## ABSTRACT

Simulation of the lifting of dust from the planetary surface is of substantially greater importance on Mars than on Earth, due to the fundamental role that atmospheric dust plays in the former’s climate, yet the dust emission parameterisations used to date in Martian global climate models (MGCMs) lag, understandably, behind their terrestrial counterparts in terms of sophistication. Recent developments in estimating surface roughness length over all Martian terrains and in modelling atmospheric circulations at regional to local scales (less than  $O(100\text{ km})$ ) presents an opportunity to formulate an improved wind stress lifting parameterisation. We have upgraded the conventional scheme by including the spatially varying roughness length in the lifting parameterisation in a fully consistent manner (thereby correcting a possible underestimation of the true threshold level for wind stress lifting), and used a modification to account for deviations from neutral stability in the surface layer. Following these improvements, it is found that wind speeds at typical MGCM resolution never reach the lifting threshold at most gridpoints — winds fall particularly short in the southern midlatitudes, where mean roughness is large. Sub-grid scale variability, manifested in both the near-surface wind field and the surface roughness, is then considered, and is found to be a crucial means of bridging the gap between model winds and thresholds. Both forms of small-scale variability contribute to the formation of dust emission ‘hotspots’: areas within the model gridbox with particularly favourable conditions for lifting, namely a smooth surface combined with strong near-surface gusts. Such small-scale emission could in fact be particularly influential on Mars, due both to the intense positive radiative feedbacks that can drive storm growth and a strong hysteresis effect on saltation. By modelling this variability, dust lifting is pre-

dicted at the locations at which dust storms are frequently observed, including the flushing storm sources of Chryse and Utopia, and southern midlatitude areas from which larger storms tend to initiate, such as Hellas and Solis Planum.

30 The seasonal cycle of emission, which includes a double-peaked structure in northern autumn and winter, also appears realistic. Significant increases to lifting rates are produced for any sensible choices of parameters controlling the sub-grid distributions used, but results are sensitive to the smallest scale of variability considered, which high-resolution modelling suggests should be

35 O(1 km) or less. Use of such models in future will permit the use of a diagnosed (rather than prescribed) variable gustiness intensity, which should further enhance dust lifting in the southern hemisphere in particular.

## 40 1 Introduction

Atmospheric dust on Mars is of fundamental importance to the overall climate system, as it can alter — through strong absorption of incoming solar radiation — the strength of the global-scale circulation [Haberle et al., 1982] and the characteristics of atmospheric eddies [Hourdin et al., 1995], as well as act  
45 as condensation nuclei for water or CO<sub>2</sub> ice clouds [Määttänen et al., 2005]. Martian atmospheric dust exhibits strong spatial and temporal variability in optical depth. A spectacular example of this variability is the occurrence of planet-encircling dust storms in southern summer [Zurek and Martin, 1993]. Those events are, however, relatively rare, and the majority of Martian years  
50 involve dust lifting, emission, and transport in a more regionally confined fashion [e.g., Smith, 2004]. Regional dust storms have been observed to occur with greater regularity in the midlatitudes of both hemispheres [Cantor et al., 2001], although dust storms occur in equatorial and tropical regions too, albeit perhaps more sporadically [Määttänen et al., 2009]. Interestingly,  
55 the depth of coverage of dust on the planetary surface has also been found to be rather inhomogeneous, implying a long-term removal of dust from southern midlatitudes and deposition in northern subtropics [Ruff and Christensen, 2002].

A key question in understanding the dust cycle on Mars, as well as on Earth  
60 and on Titan, is how dust particles are lifted from the surface into the atmosphere [Kok et al., 2012, for a review]. On Mars, the lifting of dust from the surface appears as a strongly threshold-dependent process, with a positive radiative feedback that amplifies the interannual variability of the Martian climate, through the initiation of dust storms of varying sizes. This fact was made

65 apparent through the use of interactive dust lifting schemes in Martian global  
climate models (MGCMs) [Murphy et al., 1995, Newman et al., 2002a]. Two  
distinct lifting mechanisms have been parameterised in MGCMs: near-surface  
wind stress [Bagnold, 1954], and dust devils [dusty turbulent whirlwinds, see  
Balme and Greeley, 2006, for a review]. MGCM and observational studies sug-  
70 gest that wind stress lifting, rather than dust devils, plays the dominant role in  
the initiation of regional and global dust storms [Newman et al., 2002b, Kahre  
et al., 2006, Montabone et al., 2005, Cantor et al., 2006], making this mech-  
anism the more important to MGCMs attempting to replicate the observed  
degree of interannual climate variability.

75 The knowledge of physical processes and feedbacks responsible for dust lift-  
ing on Mars is still in relative infancy. Several putative key phenomena have  
not been considered thus far, due to a lack of either relevant observational  
constraints or appropriate modelling tools.

(1) The aerodynamic surface roughness length,  $z_0$ , controls the transfer of  
80 momentum between the surface and the surface layer, i.e. the lowermost  
part of the Planetary Boundary Layer (PBL). It is thus key to the wind  
stress lifting mechanism; yet a globally uniform value of  $z_0$  has, to date,  
been used in all existing MGCMs. Furthermore, dust lifting thresholds  
include a dependence on  $z_0$  that has been neglected in MGCMs so far.  
85 Recent global mapping of  $z_0$  at high resolution by Hébrard et al. [2012]  
provides an opportunity to assess the influence of  $z_0$  spatial variability  
on surface layer physics and lifting thresholds.

(2) Discussions in the literature about dust lifting on Mars (and subsequent  
lifting parameterisations in MGCMs) do not take into account the ef-  
90 fect of varying atmospheric stability on the vertical profile of wind in the

surface layer [Monin and Obukhov, 1954, Garratt, 1992]. This directly affects the conversion of atmospheric momentum into surface drag. Since the Martian PBL undergoes a strong diurnal cycle between daytime superadiabatic and nighttime ultra-stable regimes [e.g., Schofield et al., 1997, Smith et al., 2006], this stability effect should be included when modelling dust lifting.

(3) MGCM horizontal grid spacing is typically a few hundred kilometres, which is inadequate for representing important mesoscale circulations, such as slope-induced flows [Tyler et al., 2002, Rafkin and Michaels, 2003, Spiga et al., 2011] and turbulent PBL circulations resolved by Large-Eddy Simulations (LES) [Michaels and Rafkin, 2004, Spiga et al., 2010]. The former is referred to hereafter as ‘mesoscale variability’, the latter as ‘turbulent gustiness’, and both of them as ‘sub-grid scale (wind speed) variability’ (from an MGCM-grid perspective). As a result, unless a specific parameterisation of those effects is included [e.g., Michaels, 2006], an MGCM will severely underestimate the maximum horizontal wind speed reached close to the surface, and therefore the potential for various lifting mechanisms to be activated. Indeed, it has been found that dust loading in the African desert is more highly correlated with near-surface gustiness than it is with the mean wind speed at GCM resolution [Engelstaedter and Washington, 2007]. In addition, sub-grid scale variability in roughness length  $z_0$  should be accounted for, since small variations in  $z_0$  can strongly affect dust lifting thresholds [e.g., Raupach et al., 1993].

