Abstract: The honesty of people in an online panel from 15 countries was measured in two experiments: reporting a coin flip with a reward for "heads", and an online quiz with the possibility of cheating. There are large differences in honesty across countries. Average honesty is positively correlated with per capita GDP. This is driven mostly by GDP differences arising before 1950, rather than by GDP growth since 1950. A country's average honesty correlates with the proportion of its population that is Protestant. These facts suggest a long-run relationship between honesty and economic development. The experiment also elicited participants' expectations about different countries' levels of honesty. Expectations were not correlated with reality. Instead they appear to be driven by cognitive biases, including self-projection.

- Average honesty of resident nationals of 15 countries was measured in two experiments
- There are large cross-country differences in honesty
- Honesty correlates at country level with GDP and Protestantism
- Participants' expectations about honesty in different countries were also elicited
- Expectations were not correlated to reality, but driven by cognitive biases

Honesty, beliefs about honesty, and economic growth in 15 countries

David Hugh-Jones*

April 12, 2016

Abstract

The honesty of people in an online panel from 15 countries was measured in two experiments: reporting a coin flip with a reward for “heads”, and an online quiz with the possibility of cheating. There are large differences in honesty across countries. Average honesty is positively correlated with per capita GDP. This is driven mostly by GDP differences arising before 1950, rather than by GDP growth since 1950. A country’s average honesty correlates with the proportion of its population that is Protestant. These facts suggest a *long-run* relationship between honesty and economic development. The experiment also elicited participants’ expectations about different countries’ levels of honesty. Expectations were not correlated with reality. Instead they appear to be driven by cognitive biases, including self-projection.

The 19th-century Chinese scholar Feng Guifen attributed British economic success to four causes: utilizing manpower, superior agriculture, control over rulers, and “the necessary accord of word with deed” (quoted in Spence 2001). These explanations map on to standard answers to the biggest question in economics¹: why are some countries richer than others? Feng’s first two causes relate to the factors of land and labour, and the third to political economy explanations of economic growth (Acemoglu and Robinson, 2013). The fourth and final cause points to a cultural variable: the propensity to tell the truth and keep one’s promises, that is, honesty.

Honesty might be good for growth because it encourages economic interactions beyond a narrow circle. When people are honest, bare promises act like contracts, allowing gains from cooperation in situations where formal contracts would be hard to write or enforce. If honesty varies across cultures, as Feng proposes, then this mechanism may explain why levels of wealth vary too. On this account, honesty should be particularly important in environments with weak institutions (so that contracts are hard to enforce) and without technology for

3
4
5 monitoring (so that contracts are hard to monitor). That description fits most pre-industrial societies. Modern
6 societies, on the other hand, have relatively effective institutions, plus technological advances that make moni-
7 toring easier.² In these respects, even today’s developing economies are far ahead of where they were in the past.
8 So, we might expect honesty to be most important for economic development early in history. In the context of
9 eighteenth-century Britain, Mokyr (2008) argues: “It is simply not plausible that third-party enforcement was
10 the main institution on which economic progress relied during the Industrial Revolution.” Instead, order was
11 provided by “social conventions and self-enforcing modes of behavior”, including “a sense of honesty”. By the
12 nineteenth century, though, formal institutions played an increasingly prominent role.

19 This paper reports experimental research on cross-national differences in honesty. People from 15 countries
20 took part in an online survey containing two incentivized experiments measuring honest behaviour. I use both
21 the well-known coin flip experiment, where subjects report the result of a coin flip and are offered money for
22 reporting “heads”, and a new experimental paradigm: an online quiz in which subjects were able to cheat and
23 this could be detected. This dual design lets me check that results are robust to using different honesty measures.
24 This is important, because differences between countries may reflect reactions to one specific experimental
25 paradigm: I discuss a possible example below. I also use an online sample, rather than drawing from university
26 subject pools like much previous research. Though it is still not a true random sample, this sample is more
27 diverse and closer to the population on some demographic variables.
28
29
30
31
32
33
34

35 With data from the experiments, I first test Feng’s basic intuition that levels of honesty differ between
36 societies. Then, taking country average levels of honesty, I relate them to economic development at different
37 times in history. I also test whether honesty is related to religion, a cultural variable that is often believed to
38 affect economic outcomes, and to a measure of country-level corruption. Contrary to some previous research, I
39 find large differences in honesty between countries. Inter-country differences relate to economic growth before
40 1950, but are unrelated to growth since then. This seems to support the argument above, that the relationship
41 between honesty and economic growth exists over the historical long run.
42
43
44
45
46
47

48 The ability to realize gains from trade and cooperation may depend not just on partners’ honesty, but also
49 on their mutual trust. People hold beliefs about the honesty of both their fellow citizens, and those in other
50 countries. Under rational expectations, these beliefs would be correct on average. However, a large literature
51 in psychology examines *stereotypical* beliefs about groups (McGarty, Yzerbyt and Spears, 2002). Stereotypes
52 may, but need not, be accurate (Jussim et al., 2009). Different groups’ beliefs about each other can affect
53
54
55

56 ²Cowen and Tabarrok (2015) list a number of recent technologies that improve monitoring and reduce moral hazard, including online
57 reviews, credit checks, remote attendance monitoring for workers and escrow systems. Earlier advances include double entry accounting,
58 the telegraph and telephone, and on the institutional side speedy access to justice and impartial bureaucracies.
59
60
61
62

3
4
5 how they interact. For instance, the German public’s willingness to support debt bailouts may be affected by
6 stereotypes about Southern Europeans (Soll, 2015). So it is important to understand how these beliefs are
7 formed. Participants in the experiment were asked to predict the average honesty of other participants from
8 different countries. The data support neither rational expectations, nor the alternative hypothesis that people
9 predict others’ honesty from their experience in their own country. Instead, these beliefs are driven by biases,
10 including self-projection and, surprisingly, pessimism about the honesty of people in one’s own country.
11
12
13
14
15

