The population genetic structure and phylogeography of masu salmon were investigated by using variation in the mitochondrial NADH dehydrogenase subunit 5 gene (*ND5*) and six polymorphic microsatellite loci among a total of 895 fish representing 18 populations collected from Japan (9), Russia (7), and Korea (2) from 2000 to 2008. An analysis of *ND5* nucleotide sequences revealed 22 variable sites in about 560 bp in the 5' half of the gene, which defined 20 haplotypes, including some associated with geographical regions. Haplotype and nucleotide diversities were greater in the populations in Japan and Korea than in those in Russia, indicating greater genetic diversity in the Japanese and Korean populations than in the Russian populations. All the microsatellite loci examined showed a high level of variation, but the expected heterozygosity indicated a similar level of genetic diversity among the populations of the three regions, contrary to the results for *ND5*. However, AMOVA and pairwise population F_{ST} estimates for both *ND5* and the microsatellite markers indicated a similar pattern of moderate genetic differentiation among populations of the three regions, and large population groups on the coasts of the Sea of Japan, Sea of Okhotsk, and Pacific Ocean in the Far East. From a mismatch distribution analysis and neutrality test, the observed genetic structure appears to have been influenced primarily by bottlenecks during glacial periods and population expansions during interglacial periods in the late Pleistocene.

Key words: genetic variation, masu salmon, microsatellite, mitochondrial *ND5*, phylogeography, population structure

INTRODUCTION

Masu salmon, *Oncorhynchus masou masou* (Brevoort), is endemic to the Far East, ranging from the southwestern Kamchatka Peninsula southward to Sakhalin, Hokkaido, and western Honshu, and extends from the Primorye region to the Korean Peninsula (Kato, 1991). Masu salmon has a diverse life history, with both river-resident and anadromous forms (Kato, 1991). Spawning adults, like other Pacific salmons, home to the natal river, with the rare occurrence of strays into non-natal rivers (Kato, 1991), which leads to

partial genetic differentiation among river populations.

Although masu salmon is an important fisheries species, its commercial catch has decreased over the years (Miyakoshi et al., 2001, 2004). Hatchery programs have been established to release fry artificially obtained from eggs of the limited spawning groups, which will cause decreased genetic diversity of subsequent breeding groups, possibly affecting the genetic structure of natural breeding groups (Noguchi and Taniguchi, 2007). Genetic diversity is important for the long-term survival of natural populations, because it confers the ability to adapt to changing environmental conditions, thereby increasing their fitness (Frankel and Soule, 1981; Hoffmann and Sgrb, 1995). Genetic variation must be characterized in both wild and cultured masu salmon populations to effectively manage and conserve diversity. In this regard, molecular genetic markers may be used to help identify lines or strains, define

stock diversity, monitor inbreeding, diagnose simply inherited traits, and even improve stocks through marker-assisted selection (Taniguchi et al., 1996; Davis and Hetzel, 2000). The population structure of masu salmon has so far been characterized with a few genetic studies using polymorphic allozymes (Okazaki, 1986) and mitochondrial DNA analyses relying on restriction fragment length polymorphism (RFLP) (Kijima and Matsunami, 1992; Suzuki et al., 2000) and nucleotide sequence variation (Edpalina et al. 2004; Kitanishi et al. 2007). However, molecular population genetic studies have not been conducted widely in the natural range of masu salmon in the Far East.

Kitanishi et al. (2007) found substantial variation in nucleotide sequences of a region of the mitochondrial NADH dehydrogenase subunit 5 gene (*ND5*) in masu salmon fry collected from Hokkaido Island, Japan. Their findings indicate a high potential for mitochondrial DNA sequence analysis in estimating genetic variation in masu salmon populations. Because of its rapid evolutionary rate compared to nuclear DNA, mitochondrial DNA allows the magnified examination of matrilineal differences among genetically discrete populations. However, males and females of a species may differ in the mechanisms of or behavior related to dispersal. Thus, population structures estimated with maternally inherited mitochondrial DNA alone may differ from that assessed with biparentally inherited nuclear DNA markers, such as microsatellites (ms). Microsatellites can effectively reveal extensive allelic variation and high levels of variability (O'Connell and Wright, 1997), allowing the detection of differences even among closely related populations. In addition, both mitochondrial and microsatellite DNA require relatively few samples for estimating variation and do not require lethal sampling.