Surface roughness length, atmospheric stability, and sub-grid scale variability could act together to modify both the wind stress exerted by the atmosphere on the surface, and the threshold wind stress for dust particles to be lifted

from the surface. For instance, the ‘hotspot’ theory of dust lifting on Earth [Gillette, 1999] implies that appropriate parameterisations of sub-grid scale variability are needed to simulate the observed dust lifting rates [Cakmur et al., 2004, Okin, 2005]. In Martian studies, apart from dust devil parameterisations [Rennó et al., 1998] which account for only a part of the dust lifting related to turbulent gustiness [another one being horizontal winds associated with convective cells, see e.g., Spiga and Lewis, 2010, Figure 5], none of the three aforementioned phenomena has been examined nor taken into account in global-scale dust lifting models, aside from an early attempt by Newman et al. [2002b] to explore the use of parameterised turbulent gustiness. It is the aim of this paper to explore, in the Martian environment, the nature and magnitude of each of these three components, as well as their impact both on dust lifting rates, and the spatial and seasonal variability of dust lifting events.

## 2 Dust lifting thresholds at MGCM resolution

In this section, three issues, each important in the calculation of dust lifting rates at the scale of an MGCM horizontal grid, are dealt with in turn: spatial heterogeneity in surface roughness length (including a presentation of a global map of this variable), calculation of the lifting threshold itself using formulae derived from physical principles, and the impact of atmospheric stability in the conversion of atmospheric wind to drag velocity. The first and third of these are new additions to the existing studies of Martian dust lifting with GCMs.

For many years, the only measure of the aerodynamic roughness length,  $z_0$ , at the Martian surface came from the Viking landers, for which a value in the range 0.1–1 cm was estimated [Sutton et al., 1978]. As a result, values within this range have been assumed in MGCMs thus far, without spatial  
 145 variation. Other surface landers have made similar estimates of  $z_0$ , including 3 cm at the Mars Pathfinder landing site [Sullivan et al., 2000], and a range of values 0.07–0.60 cm along the path of the Spirit Rover [Greeley et al., 2008]. The latter indicates though that significant variations in roughness length within short distances are possible over the planet’s surface. On Earth, it has  
 150 been found that accounting for spatial heterogeneity in surface characteristics greatly improves the performance of dust emission models [e.g., Callot et al., 2000].

Recently, Hébrard et al. [2012] yielded a global  $z_0$  map covering the full Martian surface, at a resolution of  $\frac{1}{8}^\circ \times \frac{1}{8}^\circ$ , well in excess of typical MGCM res-  
 155 olutions ( $\sim 5^\circ$  in latitude and longitude). The dataset was derived from rock abundance maps obtained from TES thermal inertia data [Nowicki and Christensen, 2007]. The completed  $z_0$  map is displayed in Fig. 1. At full resolution, values of  $z_0$  span three orders of magnitude, from  $\sim 0.001$  cm to 2 cm (a comparable range of values to the range encountered on Earth [MacKinnon et al.,  
 160 2004]). The southern hemisphere, particularly in the 30–60°S region that is key for dust storm activity in southern summer, is characterised by large roughness lengths ( $\gtrsim 0.5$  cm). By contrast, the vast majority of the northern hemisphere is smooth, with values of  $z_0 \lesssim 0.1$  cm over much of the low-thermal-inertia plains at 15°S–30°N. The flushing dust storm channels of Acidalia-Chryse

Fig. 1. Global map of surface roughness length (shading), from the data described in Hébrard et al. [2012]. The range covers approximately 0.001 cm (white) to 2 cm (black), and shading is on a logarithmic scale. Stars mark the location of dust storms observed by Cantor et al. [2001], coloured according to the time of year at which they occurred, from  $L_s = 109\text{--}129^\circ$  (yellow) through purple, red, green and blue to  $250\text{--}274^\circ$  (black). The map features streaks in the meridional direction, an artefact of the tracks followed by the satellite from which the data were retrieved.

165 ( $\sim 60^\circ\text{W}$ ) and Utopia-Isidis ( $\sim 90^\circ\text{E}$ ), however, exhibit fairly large roughness lengths. This Hébrard et al. global dataset features a significant number of pixels with  $z_0$  close to 1 cm, confirming that this value was a reasonable choice for use in MGCMS in previous work, but the  $z_0$  field is very inhomogeneous, and 84% of the surface possesses a roughness length below 1 cm. The largest  
 170 value in the map is 2.02 cm. A large inhomogeneity was also found by Heavens et al. [2008], who previously produced two different versions of the  $z_0$  map (but which appear less consistent with in situ measurements than the Hébrard map does [see Hébrard et al., 2012]).

Overlaid in Fig. 1 are the locations at which dust storms were observed by

175 Cantor et al. [2001] over a substantial fraction of one Martian year. Although  
the detection of a dust storm does not strictly imply local dust lifting, the  
majority of the storms marked were smaller than regional in extent, such that  
it may be assumed that the initial lifting activity occurred relatively close  
(in global terms) to the observed storm site. The majority of these small  
180 dust storms occurred along the seasonally shifting edges of the polar CO<sub>2</sub>  
ice caps, where large surface temperature gradients lead to conditions of high  
baroclinic instability (as well as a ‘sea breeze’ circulation [Toigo et al., 2002]),  
and therefore to strong peak wind speeds. Note that dust lifting apparently  
occurs at locations with a wide range of  $z_0$  values, from the smooth north polar  
185 regions to the rougher southern midlatitudes. Dust storms seem to be absent  
from a band at 20–30°S, which features some of the largest  $z_0$  values, though  
this may be primarily due to the fact that the seasonal CO<sub>2</sub> cap (and therefore  
the winter baroclinic zone) never extends this far north. Nevertheless, a robust  
outcome from Fig. 1 appears to be that in regions of  $z_0 \gtrsim 0.5$  cm, dust storms  
190 are frequent occurrences.

## 2.2 *Effect of $z_0$ on the lifting threshold $u_*^t$*

On Earth, after near-surface wind speed, the roughness length  $z_0$  is thought to  
be the most important control on dust lifting rates [Gillette, 1999]. The rate  
of dust emission for a given drag velocity depends on how much of this drag  
195 is exerted on the erodible (dust-covered) surface, and how much is ‘lost’ on  
the roughness elements — rocks and pebbles that impede the flow and shelter  
parts of the surface. Dust emission therefore occurs with greater amplitude, or  
at a lower threshold drag velocity, where the surface roughness length is small,

while emission may be extremely rare in locations with large  $z_0$  [Laurent et al.,  
200 2008]. On Mars, however, relatively large roughness lengths do not seem to  
prohibit dust lifting, as evidenced by the array of dust storms marked in Fig.  
1. An interesting point of additional complexity is that some dust is likely to  
rest on top of the non-erodible elements [Jakosky et al., 2006], after settling  
out of the atmosphere, and could be more easily lifted due its exposure to  
205 the unimpeded flow just above the roughness elements. This is beyond the  
scope of this paper, and we simply assume that all dust lies on the surface,  
distributed homogeneously amongst the non-erodibles.