16 A growing literature in economics uses incentivized experiments to study honesty. Initial experiments ex-
17 amined whether people’s unwillingness to lie was related to costs (Gneezy, 2005; Charness and Dufwenberg,
18 2006; Vanberg, 2008). More recent work has revealed variety in the motivations of liars: people may lie to
19 benefit others (Erat and Gneezy, 2012) or in such a way as to make their lie less obvious (Fischbacher and
20 Föllmi-Heusi, 2013). There is also some evidence for heterogeneity: women are less willing to tell a lie (Dreber
21 and Johannesson, 2008). Abeler, Becker and Falk (2014) run the coinflip paradigm within a telephone survey
22 of a representative sample of Germans, and find that complete honesty cannot be ruled out.
23
24
25
26
27

28 Within a broader literature comparing social preferences across cultures (e.g. Croson and Buchan 1999;
29 Henrich 2004; Henrich et al. 2006; Herrmann, Thöni and Gächter 2008), some existing papers have compared
30 honesty across countries. Holm and Kawagoe (2010) run a sender-receiver game in Sweden and Japan, finding
31 no differences in average levels of truth-telling. Pascual-Ezama et al. (2015) report an experiment among
32 university students in 16 countries. Subjects were asked to flip a coin and report the result; reporting heads was
33 rewarded with a chocolate. Cross-country differences in honesty are small and insignificant. Mann et al. (2015)
34 run a “dice rolling” game, similar to the coin flip, in five countries. They find small, marginally significant
35 differences in honesty. Both these studies offered relatively low incentives (a chocolate, and 20 cents average per
36 lie, respectively), which may explain the low levels of dishonesty and small differences they report. Dieckmann
37 et al. (2015) run a “coin flip” game in five European countries and find significant differences in honesty between
38 countries. They also examine subjects’ incentivized assessments of different nations’ honesty, with results
39 similar to those reported here. In a recent paper, Gächter and Schulz (2016) also find inter-country differences.
40 There are two key differences between their paper and this one: first, they use student subject pools, while I use
41 people from online market research panels; second, I test honesty using two different paradigms, whilst they
42 use a dice rolling paradigm only. Both choices are discussed further below.

54 This paper also speaks to the literature on cross-country differences in trust and social capital. Most cross-
55 country comparative research on trust uses survey data (Porta et al., 1997; Knack and Keefer, 1997). A poten-
56 tially important proximate cause of trust is trustworthiness, including honesty. More than questions on trust,
57
58
59
60
61
62
63
64
65

1
2
3
4
5 survey questions on trustworthiness face the problem that respondents may not always answer truthfully. Be-
6
7 havioural data can therefore play an important role in measurement, and indeed several papers have used the
8
9 trust game (Berg, Dickhaut and McCabe, 1995) to measure trust and trustworthiness across cultures (Yamagishi,
10
11 1988; Buchan, Croson and Dawes, 2002; Holm and Danielson, 2005; Bornhorst et al., 2010). The paradigms
12
13 used here have the advantage over the trust game that they require no interactions between participants, making
14
15 them simpler to administer. A subtler difference is in what the experiments measure. Responder behaviour in
16
17 the trust game may be affected by several factors, including altruism towards one’s partner, reciprocity and a
18
19 perceived social norm. In the experiments here, respondents face a simpler choice between honesty and material
20
21 self-interest. Below, I examine the relationship of honesty with questionnaire and behavioural measures of trust,
22
23 and find no evidence that they are related at country level.

24
25 This paper’s contribution, then, is to estimate the honesty of a demographically diverse sample in a large
26
27 set of countries, using two different incentivized experiments; to relate the country-level results to economic
28
29 development and cultural background; and to look at expectations about people’s honesty in different countries.

30
31 **Design**

32
33 The experiment was implemented in Qualtrics, an online survey platform. Participants were recruited from
34
35 15 countries, in two waves. The first wave consisted of 804 respondents from Brazil, China, Greece, Japan,
36
37 Russia, Switzerland, Turkey, and the United States. The second wave added 735 respondents from Argentina,
38
39 Denmark, Great Britain, India, Portugal, South Africa, South Korea, and Turkey.³ The countries were chosen
40
41 to provide a mix of regions, levels of development, and levels of social trust. Initial analysis of the first wave of
42
43 countries showed significant cross-country differences. The second wave was added so as to learn more about
44
45 the correlates of honesty at country level. For simplicity, the analysis combines data from both waves.

46
47 Participants were members of managed online panels. These are typically used by firms for market research.
48
49 Members are recruited from across the web. They sign up to receive regular invitations to surveys and question-
50
51 naires. Recruitment materials usually emphasize both material benefits of taking part (“share your opinion to
52
53 win gifts, cash and test products”) and non-material benefits (“have your say”). Sample frames for individual
54
55 surveys are then selected and a randomized sample of candidates is invited to participate by email. Sometimes
56
57 extra participants are recruited directly from the web. To get a particular demographic profile, quota sampling is
58
59 used: individuals are invited until enough people from a given category (e.g. a particular gender and age group)

65

³Abbreviations: Argentina AR, Brazil BR, China CN, Denmark DK, Great Britain GB, Greece GR, India IN, Japan JP, Portugal PT, Russia RU, South Africa ZA, South Korea KR, Switzerland CH, Turkey TR, United States US.

