22

23 **Abstract** *Gymnocanthus herzensteini* and *G. intermedius* (Cottidae) larvae are common in northern
24 Japan but can be difficult to distinguish. In this study, morphological observations and mitochondrial
25 DNA analyses were conducted to determine if melanophore patterns could be used to distinguish the
26 two species. The morphological observations identified two groups with distinct melanophore
27 patterns. Subsequent molecular analyses determined with high bootstrap values that the group with
28 numerous body melanophores was *G. intermedius*, and the group with fewer melanophores was *G.*
29 *herzensteini*. These results indicate that melanophore distribution patterns in larvae are useful for
30 identifying *G. intermedius* and *G. herzensteini*.

31

32 **Keywords** *Gymnocanthus* · sculpins · melanophores · morphology · DNA barcoding

33 **Introduction**

34

35 The family Cottidae (Teleostei) comprises about 70 genera and 275 species, which generally spawn
36 demersal eggs on various matrixes, such as rocks, sand, seaweeds, sponges or other structures
37 (Munehara 2011). The hatchlings are pelagic, but the flexion and postflexion larvae are benthic.
38 *Gymnocanthus herzensteini* and *G. intermedius* occur sympatrically and concurrently over shallow
39 sandy bottom in northern Japan, and have similar early life histories; they spawn in winter and move
40 to the sandy bottom from April to May (Munehara et al. 2009). Adults of these two species can be
41 distinguished based on differences in the skin flaps on the eyes, the form of the dorsal fin, the
42 distribution of melanophores on the pectoral fins (with 3-4 dark transverse bands, but narrow than
43 pupil in *G. intermedius*), and the number of spines and fin rays (Nakabo and Kai 2013), but these
44 diagnostic characteristics can be similar in immature individuals.

45 The characteristics used for identifying the early life stages, including the numbers of spines, fin
46 rays and myomeres (Okiyama 1988), are easily destroyed during collection. Furthermore,
47 morphological data are available for *G. intermedius* larvae and juveniles (collected by larval net,
48 Okiyama 1988), but for *G. herzensteini* larvae only through the preflexion stage (reared, Kyushin
49 1970). These obstacles have limited our understanding of ecological characteristics of individual
50 species such as larval and juvenile distribution and abundance, and recruitment dynamics.

51 Another characteristic that can be used to distinguish the early life stages of several fish groups is
52 melanophores on other body parts (e.g., the head, gut, body, finfolds and fins for Agonidae, Busby
53 1998; the antero-ventral postanal and gut dorsal to the pelvic bone for Lutjanidae, Clarke et al. 1997).
54 In addition to morphological identification methods, genetic methods such as DNA barcoding are
55 increasingly being used to identify specimens, but to develop a global DNA-based barcode
56 identification system requires nucleotide sequence data from numerous species (Lakra et al. 2011). In
57 the present study, morphological and molecular analyses together confirmed that melanophore
58 distribution patterns can be used to distinguish larvae of *G. herzensteini* and *G. intermedius*.

59

60

61 **Materials and methods**

62

63 Samples were collected in Funka Bay, southwest Hokkaido. For molecular analyses, 18 larvae were
64 collected with a hand net by SCUBA diving in May 2010. Specimens used for the examination of
65 morphological characters were collected by SCUBA diving in May of 2010 (n=18) and using a sledge
66 net (Munehara et al. 2009) in May of 2012 (n=1,752). *Gymnocanthus* larvae were identified based on
67 descriptions published in Kojima (1988) and Shiogaki (1988). The developmental stages described by
68 Leis and Carson-Ewart (2000) were used. All larvae were observed under a microscope (BX51,
69 OLYMPUS), and the body length (BL) was measured to the nearest 0.01 mm. The body-part terms and
70 morphological characters described by Leis and Carson-Ewart (2000) were used. All specimens
71 collected in May of 2012 were deposited in the Hokkaido University Museum, Hakodate (HUMZ, *G*
72 *intermedius*: HUMZ 223343, *G. herzensteini*: HUMZ 223344).