Wind stress dust lifting is usually treated in MGCMs as a threshold-dependent  
process, occurring only when the drag velocity  $u_*$  exceeds a threshold value  $u_*^t$   
[e.g., Iversen and White, 1982], i.e. when

$$u_* > u_*^t.$$

When the wind is strong enough, erodible material becomes mobilised and  
flows along the soil bed. Conventionally, this is assumed to occur most read-  
210 ily for sand-sized particles, of diameter  $\sim 100 \mu\text{m}$ , in which case the process  
is called saltation. These particles are too heavy to be maintained in sus-  
pension, but can eject smaller particles (whose stronger interparticle cohesion  
prevents them from being lifted directly by the wind) into the atmosphere  
through their impacts on the surface (‘sandblasting’). Therefore, the resulting  
215 vertical dust flux is generally considered to be proportional to this saltation  
flux [e.g., Marticorena and Bergametti, 1995]. The combination of saltation  
and sandblasting is believed to be the primary mechanism for non-convective  
dust emission on Earth, and possibly on Mars [Greeley and Iversen, 1985].  
There has been a suggestion [Sullivan et al., 2008] that direct detachment of

loosely bound, low-density clumps of dust particles is in fact the preferred  
lifting mechanism on Mars — we address this possibility in section 2.3. In  
any case, the essential point is that non-convective dust lifting is a strongly  
threshold-dependent process, and this threshold is dependent on roughness  
length.

The threshold drag velocity on a surface covered by non-erodible elements is  
obtained as a modification to the threshold that applies to a smooth surface  
(free of obstacles),  $u_{*s}^t$ , as

$$u_*^t = \frac{u_{*s}^t}{f_{\text{eff}}(z_0)}, \quad (1)$$

where  $f_{\text{eff}}(z_0)$  is the drag partition function, which accounts for the distribution  
of momentum between the underlying surface and roughness elements, and is  
a function of  $z_0$ . In previous modelling studies on Mars, although a uniform  $z_0$   
value of  $\sim 1$  cm has been used in the calculation of  $u_*$  (see later), the effect of  
 $z_0$  on the threshold drag velocity has been neglected:  $f_{\text{eff}}$  has been implicitly  
set equal to one (equivalent to assuming  $z_0 = 0$ ), making lifting thresholds  
at all model gridpoints quite significantly lower than they are theorised to be  
in reality. In fact,  $f_{\text{eff}}$  is always less than one, making the threshold velocity  
for a rough surface larger than that for a smooth surface, particle size and  
local conditions being the same. This key problem has been overlooked in  
previous studies that attempted to use a physically based threshold [Newman  
et al., 2002a, Kahre et al., 2006], which as a result used thresholds that were  
unrealistically low over much of the planet.

Many different formulations for the drag partition coefficient  $f_{\text{eff}}$  have been  
proposed in the terrestrial literature [Raupach et al., 1993, Alfaro and Gomes,  
1995, Marticorena and Bergametti, 1995, MacKinnon et al., 2004]: these are

Fig. 2. A comparison of various forms for  $f_{\text{eff}}$  proposed in the literature. The form of Raupach et al. [1993], an extension of which was presented by Okin [2005], is expressed as a function of roughness density,  $\lambda$ , rather than roughness length  $z_0$ , so a conversion from  $\lambda$  to  $z_0$  is needed. For simplicity, we use  $z_0 = \frac{H\lambda}{2}$  from Wooding et al. [1973], where  $H$  is the average rock height, which we set to  $H = 20$  cm, in preference to a more sophisticated semi-empirical relationship derived from formulae in Hébrard et al. [2012]. The thick solid line, from Raupach et al. [1993] with  $m = 1$ , is the function that we adopt for the majority of this paper.

plotted, for comparison, in Fig. 2. Which one is suitable for Mars? All the forms of  $f_{\text{eff}}$  approach unity as  $z_0$  approaches the value that applies to a ‘smooth’ surface, and each function predicts that  $f_{\text{eff}}$  is less than  $\sim 0.6$  at roughness lengths of 0.5 cm and above. Yet there are (potentially important) differences between the various forms.

The Marticorena and Bergametti [1995] function relies on Arya’s [1975] model which assumes a logarithmic wind profile downwind of an obstacle (roughness

element) and matches it with the background (also assumed) logarithmic profile in order to get  $u_*^t$  as a function of  $u_{*s}^t$ , the threshold for the smooth surface between roughness elements. The model is validated by wind-tunnel profiles of Marshall [1971], which used cylinders and hemispherical obstacles as the roughness elements. We decide to rule out the Marticorena and Bergametti function for Mars, as it does not allow any lifting above  $z_0 = 0.4$  cm and requires very strong winds at  $z_0$  above  $\sim 0.1$  cm, which appears to be at odds with the observed dust storm occurrences shown in Fig. 1. It might be explained by the fact that Arya’s model was first designed to represent situations where roughness elements are not too closely spaced [Marticorena and Bergametti, 1995], with roughness density  $\lambda < 0.05$ , or roughness length  $z_0 \lesssim 0.5$  cm, which is exceeded at a considerable number of Martian sites.

The MacKinnon et al. [2004] function is a modified form of Marticorena and Bergametti’s, allowing for larger roughness lengths, though this fit appears to involve an unphysically large value for one of the parameters in the equation: ‘roughness factor’  $x$  (see their Eq. (20)), which is supposed to be of the order of the distance between two obstacles [Arya, 1975], but for which a value of  $O(10^4)$  is used. MacKinnon et al. [2004] were aiming to match field measurements where roughness elements comprised vegetation (plants, grass, etc.), which is thus a different scenario to Marshall’s [1971] wind-tunnel experiments, and to the Martian surface, where roughness elements (rocks) are less porous. In addition to the shortcomings of Marticorena and Bergametti [1995] and MacKinnon et al. [2004] with respect to our purpose for Mars, the initial Arya [1975] model on which both functions rely was built assuming logarithmic wind profiles, which is an assumption that should be discarded in Martian conditions (see section 2.4).

Another function, from Alfaro and Gomes [1995], is a fit to a single set of  
 275 experimental wind-tunnel data, by studying the influence of the roughness  
 length of the underlying surface ( $z_{0,s}$ ), and not of the non-erodible elements  
 ( $z_0$ ). They produced an updated expression for  $f_{\text{eff}}$ , which also relies on Arya's  
 [1975] model, by closely taking into account the possible variations of  $z_{0,s}$  with  
 different surface textures. However, because their function was derived from a  
 280 restricted set of experimental data we will rather concentrate on what appears  
 to be the most reliable expression for  $f_{\text{eff}}$  so far: that of Raupach et al. [1993].

The Raupach et al. formulation, which used the Marshall [1971] data in its  
 derivation, has since been tested against a number of wind tunnel and field ex-  
 periments [Wolfe and Nickling, 1996, Gillies et al., 2007]. Okin [2008] updated  
 the Raupach formulation, evaluating it against a wider range of experimental  
 data, and added a correction to the high- $z_0$  end at which the original Rau-  
 pach fit lost validity. Okin did not provide a readily applicable equation for  
 $f_{\text{eff}}$ , but his retention of the basic Raupach functional shape, its support from  
 abundant measurement studies, and the considerations exposed above regard-  
 ing the other functions, lead us to favour the Raupach et al. [1993] approach  
 as the most reliable of the functions presented here, at least for the Martian  
 case. Hence, in subsequent sections, we primarily use the Raupach et al. drag  
 partition function, but comparative calculations using the MacKinnon et al.  
 [2004] form (which gives a smaller variation in  $f_{\text{eff}}$  along the relevant range  
 of  $z_0$ ) are also described, to illustrate the sensitivity to this choice. Using the  
 conversion  $z_0 = \frac{H\lambda}{2}$ , where  $H = 20$  cm [Wooding et al., 1973], the Raupach  
 et al. function is

$$f_{\text{eff}} = \sqrt{\frac{1}{\left(1 - \frac{2m\sigma z_0}{H}\right) \left(1 + \frac{2m\beta z_0}{H}\right)}}$$

where  $(\beta, \sigma, m) = (170, 2, 1)$ . The three parameters represent the ratio of the drag coefficients of an isolated non-erodible element to that of the smooth surface, the ratio of basal to frontal area of the non-erodible elements, and the  
 285 ratio of average to peak surface stress over a bare surface. In the absence of any Mars-specific information, we use the set of values tentatively recommended by Raupach et al. [1993]; we note support in the model results of Okin [2008], however, for a steeper drop-off of  $f_{\text{eff}}$  at high  $z_0$  when non-porous obstacles (i.e. Martian rocks) are involved, which suggests that the use of the larger  
 290  $m = 1$  is appropriate, as seen in Fig. 2.