In this study, we analyzed genetic variation and population structure in masu salmon by analyzing *ND5* sequences and polymorphic microsatellite loci in nearly 900 homing fish from 18 populations in Japan, Russia, and Korea. We also examined the historical demography of masu salmon to aid in biodiversity conservation and stock management.

MATERIAL AND METHODS

Fish sampling and DNA extraction

Liver or adipose fin from 895 masu salmon representing 18 river populations in Japan (seven in Hokkaido and two in Honshu), Russia (one in Primorye, one in Kamchatka, and five in Sakhalin) and Korea (two) were collected from 2000 to 2008 (Fig. 1; Table 1). All tissue samples were fixed in ethanol and stored at room temperature until DNA extraction. Total genomic DNA was extracted from ethanol-fixed tissues with a Gentra Puregene Tissue Kit (QIAGEN) following the manufacturer's protocol. Extracted DNA was dissolved in TE buffer (10 mM Tris-HCl, 1 mM EDTA, pH 7.3), subjected to electrophoresis in 1% agarose

gel, and stained in ethidium bromide to check the size and quality.

ND5 analysis

About 560 bp of the 5' half of *ND5* were amplified with primer pair ND5-1F and ND5-3R (Kitanishi et al., 2007). Novel reverse primers ND5-R1 (R-AGAATGAGGCCCATAGAGG) and ND5-R2 (R-TAGGCTCCCGATTGTGAGAC), were designed for direct nucleotide sequencing.

PCR amplification was carried out in an automated thermal cycler in 20- μ l reaction volumes containing 1–2 μ l of genomic DNA, 2 μ M each primer, 0.25 mM each dNTP, 1 unit of *Taq* DNA polymerase, and 2 μ l of 10X reaction buffer (with 1.5 mM $MgCl_2$). The temperature profile was 5 min at 92°C; 36 cycles of 95°C for 45 s, 56°C for 30 s, and 72°C for 2 min; and 72°C for 5 min. After electrophoresis in 1% agarose gels, PCR products were purified with AMPure magnetic beads (Agencourt, Beverly, MA). After a sequencing reaction with an ABI BigDye Terminator Cycle Sequencing Ready Reaction Kit version 3.1, purified PCR products were directly sequenced on an ABI PRISM 3130XL Genetic Analyzer (Applied Biosystems).

A multiple alignment of *ND5* sequences was performed with GENETIX-WIN version 4.0.1 (Software Development, Japan) to identify sequence variants, from which haplotypes were defined. DNAsp 4.0 (available at <http://www.ub.es/dnasp>) was used to estimate nucleotide diversity (π) and divergences between haplotypes and lineages (d_{xy}). The number of net nucleotide substitutions (D_{xy}) between haplotype lineages was computed according to Nei (1987), as $D_{xy} = d_{xy} - (d_{xx} + d_{yy})/2$, where d_{xy} is the mean nucleotide divergence between pairs of haplotypes in lineages x and y, respectively.

Microsatellite analysis

We analyzed six microsatellite loci (Oma02, Oma03ke, Oma04my, Ots520, One111, and Omi87TUF) developed for masu salmon and other salmonids (Noguchi et al., 2003; Takayama et al., 1991; Andersson et al., 1995; Naish and Park, 2002; Olsen et al., 2000; Hara et al., unpublished data, GenBank AB213231). PCR conditions, especially annealing temperatures, were optimized for amplification of the six loci when necessary.