1
2
3
4
5 have completed the survey. So, these panels are not probability samples of the country populations: quota sam-
6 pling provides balance across gender and age, but respondents could be unrepresentative in other dimensions.
7 For example, all Swiss respondents answered in French, although German was available as a questionnaire
8 language.
9

10
11 How does online sampling compare with the widely-used method of recruiting participants from university
12 lab subject pools? Both methods typically involve a subset of the population (students; internet users), from
13 which participants are recruited to a database and subsequently receive invitations to participate in experiments.
14 Both clearly risk selection on observables and unobservables at each stage. To get a sense of the issues involved,
15 among the 15 sample countries, entry rates into higher education varied from 18.8% in South Africa to 87.8%
16 in Denmark (OECD statistics for 2013); 2014 internet penetration rates varied from 19.2% in India to 96.1%
17 in Denmark (internetlivestats.com). Quota sampling guarantees a reasonable spread of age groups, and other
18 demographics (e.g. education) are likely to be closer to the country population than student samples. In short,
19 student samples may be better at capturing the moral standards of a country's elite, while online panels may
20 better reflect those of ordinary people.
21
22

23
24 Another difference with a standard laboratory experiment is that no experimenter is present. This reduces
25 control: for example, subjects may have answered in the presence of others. Conversely, it may also reduce
26 experimenter demand and social desirability effects.
27
28

29
30 The experiment contained two different measures of honesty. In the *coin flip*, respondents were asked to get
31 a coin ready and had to confirm they had done this. On the next screen, they were asked to flip the coin and
32 report the result. They were told that they would get extra money (either \$3 or \$5) if they reported "heads". So,
33 respondents who flipped "tails" faced a choice between telling the truth and getting paid. This paradigm allows
34 us to estimate aggregate honesty, from the difference between the proportion reporting heads, and the 50%
35 proportion expected if everyone tells the truth. It has been used in several previous experiments (e.g. Bucciol
36 and Piovesan 2011; Fischbacher and Föllmi-Heusi 2013; Abeler, Becker and Falk 2014; Pascual-Ezama et al.
37 2015).
38
39

40
41 In the *quiz*, subjects were given a test on the topic of music, consisting of six open-ended questions. They
42 were asked not to look up the answers on the internet, and they had to tick a box confirming they had answered
43 on their own before moving on. Since the survey was web-based, and respondents were not monitored, they
44 could always actually look up the answers online. Participants were offered a money incentive (\$3 or \$5) if they
45 answered all the questions correctly. So, they faced a temptation: they could cheat by looking the answers up,
46 and lie by ticking the checkbox to affirm they had not done so. The questions were:

1. Who wrote the composition "Für Elise"?
 2. What is Lady Gaga's real first name?
 3. Name the drummer of the rock group Nirvana.
 4. In what year was Claude Debussy born?
 5. How many valves are there on a standard modern trumpet?
 6. Name the town and state of the US where Michael Jackson was born.

The topic of music was chosen so as to minimize the test's cultural bias: Lady Gaga and Michael Jackson have global name recognition, and classical music is also known in non-Western societies. Questions 2, 4 and 6 were designed to be very easy to look up online: they can be answered, in any of the quiz countries and languages, by typing "Lady Gaga", "Debussy" or "Michael Jackson" into Google.⁴ They were also designed to be very difficult for almost anyone to answer without cheating, and I check this below.

The order of the coin flip and quiz experiments was randomized. After completing both experiments, subjects answered a 15 question integrity questionnaire taken from Whiteley (2012). This asks participants to rate whether 15 actions are "always", "sometimes", "rarely" or "never" justified. Typical actions include "making up things on a job application" and "driving faster than the speed limit". Next, subjects were told that some people from one specific country out of the countries in their wave had also taken the coin flip question. They were asked to guess what percentage of people from that country answered "heads". Someone who believed that people in the country were all honest (all dishonest) would guess 50% (100%). Half of the respondents were offered \$2 extra if their answer was within 10 percentage points of the true figure (treatment INCENTIVE). The experiment finished with a brief questionnaire on demographics. Wave 2 included additional demographic questions, as well as four questions on self-reported unethical behaviour. Survey materials were professionally translated into the countries' major languages.

The sample within each nation had equal numbers of men and women, and equal numbers of five age groups (18-24, 25-34, 35-44, 45-54, 55+). Payments were made to respondents by Qualtrics in addition to its standard payment to respondents and by the same mechanism: rewards are translated into points which can be spent on various items including vouchers, gift cards, tickets for cash lotteries and so on. This payment mechanism, as well as purchasing power differences, makes it hard to equalize the value of incentives across countries. However, several papers suggest that lying does not respond to incentive size (see above). To check

⁴Google is not widely used in China, but other search engines give equally easy access to these answers.

1
2
3
4
5 whether incentive sizes would affect my results, I randomized the size of payments offered. Half the subjects
6 were assigned to the HIGH payment treatment. They were offered \$5 for reporting heads in the coin flip and
7 \$5 for getting all quiz questions right. The remaining subjects were assigned to the LOW payment treatment,
8 where both payments were \$3. This difference between payments is about the same as differences in purchasing
9 power between sample countries.⁵ If the HIGH/LOW treatments did not affect behaviour, this should make us
10 less worried that differences between countries come from different ineffective incentive sizes. The HIGH/LOW
11 and INCENTIVE treatments, and the order of the two honesty experiments, were balanced within countries.
12
13
14
15
16
17
18
19

20 **Results**

21
22 Descriptive statistics are shown in the appendix. Only country residents who stated that they were of the
23 country’s nationality are included in the analysis (e.g. residents of Turkey who gave their nationality as Turkish),
24 so numbers of respondents vary between countries.⁶
25
26
27