The use of a realistic drag partition function  $f_{\text{eff}}$ , which has values significantly smaller than 1 at high  $z_0$ , results in substantial increases to the calculated lifting thresholds  $u_*^t$  for medium-to-large roughness lengths. However, the impact of  $z_0$  on model dust lifting is more complicated, since  $z_0$  also enters into the calculation of the drag velocity  $u_*$  from the atmospheric wind speed ( $u$ ) near the ground. For conditions in which a logarithmic vertical wind profile can be assumed [Priestley, 1959],

$$u_* = \frac{\kappa u(z_1)}{\ln\left(\frac{z_1}{z_0}\right)} \quad (2)$$

where  $\kappa$  is von Kármán's constant ( $= 0.4$ ), and  $z_1$  is height of the lowest model level, usually a few metres in MGCMs (this applies to boundary layer conditions of neutral stability: we discuss the more general case in section 2.4). From equation (2), the larger  $z_0$  is, the larger  $u_*$ ; therefore, rough surfaces feel a stronger drag force from a given near-surface wind than smooth surfaces do. The effect of surface roughness on lifting at a given  $u(z_1)$  is dependent on the balance between the increase to  $u_*$  and the increase to  $u_*^t$  with increasing  $z_0$ . This balance is sensitive to the particular expression chosen for  $f_{\text{eff}}$ . Combining (1) and (2), we can speak of a threshold wind speed at height  $z_1$ , that

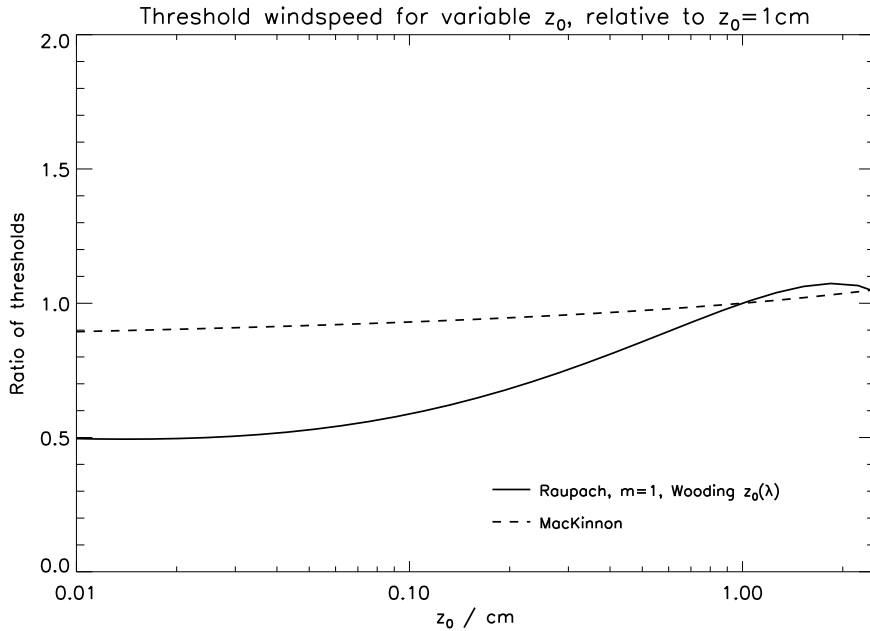

Fig. 3.  $u(z_1)^t/u(z_1)_{z_0=1\text{cm}}^t$ , the ratio between threshold wind speeds (at height  $z_1$ ) using a variable  $z_0$  and using a fixed  $z_0$  of 1 cm, for the Raupach (+Wooding) and MacKinnon drag partition functions, under conditions of neutral stability at the near-surface. Deviations of the lines from a ratio of one imply that model dust lifting rates will vary as a function of  $z_0$ . The Raupach function is known to be unreliable beyond  $\sim 2$  cm (seen in the turning of the solid curve at the upper end of the plotted range), but the largest roughness length in the full-resolution Martian map is 2.02 cm, and 99.8% of pixels have values below 1.8 cm; at  $5^\circ$  resolution, as used in section 2.5, the largest value is 1.46 cm.

corresponds to a drag velocity  $u_*^t$ :

$$u(z_1)^t = \frac{u_{*s}^t \ln\left(\frac{z_1}{z_0}\right)}{\kappa f_{\text{eff}}(z_0)}.$$

It is this quantity, therefore, that controls the viability of model dust lifting at a given  $u(z_1)$  (note, also, that  $u_*/u_*^t = u(z_1)/u(z_1)^t$ ).

Fig. 3 shows the ratio between  $u(z_1)^t$  and  $u(z_1)_{z_0=1\text{cm}}^t$ , the threshold wind

speed when a fixed  $z_0$  of 1 cm is used, as a function of  $z_0$ , for conditions  
295 of neutral stability. For the Raupach et al. [1993] formula (solid line),  $f_{\text{eff}}$   
decreases rapidly as  $z_0$  becomes large, and as a result,  $u_*^t$  increases more rapidly  
than  $u_*$  does, meaning that a larger wind speed is required at high  $z_0$  than  
at lower  $z_0$  values. The difference in threshold wind speed over the range of  
 $z_0$  encountered on Mars is around a factor of two. For the MacKinnon et al.  
300 [2004] formula (dashed line), on the other hand, lifting is only slightly more  
difficult at large  $z_0$  than at small  $z_0$  — wind speeds vary by only around 10%  
over the relevant  $z_0$  range.

This dependence is important for two reasons: firstly, it will affect the spatial  
distribution of annual mean dust lifting in an MGCM (the Raupach form will  
305 make lifting from the high- $z_0$  areas of the southern hemisphere relatively un-  
favourable, in comparison to the MacKinnon form); secondly, it will determine  
the extent to which sub-grid scale variability in  $z_0$  is important for MGCM  
dust lifting (since the dependence applies down to scales much smaller than  
an MGCM gridbox). Sub-grid scale variability, through the contribution of  
310 hotspots to total gridbox lifted flux, will be most important when threshold  
 $u_*^t$  varies most strongly with  $z_0$ , while variability in  $z_0$  will be unimportant if  
 $u_*^t$  is in fact insensitive to  $z_0$ . Since we are treating the Raupach et al. [1993]  
partition function as the more plausible of the two, the lesson of Fig. 3 is that  
dust lifting should be relatively difficult in the Martian southern hemisphere,  
315 and that sub-grid scale variation in  $z_0$  will be important in this regard.