PCR was performed in a 10- μ l reaction volumes containing 0.5 μ l of genomic DNA, 2 μ M each primer, 0.25 mM each dNTP, 1 unit of *Taq* DNA polymerase, and 1 μ l of 10X reaction buffer (with 1.5 mM $MgCl_2$). The temperature profile was 5 min at 94°C; 28 cycles of 94°C for 40 s, annealing (see below for temperatures) for 40s, and 72°C for 40 s; and 72°C for 40 min. The annealing temperatures used were 52°C for Ots520; 54°C for One111; 56°C for Oma02, Oma03ke, and Oma04my; and 61°C for Omi87TUF. The size of fluorescence-labeled allele fragments was measured on an ABI PRISM 3130XL automated sequencer, followed by analysis with GeneMapper version 3.7 (Applied Biosystems).

Population genetic analyses

To estimate the genetic variation among and within the 18 populations, haplotype diversity (h), nucleotide diversity (π), and pairwise population F_{ST} values were determined by using ARLEQUIN version 3.1 (Excoffier et al., 2005). The hierarchical nesting of genetic diversity was estimated with analysis of molecular variance (AMOVA) implemented in ARLEQUIN.

A nested clade phylogeographical analysis (NCPA) using *ND5* data was conducted with ANECA v1.2 (Panchal and Beaumont, 2007), a fully automated implementation of NCPA that includes TCS v 1.21 (Clement et al., 2000) and GeoDis v2.5 (Posada et al., 2000). A nested-design cladogram was constructed at 95% parsimonious connection probability limit to infer phylogenetic relationships among *ND5* haplotypes. Geographical distances within and among nested clades, clade distance (D_c), and nested clade distance (D_n) were calculated and compared among interior and tip clades, and the null hypothesis of no geographic association among haplotypes or clades at each nesting level was tested with 10,000 random permutations using GeoDis ver. 2.5. The inference key of Templeton et al. (1995) was used to infer the historical process that determined the population structure at each nesting level.

The distributions of pairwise genetic differences between individual haplotypes were analyzed with sudden expansion model (Rogers and Harpending, 1992). Goodness-of-fit tests (sum of squared deviations and Harpending's raggedness index) comparing

the observed to the estimated mismatch distributions were conducted with ARLEQUIN version 2000 (Schneider et al., 2000). The timing of expansions was inferred from the mode of mismatch (τ), assuming a 3-year generation time for masu salmon. As the *ND5* mutation rate was unknown for masu salmon, we estimated the time of sudden expansions by the using divergence rate of *ND5* in snook (Centropomidae) (Kitanishi et al., 2007), with a range in mutation rate of 1.0–4.4% per Myr.

For the microsatellite analysis, the number of alleles per locus, expected and observed heterozygosities, departure from Hardy-Weinberg equilibrium (HWE), and linkage disequilibrium were calculated with GENEPOP version 3.4 (Raymond and Rousset, 2004). Allele frequencies, gene diversity, and allelic richness for each population and locus were calculated with FSTAT 2.9.3 (Goudet, 2001). Tests for the occurrence of null alleles were performed with MICRO-CHECKER 2.2.3 (Oosterhout et al., 2004). Pairwise F_{ST} values and AMOVA between samples were performed with ARLEQUIN version 3.1 (Excoffier et al., 2005). In addition, genetic relationships among the populations were evaluated on a consensus tree based on Cavalli-Sforza and Edwards chord distances (1967) generated by using the Seqboot, Neighbor, and Consensus options in PHYLIP v. 3.6 (Felsenstein 2004), with a bootstrap analysis of 1000 resamplings of the loci examined.

RESULTS

ND5 variation in masu salmon

Sequence analysis of a 561 bp fragment from the 5' half of *ND5* detected 22 variable nucleotide sites among 895 individuals from 18 populations (Table 2), which defined a total of 20 haplotypes, including 10 of 13 previously reported (Kitanishi et al., 2007) and 10 newly identified, H14 to H23 (Table 2). Nucleotide sequences of the 10 novel haplotypes were deposited in the DDBJ/EMBL/GeneBank database under accession numbers AB469790–AB469799.

