportional decrease in the leachate. However, the leaching of As as a function of the number of extraction was different in the T sample compared to the rest of the excavated rocks. Arsenic concentration in the T sample had a distinct flushing-out trend which was not apparent in the other rock samples. In other words, As from the T sample behaved more conservatively than those of the other rock samples. These differences could be attributed to the pH of the rock-water system and its complex interactions with the different As-bearing solid phases of the rock. In the T sample, acidic pH of the leachate resulted in the higher mobility of As (Figure 3) as well as more rapid dissolution of As-bearing soluble minerals (Figures 5d and h). In addition, the acidic pH prevented the precipitation of

dissolved Fe as Fe oxyhydroxides/oxides, which could effectively reduce the concentration of As in the leachate through adsorption and co-precipitation (Dzombak and Morel, 1990; Jang and Dempsey, 2008). In contrast, As in the samples of sedimentary origin (*i.e.*, S, N and H samples) has low mobility because of the slightly alkaline pH that enhances adsorption (Tabelin and Igarashi 2009).

Because the T sample has very little organic carbon content, majority of the As associated with the sulfides/organic matter phase is in sulfide minerals like pyrite. In addition, majority of the exchangeable As fraction in this sample may have been formed due to the atmospheric oxidation of pyrite in the rock prior to sampling (Tabelin *et al.* 2012a; Tabelin *et al.* 2012b). Thus, the release of As from the T sample during the first couple of extraction was probably controlled by the dissolution of As-rich soluble phases like Fe-sulfates and amorphous Fe oxyhydroxides, resulting in the observed flushing-out As concentration trend. After most of these soluble As-bearing phases had been dissolved, the rock continued to release As, albeit at lower concentrations, because of the continued oxidation of pyrite found in the rock. These deductions are supported not only by the similar flushing-out trends of Fe and  $\text{SO}_4^{2-}$  but also of the strong positive correlations between As and  $\text{SO}_4^{2-}$  concentrations in the leachate regardless of the solid-liquid ratio.

The mobilization of As in the S, N and H samples is most probably controlled by the combined effects of dissolution of soluble minerals, oxidation of pyrite, neutralization of calcite/koktaite and adsorption/desorption of As onto minerals found in the rock like Fe/Al oxyhydroxides/oxides and clay minerals. The oxidation of pyrite and the continued dissolution of calcite in these samples were evident in the significant concentrations of  $\text{Ca}^{2+}$  and  $\text{SO}_4^{2-}$  even after repetitive washing (Figures 4, 6 and 7). Furthermore, strong positive correlations between

As and  $\text{SO}_4^{2-}$  support the importance of pyrite oxidation and the dissolution of soluble phases like Fe-sulfates in the release of As from these rocks (Tables 4, 5, 6 and 7). In addition, the mobility of As in these samples was strongly influenced by the availability of adsorbents like Fe/Al oxyhydroxides and clay minerals. Based on previously published works, the movement of As in a system is substantially retarded because of its strong adsorption affinity to Fe/Al oxyhydroxides/oxides and clay minerals like kaolinite (Cornelis *et al.* 2008; Dousova *et al.* 2003; Dzombak and Morel 1990; Gosh and Teoh 1985; Lin and Puls 2000; Wang and Mulligan 2006).

Boron and Se had strong positive correlations with  $\text{SO}_4^{2-}$  similar to As, which suggests that the mechanisms controlling the release of these elements from the excavated rocks are identical. However, discrepancies between the leaching behaviors of B and Se as functions of pH and number of extraction and those of As may imply that B and Se behave more conservatively than As. This means that B and Se are not easily affected by co-precipitation and/or adsorption reactions. In addition, moderate positive correlations of B and Se concentrations to the  $\text{Cl}^-$  concentration indicate that flushing-out of diagenetic sea water from the excavated rock of sedimentary origin is an important release mechanism of B and Se (Tables 4, 6 and 7). These deductions are supported by the less pH-dependent behaviors of B and Se compared to As, their flushing-out leaching trends and their association with phases that dissolve easily. Additionally, the effects of dilution were more pronounced on the leachate concentrations of B and Se than As. Coexisting ions like  $\text{Ca}^{2+}$ ,  $\text{Na}^+$ ,  $\text{Cl}^-$  and  $\text{SO}_4^{2-}$  generally had flushing-out trends, and were also strongly influenced by dilution. The concentrations of  $\text{Na}^+$  and  $\text{Cl}^-$  in the H sample were significantly higher than the other samples and could be attributed to the pre-existing geological condition during its deposition. This sample is mudstone and most of the cations and anions

found in this rock may have come from the sea during its diagenesis (Figure 7). In addition, dramatically higher B concentration in the leachate of the H sample in comparison to the other samples probably comes from the flushed-out diagenetic sea water retained in this sedimentary rock.

#### *4.2 Engineering implications*

Removal of hazardous elements using the consecutive washing technique employed in this study was promising especially for the removal of B and Se from excavated rocks, but was less effective when applied to As. Oxyhydroxides/oxides of Fe and Al as well as clay minerals found in the excavated rock partly retarded the leaching of As, but were not enough to lower its concentration down to the environmentally acceptable level. Moreover, majority of As in these rocks were found with sulfides/organic matter, which indicates that the rock could continue to release considerable amounts of As as long as available sulfide minerals continue to oxidize. Therefore, it is important to combine other mitigation techniques to address the problem associated with excavated rocks especially in cases where the rock contains several hazardous elements with different leaching properties. For example, it is possible to apply the washing technique as a preliminary step to remove more soluble hazardous elements like B and Se. This would then be followed by mitigation techniques like adsorption and neutralization to address the problem associated with the acidic leachate pH and As.

### **5. CONCLUSIONS**

Tunnel construction projects in Japan continue to excavate large volumes of rocks that are problematic because of their significantly high contents of hazardous contaminants like As, B, Se and heavy metals. Arsenic in the rock was found mostly with the sulfides/organic matter fraction

while B and Se were mostly associated with the more soluble phases. Variations in the pH of the rock-water system dramatically changed the leaching behavior of As, but was not observed in those of B and Se. The release of As from the excavated rocks was controlled by dissolution of soluble phases in the first couple of washing steps and by pyrite oxidation and adsorption/desorption later on. On the other hand, B and Se were removed by the combined flushing-out of diagenetic sea water and dissolution of soluble phases. Increasing the number of extraction after the removal of majority of these soluble phases had little effect on the concentrations of B and Se in the leachate. The six-step washing technique effectively removed most of the B and Se contents of the excavated rocks because both of these elements were less affected by the pH and were mostly associated with the soluble phases. However, removal of As from the rock using the same technique was ineffective because this element had a more complex pH-dependent leaching behavior than those of B and Se, and was mostly associated with the sulfides/organic matter fraction that dissolves at kinetically slower rates.