### 2.3 Explicit calculation of $u_*^t$

Equation (1) shows that, in addition to  $z_0$  (through  $f_{\text{eff}}$ ), the threshold drag velocity on a smooth surface,  $u_{*s}^t$ , is needed to determine the threshold for lifting on a rough surface. It can be obtained from one of several available theoretical or semi-empirical formulae. A formulation that has been often used in dust lifting studies on both Earth and Mars [e.g., Kang et al., 2011, Kok et al., 2012, Menut et al., 2013, Mulholland et al., 2013] is that of Shao and Lu [2000]:

$$u_{*s}^t = \sqrt{A_N \left( \sigma_p g D_p + \frac{\gamma}{\rho D_p} \right)}, \quad (3)$$

where  $\sigma_p = \frac{\rho_d}{\rho}$ , the ratio of dust particle density to atmospheric density,  $D_p$  is the dust particle diameter,  $g$  is the gravitational acceleration,  $\gamma \approx 3 \times 10^{-4} \text{ kg s}^{-2}$  and  $A_N \approx 0.0123$ . The constants  $\gamma$  and  $A_N$  encompass particle arrangement, particle Reynolds number at threshold drag velocity and the interparticle electrostatic force, and their values, which are not Earth-specific, were determined empirically by fitting to wind tunnel data. This formula can be differentiated with respect to particle diameter to find the minimum threshold velocity:

$$u_{*s}^t = \sqrt{2A_N} \left( \frac{\gamma \rho_d g}{\rho^2} \right)^{\frac{1}{4}}, \quad (4)$$

which applies to the most ‘erodible’ (most easily mobilisable) particles, of diameter  $D_p = \sqrt{\frac{\gamma}{\rho_d g}}$ .

With surface roughness included, combining (1) and (4), the threshold drag velocity is then given by:

$$u_*^t = \frac{\sqrt{2A_N} \left( \frac{\gamma \rho_d g}{\rho^2} \right)^{\frac{1}{4}}}{f_{\text{eff}}}. \quad (5)$$

The value of this threshold depends crucially on the dust particle density  $\rho_d$ ,  
 320 and in this respect there is considerable uncertainty over which is most appropriate for the Martian surface. Conventionally, dust lifting modelling studies have used a ‘bulk’ density of  $\rho_d = 2500 \text{ kg m}^{-3}$  or similar for Martian dust, which leads to a minimum threshold for sand-sized particles, with diameter around  $180 \mu\text{m}$ . It is therefore assumed that saltation of these sand grains  
 325 causes the raising of micron-sized grains which remain in suspension, in agreement with size measurements of atmospheric dust [e.g., Wolff et al., 2006]. With a near-surface atmospheric density of  $\rho = 0.02 \text{ kg m}^{-3}$ , (4) then gives a smooth threshold velocity of  $u_{*s}^t = 1.4 \text{ m s}^{-1}$ . Other calculations of size-dependent  $u_{*s}^t$  have been employed, most notably that of Greeley and Iversen  
 330 [1985], but if the assumption that lifting begins at the lowest point of the  $u_{*s}^t(D_p)$  curve is retained, the resulting value does not differ greatly from (4) [Park and Park, 2010]. The uncertainty in the threshold, then, is apparently fairly small, at least within the conventional saltation-emission theory for wind stress dust lifting.

335 However, it has been noted by numerous authors [e.g., Zimbelman, 2000, Sullivan et al., 2008] that evidence of saltating sand particles is rarely found on Mars, yet the injection of micron-sized particles into the atmosphere is evidently ubiquitous. A suggested explanation for this apparent paradox is that micron-sized dust grains clump together on the surface, possibly aided  
 340 by electrification, to form loosely packed dust aggregates [Merrison et al., 2004]. These structures are much more erodible than sand particles, due to their lower density, and Martian winds may frequently be strong enough to lift the aggregates directly from the surface [Merrison et al., 2007]. Once in suspension, the tensile strength of these aggregates has been suggested to be

345 extremely low, leading to their rapid break-up into constituent, micron-sized grains [Sullivan et al., 2008].

Possible values for the density and diameter of surface dust aggregates are uncertain, but using an aggregate density of  $\rho_{d(agg)} = 750 \text{ kg m}^{-3}$  and diameter  $D_p = 500 \mu\text{m}$  (from Sullivan et al. [2009]), equation (3) produces a threshold  
350 of around 80% of that for individual sand grains, while plausible variation in density and diameter could reduce this further, to around 70% of the sand particle threshold ( $u_{*s}^t \sim 1.0 \text{ m s}^{-1}$ , equivalent to a surface stress of  $\sim 0.02 \text{ Pa}$ , in agreement with Merrison et al. [2007]).

Since part of the focus in this work is to develop the representation of dust  
355 lifting in Martian regional and global models, we retain the default assumption of modellers to date, that saltation of sand grains is responsible for the emission of micron-sized particles. However, we note that this model of Martian dust lifting appears increasingly to be in question (at least in some regions where a lack of sand movement has been observed) and so we keep in mind the  
360 possible reduction of  $u_{*s}^t$  that would be justified if direct detachment of low-density aggregates is in fact the dominant process.

#### *2.4 Consideration of non-neutral atmospheric stability for $u_*$*

Lifting rates are also dependent, for a particular near-surface wind speed, on atmospheric stability in the PBL. Under conditions of neutral stability, drag  
365 velocity  $u_*$  is given by (2), but in non-neutral conditions the assumption of a logarithmic wind profile does not hold, and a more complicated form of  $u_*$  is required. A thermal plume model, which includes a surface flux parame-

terisation that uses Monin-Ubukhov similarity theory to account for variable  
 near-surface stability, was recently added to the LMD MGCM by Colaïtis et al.  
 370 [2013], where it is described in detail. The key result of the parameterisation  
 for our purpose is that the expression for  $u_*$  in (2) is multiplied by  $\sqrt{f_m(Ri)}$ ,  
 the stability function for momentum, which varies with the bulk Richardson  
 number  $Ri$  in the lowest model layer. This function takes different forms de-  
 pending on the atmospheric stability, resulting in a decrease in  $u_*$  (compared  
 375 to the neutral case) when the boundary layer is stable ( $Ri > 0$ , commonly  
 experienced at night), and an increase in  $u_*$  in unstable conditions ( $Ri < 0$ ,  
 which typically applies from mid-morning to late afternoon).  $u_*$  can be mod-  
 ified further by a parameterisation of turbulent gustiness that is included in  
 the calculation of vertical fluxes of heat and momentum in the boundary layer.  
 380 The impact on  $u_*$  is believed to be fairly minor, but enhanced upward momen-  
 tum fluxes can reduce daytime  $u_*$ , in opposition to increases resulting from  
 instability.

The changes to  $u_*$  are usually relatively small — of the order of 20% or less  
 [see the plots of  $u_*^2$  in Colaïtis et al., 2013, Figure 6] — and peak daytime  
 385 drag velocities can be either increased or reduced, depending on ambient con-  
 ditions. The precise nature of these changes have not yet been investigated.  
 Nevertheless, since the Colaïtis et al. scheme is included in the Mars Cli-  
 mate Database used for calculations in the following subsection, we include  
 the variable stability method as part of the ‘baseline’ dust lifting model, con-  
 390 structed throughout this section, that is evaluated below using gridbox-mean  
 wind speed and  $z_0$  fields. Compared to a neutral stability approach, this new  
 surface scheme is expected to have only a small net effect on the frequency of  
 dust lifting events, but could slightly alter their spatiotemporal distribution.