The distribution of haplotypes among 18 populations of masu salmon is given in Table 3. The occurrence of haplotypes was different from one population to another, although haplotype H1 occurred in all 18 populations. Sixteen of the 20 haplotypes occurred in nine Japanese populations (625 individuals), whereas only six and seven haplotypes were found in seven Russian (230 individuals) and two Korean populations (40 individuals), respectively. Eight (H3, H7, H13 to H15, H17 to H19), three (H16, H20, H23), and one (H8) haplotypes were limited to the Japanese, Russian, and Korean populations, respectively. Haplotype H3 was restricted to Japanese populations, though it was absent in the SHA population in Hokkaido, suggesting that this haplotype characterizes the Japanese populations. In addition, haplotypes H4, H3, and H11 were relatively abundant in populations from the Sea of Japan (61%), Pacific (33%), and the Sea of Okhotsk coasts (81%) in Japan, respectively (Table 3), suggesting a regional association for these haplotypes.

The average haplotype diversity was highest in the populations in Korea (0.752), followed by those in Japan (0.535) and Russia (0.212), suggesting greater genetic variation in the Korean and Japanese populations than in those in Russia.

Microsatellite variation in masu salmon

Table 4 summarizes the number of alleles and the observed (h_o) and expected heterozygosity (h_e) for the six

Table 4. Variation at six microsatellite loci in 18 populations of masu salmon. Sampling abbreviations are listed in Table 1. *N*, number of individuals; *NA*, number of alleles; *Ar*, allelic richness; *he*, expected heterozygosity; *ho*, observed heterozygosity; *P*, estimate of probability of deviation from Hardy-Weinberg equilibrium; *, significant departure from Hardy-Weinberg equilibrium ($P < 0.05$).

possible null alleles at these loci, as determined with MICRO-CHECKER.

Population genetic structure estimated from *ND5* and microsatellites

Pairwise population F_{ST} estimates in masu salmon based on both *ND5* and microsatellites are given in Table 5. Although the F_{ST} estimates did not necessarily show clear genetic differentiation within and among regions, there appeared to be distinct in both markers between OIP (Pacific coast) and most populations on the Sea of Okhotsk or Sea of Japan coasts in all regions. Substantial differentiation in *ND5* appeared to exist between TES from the Sea of Japan and most populations from coasts of the Sea of Okhotsk in Japan. Similarly, differentiation was apparent between GAL (west coast of Sakhalin) and most other populations from coasts of the Sea of Japan or Pacific in all other regions. Microsatellite differentiation appeared to exist between UTK from the west coast of Kamchatka and other populations in all regions. A similar level of microsatellite differentiation was also evident between two

populations in Korea (NAM and WAN) and most others in all regions.

The consensus NJ tree from the microsatellite data, however, showed a population cluster with nodal bootstrap values mostly less than 50%, and thus did not distinguish geographical groups among the populations examined (see Supplemental Fig. S1 online).

AMOVA with both markers (Table 6) revealed the following population structure in masu salmon: (i) significant geographic structuring among Japan, Russia, and Korea (*ND5*, 4.54%, $P < 0.05$; microsatellites, 1.65%, $P < 0.001$; Analysis I); (ii) significant geographic structuring among the coasts of the Sea of Japan, Pacific, and Sea of Okhotsk in all regions (*ND5*, 6.12%, $P < 0.05$; microsatellites, 2.07%, $P < 0.001$; Analysis II); (iii) significant geographic structuring among the coasts of the Sea of Japan, Sea of Okhotsk, and Pacific in Japan (*ND5*, 15.14%, $P < 0.005$; microsatellites, 2.63%, $P < 0.005$; Analysis III), but not significant among Primorye, Sakhalin, and Kamchatka in Russia (*ND5*, -20.55, $P > 0.05$; microsatellites, 1.86%, $P > 0.05$) (not shown); (iv) significant geographic structuring between two coastal

Table 5. Pairwise F_{ST} estimates among masu salmon populations in all regions. The statistical significance of F_{ST} values was tested with the exact test after sequential Bonferroni adjustments (*, $P < 0.05$; **, $P < 0.001$). Sampling abbreviations are listed in Table 1. F_{ST} values > 0.05 (below diagonal, microsatellites) and F_{ST} values > 0.15 (above diagonal, $ND5$) are in bold font. The gray background denotes F_{ST} values > 0.07 (below diagonal, microsatellites) and F_{ST} values > 0.2 (above diagonal, $ND5$).