73 Genomic DNA was extracted from the whole body of all samples using a QuickGene DNA
74 extraction kit (KURABO, Japan) following the manufacturer's protocol. A 679 bp of the
75 mitochondrial cytochrome c oxidase subunit I (COI) region that has enough substitution rates to
76 distinguish species in *Gymnocanthus* (Yamazaki et al. 2013) was analyzed; this region is used by
77 taxonomists as a standard DNA barcode sequence. The COI region was amplified by PCR using the
78 primers FishF1 and FishR1 (Ward et al. 2005) following the experimental protocol of Yamazaki et al.
79 (2013). Sequences were aligned using MEGA5 (Tamura et al. 2011) with default settings and
80 manually corrected. The maximum likelihood (ML) tree was constructed using RAxML ver. 7.2.8
81 (Stamatakis 2006). MrModeltest2.3 (Nylander 2004) was used to determine the appropriate model of
82 sequence evolution. The best-fit model selected using the heuristic algorithm based on the Akaike
83 information criterion was the general time reversible model (GTR) of nucleotide substitution with the
84 gamma distribution shape parameter (G) and a proportion of invariable positions (I). The robustness
85 of nodes was estimated from 1,000 bootstrap replicates. Seven *G. intermedius*, eight *G. herzensteini*,
86 and one individual each of *G. detrisus*, *G. galeatus*, *G. pistilliger*, *G. tricuspis* and *Myoxocephalus*
87 *stelleri* that already detected the species specific nucleotides by Yamazaki et al. (2013) were added as
88 an out-group, and sequences of 51 species of Cottidae from GenBank were also included in the

89 molecular analysis (see electronic supplementary material: S1). Sequence data of *G. herzensteini* and
90 *G. intermedius* are shown in S2, and all individual sequence data have been deposited in GenBank
91 (Accession numbers are shown in Table 1).

92

93

94 **Results and discussion**

95

96 Based on the melanophore distribution patterns, 1,752 larvae were divided into two groups (Fig. 1): A
97 (n=1,260) and B (n=492). Group A ranged in size from 9.01–16.84 mm BL. Melanophores occurred
98 on the dorsal side of the head and nape in all group A specimens. An oblique series of melanophores
99 also occurred on the tail under the second dorsal fin (melanophores on tail) in some flexion specimens
100 at 9.22–11.97 mm BL, and in all flexion and postflexion specimens larger than 11.97 mm BL, but not
101 in flexion larvae at 9.01–9.22 mm BL. On the first dorsal fin, melanophores were observed on spines I
102 to VII from the base to over half the length of the spine, sometimes to the distal end. Group B ranged
103 in size from 9.06–18.27 mm BL. Melanophores also occurred on the dorsal side of the head and nape
104 in all group B individuals, but melanophores on the tail developed later than in group A;
105 melanophores on the tail occurred in some flexion specimens at 11.64–14.49 mm BL, and in all
106 flexion and postflexion specimens larger than 14.49 mm BL, but did not occur in flexion larvae at
107 9.06–11.64 mm BL. On the first dorsal fin, melanophores were observed on spines I to VII either only
108 at the base or discontinuously from the base to the distal end, and formed a band horizontal to the base
109 (Table 1).

110 The density of melanophores on both the dorsal surface of the head to nape and the first dorsal fin
111 was high in group A and low in group B. Melanophores on the first dorsal fin extended from the base
112 to between half the length of the fin and the distal end in both stages of group A, but in group B, they
113 occurred at the base in the flexion stage, and at the base or sometimes in a narrow band horizontal to
114 the dorsal base on the middle height in the flexion and postflexion stages. Melanophores on the tail
115 were continuous in group A flexion and postflexion larvae, but sometimes discontinuous in group B
116 flexion larvae.

117 In the molecular analysis, 18 larvae were sequenced. These morphological characteristics for each
118 specimen are shown in Table 2 (6 flexion larvae and 1 postflexion larva in group A, and 10 flexion
119 larvae and 1 postflexion larva in group B). The length of the partial COI sequence was 679 bp, and it
120 included 32 variable sites and 31 parsimony informative sites. All larvae in both groups A and B were
121 divided into *G. intermedius* and *G. herzensteini* clades, respectively, with high (>95%) bootstrap
122 values (Fig. 2).

123 These results indicate that melanophore distribution patterns can be used to identify *G. intermedius*
124 and *G. herzensteini* flexion and postflexion larvae. Using this diagnosis, we can clarify the differences
125 in the early life histories of these species.

126

127

128 **Acknowledgments** We thank all members of Usujiri Fisheries Station for their cooperation in
129 sampling. This study was funded by a Grant-in-Aid for Scientific Research from the Ministry of
130 Education, Culture, Sports, Science and Technology, Japan.