28 The paper contains multiple tests, with two separate dependent variables. I report unadjusted p values, but in
29 some places I mention p values adjusted for multiple testing within a specific group of tests, using the method of
30 Holm (1979). This adjustment can be used when p values are not independent, and is conservative: an adjusted
31 p value gives an upper bound for the probability, under the null hypothesis, that at least one test in the group
32 gives a false positive result. All analyses use unweighted samples: weighting age/gender groups, to reflect the
33 size of these groups within each country’s population, gives essentially unchanged results.
34
35
36
37
38

39 **Result 1** *Individuals’ dishonesty in the coin flip, dishonesty in the quiz, and self-reported unethical actions in*
40 *the past year, were positively related. However, stated ethical attitudes were not related to dishonesty in the*
41 *experiments.*
42
43
44

45 We want to be sure that different experimental paradigms capture the same underlying dimension of behaviour.
46 There are two experimental measures of honesty: respondents’ reports on the coin flip, and their scores out of
47 3 on the hard quiz questions, numbers 2, 4 and 6 (henceforth simply “quiz score”). Median quiz scores were 2
48 for those reporting heads on the coin flip, and 0 for those reporting tails (Mann-Whitney $p < 0.001$). Put another
49 way, proportions reporting heads were 62% for those scoring 0 on the quiz, 65% for those scoring 1, 68% for
50 those scoring 2, and 77% for those scoring 3. If the proportion reporting heads in a group is h , the group’s

56 ⁵A Big Mac cost between \$1.83 (India) and \$6.82 (Switzerland) among sample countries in July 2015 (The Economist, 2015). In 70 of
57 105 pairs of countries, the cost ratio was more than 3/5.

58 ⁶There are two exceptions: residents of the US and South Africa who gave their nationality as their ethnicity, e.g. “black”, “white”,
59 “Hispanic”, “Caucasian” etc; and UK residents who gave it as “English”, “Scottish”, or “Welsh”.

estimated level of dishonest reporting is $2h - 1$, so coin flip dishonesty about doubled between the lowest and the highest quiz scorers, from 24% to 54%.

Subjects in wave 2 were asked whether they had taken four unethical actions within the past twelve months: avoiding a fare on public transport; calling in sick when not actually unwell; making something up on a job application; and downloading music or videos without paying for them. 554 out of 665 subjects reported only zero or one unethical actions. Those who reported heads in the coin flip admitted to significantly more unethical actions (mean 0.79 versus 0.61, Mann-Whitney test $p = 0.039$). Number of actions reported also correlated with higher quiz scores (Spearman's $\rho = 0.09$; $p = 0.02$). This measure is not perfect, as it may capture variation in willingness to admit these actions. Still, these results provide evidence that both experiments tap the same dimension of behaviour, and have some external validity.⁷

By contrast, there is no evidence of a link between people's expressed moral attitudes and their behaviour. Answers in the integrity questionnaire ranged from 1 (an action is "always justified") to 4 ("never justified").⁸ Following Whiteley (2012), I created a moral integrity score by summing answers to all 15 questions. Mean integrity scores for those reporting heads and tails were 50.9 and 51.6 respectively. This is marginally significant in one specification (t test $p = 0.054$; Mann-Whitney $p = 0.49$), but the difference is small. The correlation with quiz scores was small and insignificant (Spearman's $\rho = 0.008$; $p = 0.8$).

Result 2 *There was significant evidence for dishonesty in all countries.*

The first graph in Figure 1 shows the proportion reporting heads by country. The right hand scale shows estimated levels of lying. In every country except Great Britain and South Africa, we can reject the hypothesis that the proportion reporting heads is 50% at the 0.05 significance level in a binomial test.

The second graph shows mean quiz scores by country. The association between quiz scores and the coin flip makes it plausible that both measures are capturing individuals' levels of dishonesty. Nevertheless, perhaps some subjects could answer the hard questions without cheating. To check this, the quiz was administered to 144 students in a laboratory, where cheating was difficult.⁹ Of the hard questions, while 25 out of 144 students got question 2 right, only two students got question 4 right, and only the same two students got question 6 right. Thus, a score above one on hard questions was extremely hard to achieve without cheating.¹⁰ In each country,

⁷Other research has found that the coin flip and similar experiments predict real world dishonest behaviour (Galeotti, Dai and Villeval, 2016; Cohn and Maréchal, 2015).

⁸"Straightliners" who gave the same answer for every question were removed from this analysis.

⁹Participants in the laboratory were from 37 countries. The most common were Romania and the United Kingdom. Subjects earned a £3 reward for getting all six questions right.

¹⁰Per-country mean quiz scores on "hard" questions were correlated as follows with four alternative measures: mean quiz scores on all questions 0.955; proportions getting all six questions right 0.609; proportions getting more than one hard question right 0.983; and scores on questions 4 and 6 only 0.984. The key results are unchanged using these alternatives (calculations available on request).

more than 30% of subjects scored above one; even if 10% of the population could do this without cheating, much more than in the laboratory sample, the hypothesis of no cheating would be rejected in every country at $p < 0.001$.

3
4
5 **Result 3** *Levels of honesty varied significantly across countries.*
6
7

8 A chi-squared test of proportion reporting heads against nationality rejects equality of proportions ($p < 0.001$).
9 A Kruskal-Wallis test of quiz scores against nationality rejects equality of medians ($p < 0.001$). Thus, both mea-
10 sures of dishonesty vary among nations.¹¹ Overall differences are large: the level of estimated misreporting in
11 the coin flip varies from 3.4% in Great Britain to 70% in China. But note that standard errors are also large.
12 The sample was designed to test for differences between countries, not to provide tight estimates for any one
13 population, so not too much weight should be placed on any individual country's score.
14
15