## 2.5 MGCM drag velocities: comparison of $u_*$ to threshold $u_*^t$

395 With complete formulations for  $u_*$  and  $u_*^t$ , we now investigate the performance of this dust lifting model under Martian conditions. The Mars Climate Database (MCD) version 5.0 [Millour et al., 2012] contains output from the LMD MGCM, from simulations performed using a variety of different forcing (dust opacity, solar intensity) fields. Simulations were performed at  
400  $5.625^\circ \times 3.75^\circ$  horizontal resolution and 30 minutes temporal resolution (for the model physics), and by using interpolation and statistics contained within the database, a full Martian year of atmospheric and surface variability can be reconstructed from the MCD. We use the MCD, with the ‘Climatology’ dust scenario (representing a typical year without a global dust storm, and  
405 displayed in Supplementary Information, Fig. S1) to construct global maps of  $u_*$  and  $u_*^t$  at spatial and temporal resolutions of  $5^\circ \times 5^\circ$  and 30 minutes respectively, to estimate the frequency at which model drag velocities exceed the threshold at each location, during the year. Details of how these fields are obtained are given in the Supplementary Information, but note that the cal-  
410 culation accounts for variable stability in the boundary layer when obtaining  $u_*$ .

The peak value of  $u_*/u_*^t$  reached at each gridpoint when using gridbox-mean values for wind speed and roughness length is plotted in Fig. 4. Values greater than one are reached at various points in the northern high latitudes, and  
415 at a few points in northern midlatitudes. The lifting threshold is exceeded at a single point in the southern hemisphere, within the Hellas basin on the northeastern slope, but over most of the southern extratropics the annual peak  $u_*$  is less than 40% of the local threshold. Note that some of the largest drag

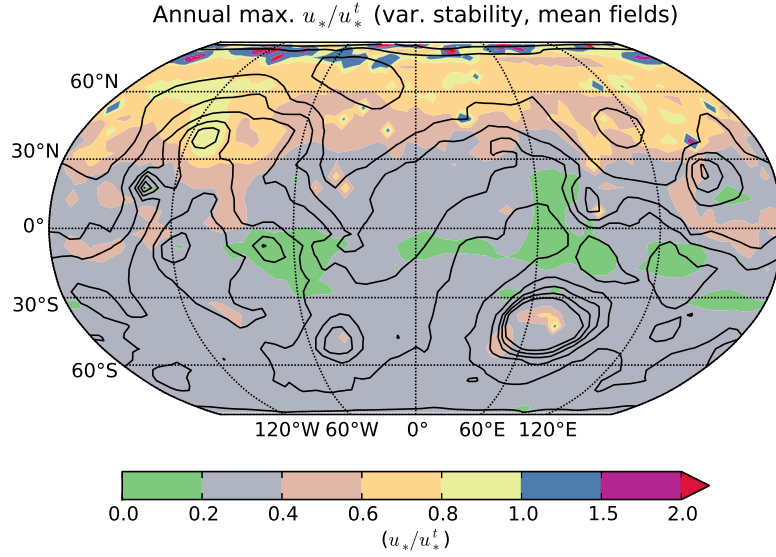

Fig. 4. The peak drag velocity reached, as a fraction of the local threshold  $u_*^t$ , during the ‘Climatological’ MCD year, using GCM mean fields for  $z_0$  and  $u(z_1)$  (with  $z_1 = 5$  m), and the variable stability scheme for converting to  $u_*$ . The surface topography is drawn in black contours, as it is in several subsequent figures.

420 velocities actually occur in the southern subtropics (in spring), but thresholds are so large in this region that they are never even approached, with the exception of the small area in Hellas. A similar result is obtained using the MacKinnon et al. [2004] drag partition function, but with somewhat increased values in the southern midlatitudes.

425 Since the majority of the excursions above the local threshold at 70–90°N occur during periods of CO<sub>2</sub> ice surface cover, when it is conventionally assumed that no dust lifting is possible (it is also worth noting that the uncertainty on  $z_0$  values in the Hébrard et al. [2012] map is largest in the high latitudes),

lifting events are shown here to be extremely rare in the LMD MGCM — and virtually non-existent in the southern hemisphere — which is very much at odds with observations that show small-scale Martian dust storms to be very frequent occurrences, particularly in the midlatitudes [Cantor et al., 2001]. If the lower thresholds that are applicable to direct lifting of low-density aggregates are applied instead, values in the plot should be scaled by a factor of  $\sim 1.4$  — this would mean the activation of lifting at further gridpoints in the northern midlatitudes, but have little impact in the southern hemisphere, where lifting would remain extremely limited.

The large differences between peak MGCM drag velocities and the threshold drag velocities calculated using the true surface roughness point to a crucial role for sub-grid scale variability in dust lifting. As we explore in the next section, parameterisation of unresolved variability may be required both for near-surface winds and for the surface roughness field, and could therefore impact both  $u_*$  and  $u_*^t$ . As well as altering the ability, in a global sense, of the MGCM to initiate dust lifting events, parameterising sub-grid scale variability could alter the spatial distribution of the most favourable sites for lifting — potentially reducing the northern hemispheric dominance seen in these MCD gridbox-mean calculations.

### 3 Exploring sub-grid scale variability

We now evaluate the extent to which unresolved spatial variations in surface roughness and in horizontal wind strength can be sources of additional lifted dust flux in an MGCM. In both cases, the hotspot theory [Gillette, 1999] predicts that the majority of dust lifting will be concentrated in areas smaller than

the typical MGCM horizontal resolution, and that — for gridbox-mean wind speeds below the mean lifting threshold — total lifting will be underestimated at coarse resolution as a result. We estimate the changes in the effective  $u_*^t$  and  $u_*$  that result from these effects, and in the next section discuss whether or not this then brings thresholds within the reach of peak MGCM drag velocities. In particular we use the ratio  $u_*/u_*^t$  in several of the following plots, since this is the crucial quantity for dust lifting with variable  $z_0$ .

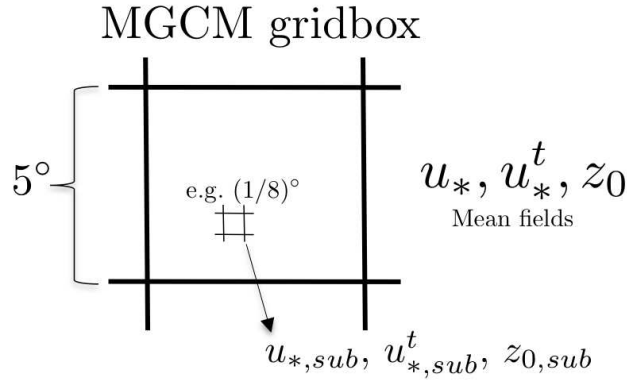

Fig. 5. Schematic representation of variable conditions within an MGCM gridbox, and the notation used to distinguish between gridbox-mean and sub-grid variables.

To clearly distinguish between gridbox-mean and higher-resolution variables, we introduce variables  $u_{*,sub}$ ,  $u_{*,sub}^t$  and  $z_{0,sub}$  to represent respectively drag velocity, threshold drag velocity and surface roughness length values within a  $5^\circ$  MGCM gridbox, while retaining  $u_*$ ,  $u_*^t$  and  $z_0$  as the gridbox-mean equivalents. The situation is illustrated by Fig. 5.