Clade 2-1 and 2-3	0.00394	0.00520	0.00178
Clade 2-2 and 2-3	0.00605	0.00820	0.00463

congruence of both mitochondrial and microsatellite markers in estimating the genetic structure of masu salmon, suggesting the existence of three large population groups in addition to previous geographical groupings of masu salmon into populations in Japan, Russia, and Korea.

Historical demography of masu salmon

The nested 95% set of plausible cladograms for the observed 20 $ND5$ haplotypes was constructed with NCPA (Fig. 2); a focal haplotype (H1) and derived haplotypes showed a clear star-like genealogy. The observed $ND5$ haplotypes were separated into six 1-step clades (1-1, 1-2, 1-3, 1-4, 1-5, and 1-6) and three 2-step clades (2-1, 2-2 and 2-3); the last group included all haplotypes in a single 3-step clade (Fig. 3). The average number of nucleotide substitutions per site and the nucleotide diversity between and within clades are presented in

Table 7. Estimates of both parameters were less than 0.01 in all cases, indicating a rather shallow genealogy for $ND5$ haplotypes in masu salmon.

Fig. 3 presents the results of the nested clades analysis of geographical distances. Mapping the distribution of the

major 2-step clades in Fig. 3 revealed that clade 2-1 was spread among most populations, clade 2-2 comprised most of the Sea of Japan and Pacific (although only one population), and clade 2-3 comprised most of the Sea of Okhotsk populations. The interpretation of these statistical

results (Fig. 3; Table 8), employing the latest inference key from Templeton et al. (1995), was restricted gene flow with isolation by distance (IBD) for clade 2-1, and contiguous range expansion (CRE) for clades 2-2 and 2-3, (Table 8). The data also suggested CRE for 1-step clade 1-6 nested in

Fig. 2. The estimated 95% plausible set of cladograms and associated nested design for the *ND5* haplotypes found in masu salmon. Clades are nested according to rules outlined in Templeton et al. (1995). Zeros indicate haplotype states that are necessary intermediates between observed haplotypes but that were not observed in the samples. Each solid line interconnecting two haplotype states represents a single mutational change. Narrow-lined boxes enclose one-step clades, which are designed by “1-x” where x is a number assigned to identify the clade; wide-lined boxes enclose two-step clades (“2-x”). Individual haplotypes are considered 0-step clades; haplotype separated by a single mutation are grouped into 1-step clades (1-1, 1-2, 1-3, 1-4, 1-5, and 1-6); and 1-step clades separated by a single mutation are grouped into 2-step clades (2-1, 2-2, and 2-3). The last group includes all haplotype in a single 3-step clade (3-1).

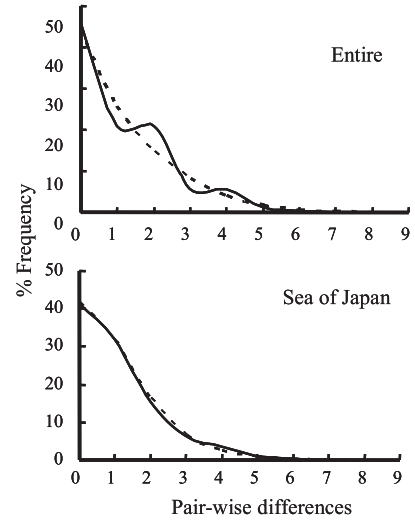

Fig. 4. Frequency distributions of pairwise nucleotide differences between haplotypes of masu salmon in the entire population and those from the Sea of Japan coasts. Solid lines, observed frequency; dashed lines, frequency distribution expected from a sudden expansion model; *SSD*, sum of squared deviations in the goodness-of-fit test. Entire population, *SSD* = 0.007, *P* = 0.649; Sea of Japan, *SSD* = 0.000, *P* = 0.927.