16 One concern may be that these results just reflect anti-Western bias – non-Western subjects may care less
17 about lying to Western researchers. Surveys were translated and carried no branding, but participants were told
18 that data from their answers would be stored at the University of Essex, so they could conceivably have drawn
19 inferences from this. A crude check is to correlate country average behaviour with distance from the UK. For per
20 cent reporting heads in the coin flip, the correlation is high (0.507) and just misses 5% significance ($p = 0.054$);
21 for quiz scores, the correlation is essentially zero (0.002, $p = 0.99$). It is hard to explain why anti-Western bias
22 would only have affected behaviour in the coin flip.
23
24

25 To confirm the inter-country differences, I run regressions with controls. Tables 7 and 8 in the appendix
26 show linear regressions of nationality dummies (with omitted category the UK) on the probability of reporting
27 heads and on quiz score. The second column in each table includes as controls gender, age group, attendance
28 at religious services, population density at the respondent's location (estimated from their IP address), incentive
29 size (*Hilow*) and treatment order (*QuizFirst*). The third column includes extra demographic controls which
30 were recorded in the second wave only: income, marital status, children, educational level, and a question on
31 the importance of religion. Effects of nationality are robust. Few other demographic variables are significant.
32 Those who report attending religious services more often are *more* likely to report heads, and score more in the
33 quiz, but this effect is not present within wave 2. Older people scored less in the quiz but were not less likely
34 to report heads. The incentive size treatment had no effect. There is a small order effect in the quiz, with those
35 who answered the quiz first scoring significantly more.

51 **Country correlates of honesty**
52

53 Now let us consider the link between country-level averages of dishonest behaviour and some interesting macro-
54 level variables. With just 15 observations, I can only report correlations, leaving causal identification for future
55

56 ¹¹This was also true among the eight wave 1 countries: heads against nationality, $p = 0.0026$; quiz score against nationality, $p = < 0.001$.
57 All these results easily survive correction for multiple hypothesis testing.

work. Another problem is that at country level, the correlation between mean quiz score and proportion reporting heads is positive but not significant (correlation 0.247, $p = 0.37$), despite the significant individual-level association. This is probably due to the small number of countries.

The most obvious result from the coin flip is that the four least honest countries are the four Asian countries, China, India, South Korea and Japan. There are certainly theories that “Asian values” differ from non-Asian values (Zakaria, 1994; Hofstede and Hofstede, 2001). However, the result does not hold in the quiz, where Japan has the *lowest* mean score. A possible explanation is that in Japan, most gambling is illegal. Therefore, Japanese respondents may have perceived the coin flip as intrinsically unethical and been more willing to lie in this context. This suggests that the Asia-other difference is specific to the coin flip paradigm, rather than reflecting a difference in honesty in general. Paradigm-specific reactions like this confirm the importance of having multiple measures of the honesty construct: without the quiz, the data might have led to an unjustified inference. Rather than combining the measures, I report correlations with each of them separately, and place more confidence in results which are robust across the two.

Result 4 *Measures of dishonesty are negatively correlated with 2011 GDP per capita. This correlation is mainly driven by GDP growth prior to 1950.*