### 3.1 Surface roughness length variability: $z_{0,\text{sub}} < z_0$

465 Although individual pixels in the surface roughness length map shown in Fig. 1 carry with them (in some cases, substantial) uncertainties, the availability of a map at a spatial resolution significantly higher than that typically used by MGCMs provides an opportunity to assess the impact on predicted dust lifting rates of sub-grid scale variability in roughness length. As shown in Fig. 470 3, for a given MGCM wind speed, lifting will be favoured at locations within a gridbox with small  $z_0$ ; that is, points at which  $z_{0,\text{sub}} \ll z_0$ . The activation point for lifting (i.e. the lowest wind speed at which some lifting occurs) is controlled by the site within a gridbox with the largest ratio of drag velocity to threshold drag velocity,  $(u_{*,\text{sub}}/u_{*,\text{sub}}^t)_{\text{max}}$ . Note that this quantity may be 475 greater than one even if the  $5^\circ$ -mean equivalent,  $u_*/u_*^t$ , is less than one, in which case the dust lifting rate will be systematically underestimated if  $z_0$  variations are not accounted for.

Fig. 6 shows, for the Raupach drag partition function, the ratio of these two quantities, that is  $\frac{(u_{*,\text{sub}}/u_{*,\text{sub}}^t)_{\text{max}}}{u_*/u_*^t}$  (which is independent of wind speed). 480 Where this ratio is  $> 1$ , dust lifting will occur at a lower wind speed when sub-grid scale  $z_0$  variability is parameterised than it does using gridbox-mean values. To avoid possible undue influence from single outlying pixels in the  $\frac{1}{8}^\circ$  map, synthetic sub-grid values  $z_{0,\text{sub}}$  were generated using standard deviations calculated for each  $5^\circ$  gridbox from the high-resolution map, assuming that 485  $z_{0,\text{sub}}$  are distributed log-normally within  $5^\circ$  gridboxes (Supplementary Information, Fig. S2 shows that this assumption is reasonable). The results shown here are for a sub-grid resolution of  $\sim \frac{1}{6}^\circ$ , and are not greatly different to the result of simply using the  $\frac{1}{8}^\circ$  map directly.

Fig. 6. The ratio  $\frac{(u_{*,\text{sub}}/u_{*,\text{sub}}^t)_{\text{max}}}{u_*/u_*^t}$  at a sub-grid resolution of  $\sim \frac{1}{6}^\circ$ , for a homogeneous mean ( $5^\circ$ ) near-surface wind speed, using the Raupach et al. [1993] drag partition function, accounting for sub-grid scale  $z_0$  variability by generating  $z_{0,\text{sub}}$  distributions with standard deviations  $\sigma_g(z_0)$  to match those calculated from the full-resolution Hébrard et al. [2012] map.

The sub-grid quantity  $(u_{*,\text{sub}}/u_{*,\text{sub}}^t)_{\text{max}}$  is twice as large as its gridbox-mean  
 490 counterpart in southern midlatitude regions, implying that dust lifting will  
 begin at a drag velocity equal to half of the mean threshold  $u_*^t$  (or equivalently,  
 at a wind speed of half the mean threshold wind speed  $u(z_1)^t$ ). The effect of  $z_0$   
 variability varies significantly with location: in the smooth northern hemisphere  
 plains, the ratio of drag velocity to threshold drag velocity  
 495 is only  $\sim 10\%$  larger with sub-grid variables than with mean variables. The  
 spatial distribution shows that the enhancement factor increases more rapidly  
 with increasing  $z_0$  than it does with increasing standard deviation of  $z_0$  values  
 within the  $5^\circ$  gridbox,  $z_0$  and  $\sigma_g(z_0)$  being strongly spatially anti-correlated

(Supplementary Information, Fig. S2). This situation exists due to the dependence of threshold on  $1/f_{\text{eff}}$  seen in Fig. 3: in a  $5^\circ$  box with a low  $z_0$  value, the threshold drag velocity is already close to  $u_{*s}^t$ , but the threshold for a  $z_{0,\text{sub}} \sim 0.1$  cm point within a box with  $z_0 \sim 1$  cm is significantly lower than the  $5^\circ$  threshold. In other words, a large spread of  $z_{0,\text{sub}}$  values creates sub-grid points lying further to the left of the mean along the (Raupach) curve of Fig. 3, but a large mean  $z_0$  is required for this displacement to make lifting significantly easier. So, it is especially important to account for sub-grid scale  $z_0$  variation in southern midlatitudes, where the box-mean  $z_0$  is large, despite the relatively low  $z_0$  spreads found here.

The values plotted in this figure represent the multiplicative factor that may be applied to Fig. 4 to account for sub-grid scale variability in  $z_0$ , at  $\sim \frac{1}{6}^\circ$  resolution. From comparison of the two figures, it can therefore be seen that  $z_0$  variability could increase the annual peak  $u_*/u_*^t$  significantly in many regions, and in the southern hemisphere this could be sufficient to push model  $u_*$  above the threshold at several more gridpoints in Hellas, and perhaps at several other isolated points. The increase to peak  $u_*/u_*^t$  will be even greater as the  $z_0$  resolution is increased further, particularly in regions of large mean  $z_0$ , where there is greater scope for sub-grid areas to exhibit significantly larger  $f_{\text{eff}}$  values than the gridbox mean.

A quite different situation arises when using the MacKinnon form of  $f_{\text{eff}}$  (see Supplementary Information, Fig. S3), due to its weaker dependence on  $z_0$ : enhancements to  $u_*/u_*^t$  of no more than 10% are produced, meaning that sub-grid  $z_0$  variations are largely irrelevant to model dust lifting. Also, the fairly uniform gradient of the dashed line in Fig. 3 means that variations in  $z_0$  affect  $u_*/u_*^t$  independently of the mean  $z_0$  value, such that enhancements to  $u_*/u_*^t$

525 tend to be largest where  $z_0$  standard deviation is largest, which is predominantly in the northern hemisphere. The magnitude of the impact on dust lifting rates of sub-grid scale  $z_0$  variability is, therefore, strongly dependent on the drag partition function used.

### 3.2 *Wind speed variability : $u_{*,\text{sub}} > u_*$*

530 The other important source of variability unresolved by an MGCM lies in wind speed itself. Within a GCM gridbox of order 100 km, there will exist smaller areas in which the surface wind speed is significantly stronger than the gridbox mean value:  $(u(z_1)_{\text{sub}})_{\text{max}} > u(z_1)$ , and, if  $z_0$  variability is set aside,  $(u_{*,\text{sub}})_{\text{max}} > u_*$ . At horizontal scales of around 1–10 km, mesoscale circulations  
535 (fronts, slope winds) could impact winds at regional scales and trigger dust lifting: this variability is resolved by limited-area mesoscale models and high-resolution MGCMs [e.g., Tyler et al., 2002]. Yet there is another crucial source of wind variability that is left unresolved by most MGCMs and mesoscale models, and deserves further attention: turbulent gustiness.