Fig. 3. Nested clade distance analysis for *ND5* haplotypes observed in masu salmon. Brackets reflect the nesting structure (see Fig. 3). Dc and Dn are clade and nested clade distances, respectively (for details see Templeton et al., 1995). Interior vs tip contrasts for Dc and Dn are indicated with ‘I-T’ in the corresponding clade, with interior clades given in bold italic font. Superscripts ^{*S} and ^{*L} indicate distance measures that are significantly smaller and larger, respectively, than expected under a random distribution of haplotypes.

clade 2-2, but for the other two 1-step clades (1-1 and 1-4), nested in clades 2-1 and 2-3, respectively, the inferences were rather ambiguous and could have been long-distance colonization and/or past fragmentation (LDC/PF) and restricted gene flow/dispersal, or past gene flow followed by extinction of intermediate populations (# in Fig. 3). The latter ambiguous interpretation was also inferred for the entire cladogram (clade 3-1) (Table 8).

The mismatch distributions for all populations and those for the Sea of Japan coasts are shown in Fig. 4, as no other population groups were significant for Tajima's D , Fu's F_S , and/or SSD (not shown). All populations together showed a sinusoidal mismatch distribution, with low to moderate peaks at 2 and 4 sequence differences, though the highest frequency was at 0 differences. The Sea of Japan populations showed no additional peaks in the distribution due to an excess of 0 and 1 nucleotide differences (Fig. 4). D , Fu's F_S , and SSD (Table 9) suggested expansion for these population groups. Either the negative D or the F_S value was marginally or distinctly significant, with substantially small SSD but higher P values, in the Sea of Japan populations ($D = -1.402$, $P = 0.058$; $F_S = -5.176$, $P = 0.049$; $SSD = 0.000$, $P = 0.927$) and all populations together ($D = -1.526$, $P = 0.024$; $F_S = -10.285$, $P = 0.016$; $SSD = 0.007$, $P = 0.649$) (Table 9), favoring sudden expansion. The τ value, which reflects the location of the mismatch distribution crest, provides a rough estimate of the time when rapid population expansion started (Rogers and Harpending, 1992; Rogers, 1995). The sudden expansion of populations was estimated to have occurred 0.049–0.217 Ma in the Sea of Japan populations, and 0.089–0.394 Ma for all populations (Table 9).

Table 8. Interpretation of the results of the nested clade analysis using the inference key of Templeton et al., (1995). *, too few clades for analysis.

Clade	Inference chain	Inferred pattern
Haplotypes nested in1-1	1-2-11-12-13-14 NO	Long-distance colonisation and/or past fragmentation(LDC/PF)
Haplotypes nested in1-4	1-2-3-5-6*-7-8 YES	Restricted gene flow/dispersal or past gene flow followed by extinction of intermediate populations(#)
Haplotypes nested in1-6	1-2-11-12 NO	Contiguous range expansion(CRE)
Haplotypes nested in2-1	1-2-3-4 NO	Restricted gene flow with isolation by distance(IGD)
Haplotypes nested in2-2	1-2-11-12 NO	Contiguous range expansion (CRE)
Haplotypes nested in2-3	1-2-11-12 NO	Contiguous range expansion(CRE)
Three-step clades nested in the entire cladogram	1-2-3-5-6*-7-8 YES	Restricted gene flow/dispersal or past gene flow followed by extinction of intermediate populations(#)

Table 9. Parameters of the sudden expansion model and estimated time since expansion for masu salmon, according to Rogers and Harpending (1992), Tajima (1993), and Fu (1997). D , Tajima's D ; F_S , Fu's F_S ; SSD , sum of squared deviations in the goodness-of-fit test; τ , time since expansion measured in mutational time units; CI, confidence interval; θ_0 and θ_1 , population sizes scaled by mutation rate before and after expansion, respectively.