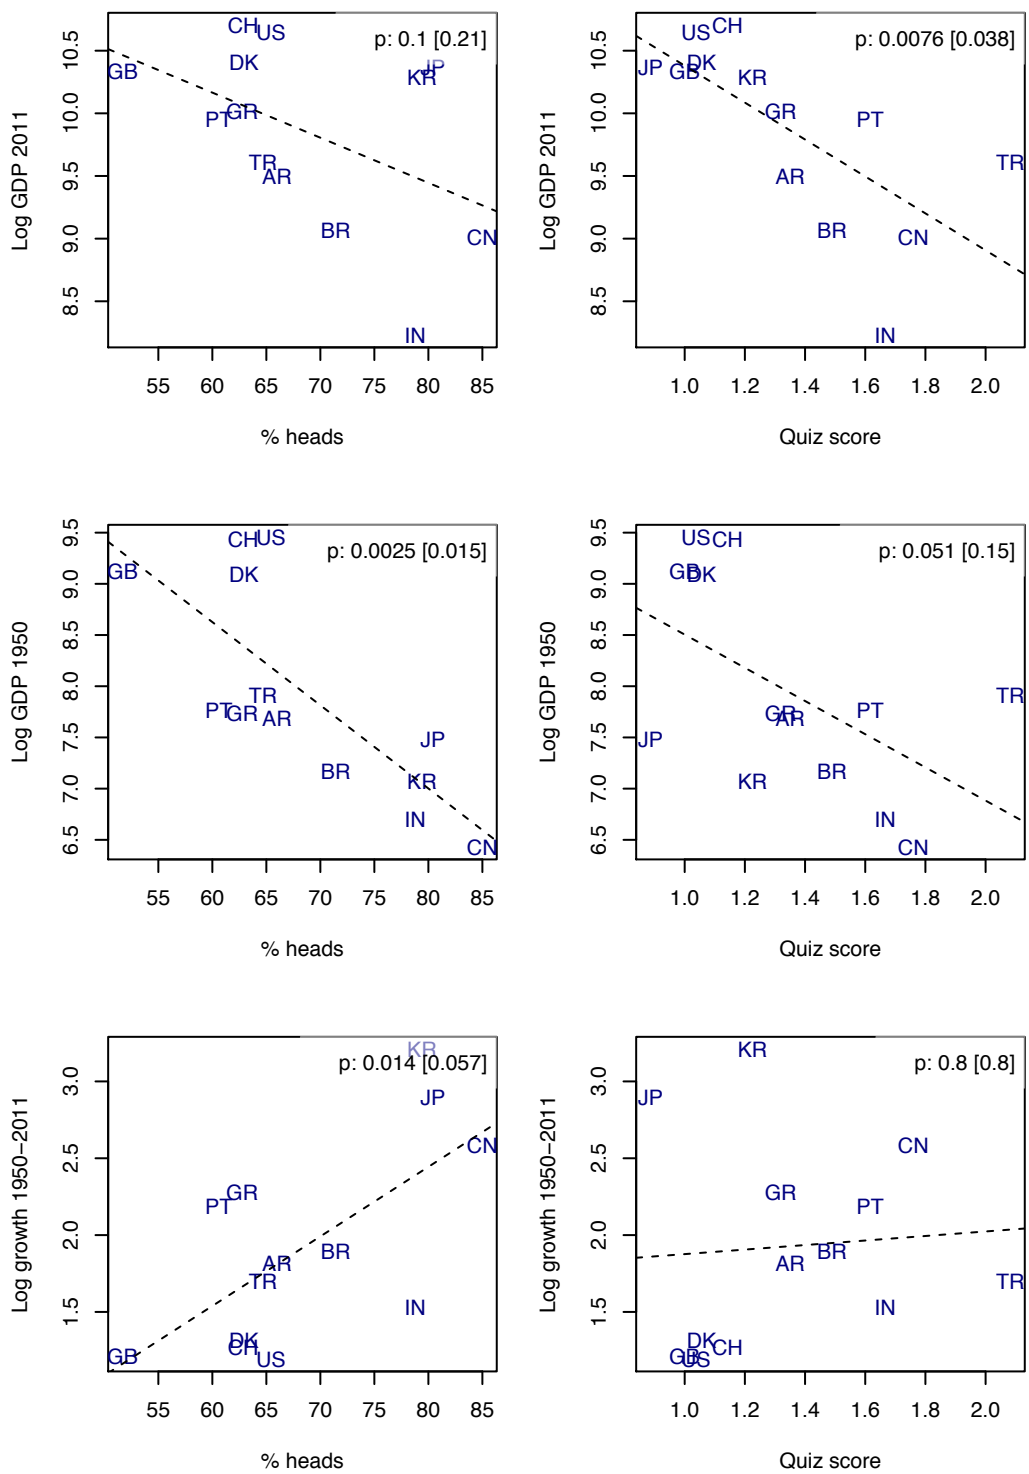

Figure 2: Dishonesty and per capita GDP. P values from correlations [in brackets: adjusted for 6 comparisons]

Figure 2 plots country averages of each measure of dishonesty against logs of three variables: GDP in 2011, GDP in 1950 and GDP growth from 1950 to 2011.¹² Lines from linear regressions are shown. Three facts stand out. First, there is a negative correlation between dishonesty and GDP in 2011, which is significant for the quiz but not the coin flip. Second, this correlation already exists for 1950 GDP. Lastly, GDP growth from 1950 to 2011 shows either no correlation, or a positive correlation, with dishonesty. Table 1 shows linear regressions. Columns 1-2 and 4-5 show the bivariate relationships for 1950 and 2011 GDP, as in the figure. Columns 3 and 6 add 1950 GDP as a control to the 2011 GDP regression. When I control for 1950 GDP, the coefficient on per cent reporting heads changes sign, while that for quiz scores remains negative and weakly significant, but shrinks. Thus, honesty was related to economic growth over some period up to 1950, but this relationship has been weaker or absent over the past 60 years.

	Log GDP 1950	Log GDP 2011	Log GDP 2011	Log GDP 1950	Log GDP 2011	Log GDP 2011

Table 1: GDP regressions

One story that fits this data is as follows: when institutions and technology are undeveloped, honesty is important as a substitute for formal contract enforcement. Countries that develop cultures putting a high value on honesty are able to reap economic gains. Later, this economic growth itself improves institutions and technology, making contracts easier to monitor and enforce, so that a culture of honesty is no longer necessary for further growth. However, since culture is highly persistent, the correlation between GDP and honesty remains visible in present-day behavioural data. Of course, other theories also fit the data, for example that the GDP-honesty correlation in 1950 was driven by an unobserved third variable.

One simple explanation for the result would be that respondents in poor countries face a greater temptation to lie, because they value the money reward more. Two pieces of evidence go against this. First, the 66% increase from a \$3 to a \$5 incentive from the LOW to the HIGH treatment did not increase lying, either in the coin flip (heads reports: 69.4% in LOW, 66.9% in HIGH) or in the quiz (mean scores: 1.39 in LOW, 1.32 in HIGH).¹³ Second, respondents in wave 2 reported their monthly income, and this also did not correlate with

¹²GDP data is from Gleditsch (2002). Russia and South Africa are excluded as they do not have data in 1950.
¹³This null result also held within individual countries. Out of 15 countries, 10 had a lower proportion of heads in the HIGH incentive

1
2
3
4
5 more lying (variable *Income* in tables 7 and 8).
6
7

8 **Result 5** *Measures of dishonesty are negatively correlated with Protestantism at country level.*
9

10 I next examine a possible root of country-level differences in honesty: religion. Different religions promul-
11 gate different norms. The classic study of Weber (2010) argues that Protestant religious teachings encouraged
12 honesty in business dealings. Barro and McCleary (2003) argue that religion affects “traits such as honesty,
13 thrift, willingness to work hard, and openness to strangers.” Similarly, Porta et al. (1997) show that country-
14 level measures of trust, from the World Values Survey questionnaire, are related negatively to membership in
15 hierarchical religions: Catholicism, Orthodoxy and Islam.
16
17

18 The percentage of Protestants in each country (Pew Research Center 2015) is correlated negatively and
19 significantly with both measures of dishonesty (coin flip $\rho = -0.581$, $p = 0.023$; quiz $\rho = -0.571$, $p = 0.026$).
20 Correlations with per cent Catholic are insignificant (coin flip $\rho = -0.23$, $p = 0.41$; quiz $\rho = 0.069$, $p =$
21 0.81).¹⁴ Not surprisingly, the correlations with Protestantism become insignificant when controlling for 2011
22 GDP (coin flip $p = 0.35$, quiz $p = 0.055$).
23
24

25 Note that at individual level, there is no evidence that religious adherence is associated with honesty. Indeed,
26 those who claim to attend services regularly, and that religion is very important to them, report heads *more* often
27 and score *higher* in the quiz (appendix tables 7 and 8). Thus, countries with a Protestant cultural background
28 have higher present-day honesty, but this difference is not necessarily reflected among present-day individuals.
29
30

31 **Result 6** *At country level, honesty is not correlated with trust, and is negatively correlated with corruption but*
32 *with weak significance.*
33
34

35 I also report correlations with existing measures of trust and corruption. Johnson and Mislin (2011) re-
36 port a meta-analysis of trust games across 35 countries, including 11 in my sample. I compare honesty in
37 both experiments with both fraction sent (“trust”) and fraction returned (“trustworthiness”). The World Values
38 Survey includes a question on trust (“Can most people be trusted?”) Lastly, the Corruption Perceptions Index
39 from Transparency International is a widely used measure of country corruption: higher scores indicate less
40 corruption. Correlations with the measures of trust and trustworthiness are insignificant and change sign., This
41 suggests that honesty captures a different dimension of behaviour from trust. Corruption perceptions are cor-
42

43 treatment than in the LOW incentive treatment, and 12 had lower quiz scores. The relationship was significantly positive at 5% only for quiz
44 scores in China. Indeed, if country A reported fewer heads than country B, then in 89 out of 105 cases, the HIGH incentive respondents in
45 country A reported fewer heads than the LOW incentive respondents in country B; for mean quiz scores, this holds in 98 out of 105 cases.

46 ¹⁴There is not enough variation in the sample of countries to look at Orthodox Christianity. P values corrected for 4 comparisons are:
47 coin flip-Protestant: 0.092; quiz-Protestant: 0.092; coin flip-Catholic: 0.82; quiz-Catholic: 0.82.

Figure 3: Average predictions of proportion reporting heads

Figure 3 shows average predictions about each country, by subjects from each country. Each cell is the average of guesses from only about 13 subjects, so standard errors are large. Nevertheless, some patterns in the data are already visible. Predictions vary systematically, both by target country (columns), and guesser's country (rows). And predictions are often higher along the diagonal, when subjects made guesses about their own country.

Subjects' predictions do not reflect reality. Table 3 reports regressions of predicted number of heads in a country on *TargetHeads*, the true percentage. Column 1 shows the bivariate correlation. It has the wrong sign.

Column 2 does the same for incentivized guesses only, with the same results. At individual level, less than one in four subjects guessed within 10 percentage points of the true figure, whether in incentivized or unincentivized treatments.

	All	Incentivized	All	Incentivized	All
(Intercept)	74.91 (4.79) ^{***}	75.85 (6.84) ^{***}	88.16 (6.33) ^{***}	90.34 (9.01) ^{***}	88.02 (6.39) ^{***}

Table 3: Coin flip belief regressions

What then drives expectations? The simplest story is that subjects may predict honesty on the basis of experience in their own country. Alternatively, subjects may “project” their own preferences and behaviours on to others: if so, those reporting heads or scoring high in the quiz may expect more dishonesty from others. Relatedly, Dieckmann et al. (2015) suggest that this “social projection” is more pronounced for social groups that are similar to one’s own. Lastly, subjects’ level of knowledge of other countries may affect their expectations, for example via reports of dishonesty or scandals in the media.

To test these theories, I added the following variables to the belief regression: *Heads*, whether the subject reported heads; subject’s own *QuizScore*; *HomeHeads*, the proportion reporting heads in the subject’s own country; *TargetIsHome*, which takes the value 1 if the target country was the subject’s own and 0 otherwise; and *TargetDistance*, the distance between subject’s country and the target country in thousands of kilometers, from the CEPII dataset (variable *distcap*; Mayer and Zignago 2011). *TargetDistance* is a proxy for subjects’ level of knowledge of the target country, and for their judgments of similarity with their own country. The experience theory predicts a positive coefficient for *HomeHeads*. The projection theory predicts a positive coefficient for *Heads* and *QuizScore*, and possibly an interaction between *Heads* and *TargetIsHome*. Social identity theory (Tajfel et al., 1971) claims that humans attribute positive characteristics to their in-group; this would predict a negative coefficient on *TargetIsHome*. Broadly, if knowledge of other countries is relevant to judgments of honesty, coefficients on *TargetIsHome* and *TargetDistance* should be significant.

1
2
3
4
5 **Result 8** *Dishonest subjects believed others would be less honest on average. Subjects in dishonest countries*
6 *believed others would be more honest. Subjects expected less honesty in their own country.*
7
8
9

10 Column 3 of table 3 shows the results. The *Heads* and *QuizScore* variables have the expected sign. Subjects
11 who reported heads or scored highly in the quiz expected others to be more likely to report heads.¹⁵ *Home-*
12 *Heads*, however, has a significant negative sign, contradicting the experience theory: subjects from less honest
13 countries took a more positive view of countries' honesty. *TargetIsHome* is positive and significant: on average,
14 subjects expected their own countries to be less honest. Lastly, the coefficient on *TargetDistance* is negative
15 but not significant. Column 4 repeats the exercise for only incentivized subjects, with essentially unchanged
16 results. Thus, respondents showed three biases. Less honest subjects expected others to be less honest (social
17 projection); subjects expected more honesty in other countries than their own; and subjects from more honest
18 countries expected others to be less honest.
19

20 The positive coefficient on *TargetIsHome* runs counter to social identity theory. Dieckmann et al. (2015)
21 suggest an explanation for a similar finding: subjects "socially project" their own behaviour on to fellow citizens
22 more than on to foreigners, and since most subjects report heads, they expect others like them to do the same.
23 To test this, column 5 repeats the regression, adding an interaction between *Heads* and *TargetIsHome*. The in-
24 teraction is not significant and is negatively signed: subjects who reported heads were not especially pessimistic
25 about their home country. So social projection seems not to be the explanation. The last result, that subjects
26 from more honest countries are more pessimistic, is also puzzling. It is not solely driven by beliefs about foreign
27 countries: it holds even among subjects who guessed about their own countries (results not shown). A possible
28 explanation for both results, which cannot be tested in this data, is media exposure: subjects might be more
29 exposed to news stories about dishonesty in their own country than in other countries, and news stories about
30 dishonesty may be more common or more salient in countries with high levels of honesty.