Populations	Sample size	D (P-value)	F_S (P-value)	SSD (P-value)	τ (95%CI)	θ_0 (95%CI)	θ_1 (95%CI)	Time since expansion (year)
Entire (18)	895	-1.526 (0.024)	-10.285 (0.016)	0.007 (0.649)	2.214 (0.467-5.539)	0.063 (0.000-0.087)	431.372 (0.398-1743.455)	89000-394000
Sea of Japan (7)	291	-1.402 (0.058)	-5.176 (0.049)	0.000 (0.927)	1.222 (0.000-5.274)	0.131 (0.000-2.213)	1283.041 (0.167-5206.387)	49000-217000

DISCUSSION

Our $ND5$ and microsatellite analyses gave congruent estimates of the population genetic structure of masu salmon in the Far East (although the extent of variance suggested by AMOVAs was always larger for $ND5$ than for microsatellites): (i) weak structuring among populations in Japan, Korea, and Russia, and large groups on the coasts of the Sea of Japan, Sea of Okhotsk, and Pacific; (ii) moderate structuring among coastal regions in the Sea of Japan and Sea of Okhotsk; and (iii) moderate structuring within Japan but not within Russia. The findings for Russia may be ascribed to substantial sampling gaps.

The clade topology of the $ND5$ haplotypes and nucleotide divergencies between or within clades in masu salmon (Fig. 2; Table 7) suggest a shallow haplotype genealogy as a whole. In particular, the lineage of haplotype H1 showed a clear star-like pattern, with the radiating haplotypes mostly region specific, suggesting their recent appearance and rapid expansion (Slatkin and Hudson, 1991; Rodgers and Harpending, 1992) in Japan, Korea, and Russia. This sort of shallow haplotype genealogy has also been reported in some other Pacific salmon and is probably the consequence of population decreases in glacial periods and subsequent recovery during interglacial periods (McCusker et al., 2000; Churikov and Gharrett, 2002; Sato et al., 2004).

Six microsatellite loci developed for masu and other salmonids were highly polymorphic in all the masu populations we examined, with locus-dependent variability but without linkage disequilibrium between loci. The observed HWE, which was distributed among loci and populations due mostly to heterozygote deficits, was likely caused by null or non-amplifying alleles arising from nucleotide polymorphisms at priming sites. Beyond the hypothesis of null alleles, the heterozygote deficiency could also have been due to other factors, such as admixture of more than two independent populations, non-random mating, or artificial or natural selection during seed production and cultivation. In this study, the heterozygote deficits did not occur in all the loci and populations, which may reflect features of the masu populations examined rather than drawbacks of the microsatellite markers employed, although the exact cause remains unknown.

Incongruent population genetic structures inferred from mitochondrial and microsatellite

markers have been reported previously for other animal groups, including mammals (Nyakaana and Arctander, 1999), birds (Piertney et al., 2000; Scribner et al., 2001), and fishes (Bernatchez and Osinov, 1995; Lu et al., 2001). Some of the discordance can be explained by differences in the mode of inheritance of the two marker systems, as the effective population size for mitochondrial markers is only one quarter that of nuclear markers. In addition, some studies have found discordances larger than expected, for example, due to sex-biased gene flow among populations in mammals and insects (e.g. Nyakaana and Arctander, 1999; Doums et al., 2002). Differential mutation rates between the two markers could also result in higher accumulation of homoplastic mutations in microsatellite DNA than in mitochondrial DNA, which would contribute to a reduction in the extent of population differentiation estimated by microsatellite DNA (e.g., Viard et al., 1998). In our study, *ND5* and microsatellite markers suggested different levels of gene flow as inferred by F_{ST} values in some pairwise comparisons (Table 5), in addition discordance in the estimated genetic diversities (see Tables 3, 4). In particular, uneven *ND5* variation among the three regions (Table 3) might reflect the consequence of human activity, as the artificial production and release of hatchery masu salmon have long been attempted in Japan (Mayama, 1992) and Russia (Zaporozhets and Zaporozhets, 2004). However, surprisingly uniform microsatellite variation among the regions (Table 4) argues against this possibility, and the effects of artificial propagation on the observed genetic structure are unknown. The observed discrepancy in patterns of population differentiation estimated by the two markers therefore could potentially be caused by multiple factors, such as different modes of transmission and evolution of these genetic systems (Lu et al., 2001). Nevertheless, these different estimates at the population level did not seem to affect the estimation of hierarchical structure between population groups by AMOVA, providing congruent results for *ND5* and microsatellites, as mentioned above.