46 **Conclusion**

47
48
49

50 Comparing levels of honesty across 15 countries appears to confirm Feng Guifen's intuition: the connection
51 between word and deed is less necessary in some places than in others. There is also some support for Feng's
52 second claim, that this connection is good for economic development. The relationship with honesty is clearer
53 for earlier economic growth, as summarized in 1950 GDP levels, than for growth since 1950. Finally, there is
54 evidence of a relationship between honesty and Protestantism, as predicted by Weber's classic theory.
55
56

57 ¹⁵An alternative explanation is that subjects who really flipped heads naively expected others to do so too. But this does not explain the
58 coefficient on *QuizScore*.

In general it is an open question whether national stereotypes are accurate (Jussim et al., 2009). In this data, beliefs about other countries' honesty had little relation to the truth, or even to the average honesty of subjects' own countries. Instead, they appear to be driven by self-projection and other cognitive biases.

The results here should be interpreted cautiously. Respondents were not a true random sample of national populations, and the two experimental measures of honesty were only weakly correlated at country level. These issues are shared with much cross-cultural experimental research. Experiments on representative samples in multiple countries are still relatively expensive and rare, and experimental economists have probably paid less attention than psychologists to questions of construct validity. To go beyond the current tentative conclusions, better sampling designs and measures will be necessary.

Nevertheless, the large cross-country differences reported here seem unlikely to be explained by sample selection alone. There is a strong case that economic development has cultural roots (Banfield, 1958; Platteau, 2000; Guiso, Sapienza and Zingales, 2006). Experiments can help to isolate cultural differences, holding incentives and institutions constant. These results support the idea that honesty is related to economic development. They also suggest that the relationship is a long run one. There is a similarity here with institutional arguments that economic and political development have long-run historical roots (e.g. Acemoglu et al. 2009). To investigate this, it will be necessary to study how cultural norms have developed historically, perhaps using new sources of textual data, in order to understand when and how culture matters, or mattered, to economic growth.

11 *You do not have to fill in this part of the survey if you do not want to: in this case, simply leave responses*
12 *blank. Data from this part of the survey will be stored at the University of Essex and may be released to other*
13 *researchers. However, this data will not include your name or any other information that could identify you.*

14
15 I consent to taking part in this part of the survey []

16
17 What is your gender?

18
19 [] Male [] Female

20
21 How old are you?

22
23 [] Under 18 [] 18-24 [] 25-34 [] 35-44 [] 45-54 [] 55 or over

24
25 In which country do you reside? ...
26
27

28
29 *Below is a short quiz on the topic of music. We will pay you \$INCENTIVE extra if you get all the questions*
30 *right. This payment will be added to your standard payment for taking the survey. Please answer the questions*
31 *on your own, without looking them up elsewhere.*

32
33 Who wrote the composition "Für Elise"?

34
35 What is Lady Gaga's real first name?___

36
37 Name the drummer of the rock group Nirvana.____

38
39 In what year was Claude Debussy born?___

40
41 How many valves are there on a standard modern trumpet?___

42
43 Name the town and state of the US where Michael Jackson was born.____

44
45 I confirm that I answered the quiz on my own, and that I did not look up any answers. []
46
47

48
49 *On the next page you will need to flip a coin.*

50
51 *Please get a coin ready before moving on!*

52
53 OK, I have a coin ready []
54

55
56 *Please now flip the coin. If the coin lands on "heads", we will pay you an extra \$INCENTIVE.*

57
58 *This payment will be added to your standard payment for taking the survey.*

Yes No

Please think about each of the following actions. In your opinion, is the action always justified, sometimes justified, rarely justified or never justified?

Always justified Sometimes justified Rarely justified Never justified Don't know

Claiming government benefits to which you are not entitled

Buying something which you know is stolen

Taking cannabis

Keeping money that you found in the street

Lying in your own interests

Having an affair when you are married

Having sex under the legal age of consent

Failing to report accidental damage you've done to a parked vehicle

Throwing away litter in a public place

Driving under the influence of alcohol

Avoiding a fare on public transport

Cheating on taxes if you have a chance

Someone accepting a bribe in the course of their duties

Driving faster than the speed limit

Making up things on a job application

Some people from RANDOM COUNTRY are answering this questionnaire.

Think back to the coin flip question. People from RANDOM COUNTRY were paid approximately the same amount as you if they flipped heads.

What percentage (%) of people from RANDOM COUNTRY do you think will report that the coin landed on heads? ____

[If in INCENTIVIZED GUESS treatment] *We will pay you an extra 2\$ if your answer is within 10% of the correct percentage.*

Please enter your nationality: ____

Do you attend religious services?

Made something up on a job application

Downloaded music or videos without paying for them

Called in sick to work when not actually unwell

Dear Professor Neilson

Please find attached my final submission as requested. I made one last-minute change, adding a couple of words to the title.

With best wishes, and once again, many thanks.

David Hugh-Jones