The AMOVAs suggested the existence of large population groups on the coasts of the Sea of Japan, Sea of Okhotsk, and Pacific, in addition to the traditional grouping of masu salmon into populations in Japan, Russia, and Korea. The extent of variation in the large grouping was similar to that of the traditional grouping for both *ND5* and the microsatellite markers (Analyses I and II), suggesting a similar pattern of inter-group and within-group gene flow in both cases. However, apparently larger within-group than inter-group variation is puzzling and possibly suggests low effects of geographical distance on limiting gene flow. In fact, subregional structure among coasts of the different oceans (Analyses III and IV) more clearly implies a limitation of gene flow by geographical distance, particularly with *ND5*, as shown by larger inter-group than within-group variation. This may also suggest different potential between the two markers for estimating genetic structure.

Our NCPA suggests that the observed genetic structure of masu salmon might have been shaped primarily by contiguous range expansion and secondarily by restricted gene flow with isolation by distance (Fig. 3; Table 8), conclusions mostly compatible with the results of AMOVA mentioned above. A low influence of isolation by distance

may be related to the high homing ability of masu salmon (Okazaki 1986), which may lead to distance-independent genetic differentiation among populations by region. In fact, another Pacific salmon, chum salmon, with less accurate homing ability than masu salmon (Salo, 1991), shows clear population differentiation with isolation by distance around the Pacific Rim (Yoon et al., 2008). Besides the biological consequence, the inference from NCPA may indicate that the historical demography of masu salmon was driven by cycles of glaciation and associated sea level changes (Nürnberg and Tiedemann, 2004).

With Tajima's D , Fu's F_S , SSD , and the mismatch distribution analysis, one or more of the parameters or estimates suggested sudden expansion of the whole population and the Sea of Japan populations (Fig. 4; Table 9) in the Late Pleistocene. In contrast, the Sea of Okhotsk populations, not fitting the sudden expansion model, likely experienced a complex demographic history, inferred from the sinuous or bimodal mismatch distribution pattern (not shown), as also seen for the entire population (Fig. 4). This may suggest that exponential population growth occurred at least twice in the past, probably associated with the movements of glaciers in the Sea of Okhotsk. Chum salmon populations are thought to have undergone dramatic reductions in size in the Sea of Okhotsk in the past, due to decreases in their ranges during glacial periods and subsequent reintroductions after the retreat of glaciers (Brykov et al., 2003). If this was also the case for masu salmon, these populations might have undergone population decreases in the Sea of Okhotsk and colonized the Sea of Japan during glacial periods (Kitanishi et al., 2007). The scenario of relatively recent, rapid population growth for masu salmon on the Sea of Japan coasts after glacial bottlenecks is favored by the star-like genealogy of haplotypes in those areas, the mismatch distribution pattern supporting the sudden expansion model, and the estimated expansion time described above. The low genetic diversity observed for the Russian populations, estimated by *ND5* haplotype diversity, may also be relevant to the probable decrease in population range in the Sea of Okhotsk during multiple glacial periods, sometime after colonization to the Sea of Japan.

In conclusion, the population genetic structure of masu salmon endemic to the Far East likely reflects demographic histories related to past glacial movements, probably in the Sea of Okhotsk. The newly detected large population groups on the coasts of the Sea of Japan, Sea of Okhotsk, and Pacific may also be primarily the consequence of this historical demography. Our population genetic data based on mitochondrial and microsatellite DNA markers will be useful in conserving and managing both the river-resident and anadromous forms of masu salmon, as rapidly decreasing commercial catches of both forms are of common urgent concern in Japan, Korea, and Russia (e.g., Kato, 1991; Augerot, 2005).

ACKNOWLEDGMENTS

This study was supported in part by Grants-in-Aid from the Fisheries Agency of Japan, the Northern Advancement Center for Science and Technology, and the 21st COE program (K-2) 'Marine Bio-Frontier for Food Production' at Hokkaido University, sponsored

by the Ministry of Education, Culture, Sports, Science and Technology, Japan.