540 The main question underlying our discussion of gustiness is the following: when a certain value is predicted by an MGCM for the ‘ambient’ wind speed, what is the typical maximum wind speed encountered within an interval of about half an hour, if one were to take into account turbulent gustiness? This also relates to the above-mentioned hotspot theory, while highlighting  
545 the important point that favoured lifting sites may be transient in nature, and shift location within a gridbox in response to a changing wind field. To address the question, we analyse results from the LMD LES model [Spiga et al., 2010], run with a background wind speed equivalent to a drag velocity

Fig. 7. Daily maximum drag velocity from an LMD LES model simulation, at horizontal resolution 100 m, in which the background  $u_*$  was  $1 \text{ m s}^{-1}$ .

$u_* = 1 \text{ m s}^{-1}$  (CaseA.w30 in Colaïtis et al. [2013]), with a horizontal resolution  
 550 of 100 m and a domain size of  $10 \text{ km} \times 10 \text{ km}$ .

Fig. 7 reveals that in many parts of the domain, the daily maximum drag velocity exceeded twice the ambient drag velocity (i.e.  $(u_{*,\text{sub}})_{\text{max}} \geq 2u_*$ ); furthermore, every gridpoint produced a daily maximum of at least  $1.5u_*$ . That is, at every gridpoint, over a full day of model integration,  $u_*$  varied by  
 555 at least 50% about the mean value. In an MGCM, the unresolved temporal variability covers much shorter periods (timesteps of around 30 minutes), so the underestimation of  $u_*$  peaks will be less severe. However, information on a second form of variability, spatial, can be obtained from Fig. 7. The domain-mean daytime maximum  $u_*$  lies below 80% of the domain-maximum  
 560 value of  $\sim 2.5 \text{ m s}^{-1}$ , which indicates the level of spatial wind variability that

can be expected from the division of a domain into 10,000 sub-grid points. For an MGCM gridbox, which at  $5^\circ$  resolution has a length of  $\sim 200$  km at midlatitudes, finer subdivision may be justified: the LES results shown here, with structures of a few hundred metres in length abundant within the domain, indicate that dust lifting hotspots could develop on scales of as little as 0.001% of the MGCM gridbox area.

To parameterise gustiness in a GCM, in both a spatial and a temporal sense, a single gridbox value of wind speed or drag velocity can be replaced by a probability density function (pdf), representing the range of values occurring within the gridbox and over the length of the timestep. A very commonly used function for modelling wind variability is the Weibull distribution [e.g., Justus et al., 1978, Gillette and Passi, 1988], with scale parameter equal to the ambient drag velocity or wind speed: Fenton and Michaels [2010] found that this distribution, with a shape parameter  $k$  of 2.5–3.0 and scale parameter  $u_*$ , provided an adequate description of the drag velocities produced by their Martian LES model (however, they noted that wind speeds deviated from the Weibull distribution when strong ambient winds were present). A similar Weibull-like distribution is obtained using our LES model, an example of which is shown in the histogram and overlaid curve of Fig. 8.

Efforts have already been made to parameterise winds using Weibull distributions in a mesoscale model, by Michaels [2006], and in an MGCM, by Newman et al. [2002b], though in the latter case a too-small value of  $k$  (based on data available at the time) was used, resulting in widespread dust lifting and underestimated interannual variability. Here we aim to utilise the more realistic  $k$  values provided by Fenton and Michaels [2010], and additionally to include a plausible limit on the impact of windspeed variability on dust emission (sug-

gested by Newman et al. [2002b] as a possible improvement to their method), through the method outlined in the next paragraph.

Fig. 8. Frequency of occurrence of  $u_{*,\text{sub}}$  values in a simulation with the LMD LES model (taking values from throughout the domain during the period of peak convection in early afternoon) using an ambient  $u_*$  of  $1 \text{ m s}^{-1}$  (histogram). Overlaid is a Weibull pdf with a scale parameter of  $1 \text{ m s}^{-1}$  and a shape parameter of  $k = 3.5$  (blue curve). An illustrative threshold drag velocity  $u_*^t$  is also shown (green dashed line) to highlight the dust lifting that can occur (red shaded area) when mean  $u_*$  is below the threshold, if a probability distribution (with a certain critical probability) is used for  $u_{*,\text{sub}}$ .

Accounting for sub-grid scale variability in surface wind allows dust lifting  
 590 activation in areas with larger mean thresholds than would otherwise be the  
 case. The limit to this increase is set by the cut-off point applied to the tail  
 of the pdf (which is where lifting hotspots are found), to represent a critical  
 (minimum) probability, in space and/or time, with which a particular wind  
 speed must occur in order to be considered as a possible initiator of a dust  
 595 lifting event. The physical intuition behind this is that there exists some limit

on the size of departures from the mean wind speed that can occur within  
 a finite area and time, as Weibull-like wind distributions cannot be applied  
 indefinitely down to arbitrarily small scales in space and/or time. Since dust  
 lifting has a strongly non-linear dependence on wind speed, it will always  
 600 be the case that extremely low-probability gust events from the tail of the  
 pdf produce some amount of dust flux in a gridbox, even if the mean wind  
 speed lies far below the threshold, unless a critical probability is defined.  
 Additionally, when very short or spatially limited bursts of saltation do occur,  
 the mobilised dust may in reality be unlikely to become entrained into and  
 605 mixed throughout the PBL (whereas in the MGCM, this occurs rapidly once  
 dust is injected into the lowest model level). The use of a critical probability  
 also ensures that the sub-grid scale parameterisation is applied only on scales  
 at which it is physically consistent, and the introduction of this parameter  
 allows us to quantify the increasing impact of sub-grid scale variability as  
 610 smaller and smaller scales are accounted for.

As an example, a probability (or frequency) of 0.01 can be interpreted equiv-  
 alently as a gust lasting one-hundredth of a timestep ( $\sim 30$  seconds), covering  
 1% of the gridbox area ( $\sim 400 \text{ km}^2$ ), or a combination of the two (from ergodic  
 theory, which says that the behaviour of an ensemble of identical systems is  
 615 equivalent to the behaviour of a single realisation over a longer time period,  
 spatial and temporal variability can be used interchangeably in this context).  
 Hence, Fig. 7 suggests that the critical probability could be at least as low as  
 $10^{-5}$  (structures are seen down to the model resolution of 100 m). The situa-  
 tion is illustrated in Fig. 8: for a particular threshold  $u_*^t$ , dust lifting can occur  
 620 with an ambient  $u_* < u_*^t$  if the gustiness is strong enough and the critical  
 probability is sufficiently low.

Fig. 9. The ratio  $\frac{(u_{*,\text{sub}}/u_{*,\text{sub}}^t)_{\text{max}}}{u_*/u_*^t}$ , accounting for sub-grid scale wind speed variability (for a constant  $z_0$ ) using a Weibull distribution with a range of  $k$  values, as a function of critical probability (note that this is equal to  $\frac{(u_{*,\text{sub}})_{\text{max}}}{u_*}$ ). Critical probabilities as low as  $10^{-5}$  are suggested by Fig. 7.

Fig. 9 shows the relative increase to  $u_*/u_*^t$  caused by gustiness, modelled with Weibull distributions with various shape parameters. Since thresholds are constant, this is equal to  $(u_{*,\text{sub}})_{\text{max}}/u_*$ . It is clear that substantial enhancements to a model's ability to lift dust will result, even with a relatively low cut-off point for the drag velocity pdf. With  $k = 2.5-3.0$  and a critical probability  $< 10^{-3}$ , peak sub-grid winds  $(u_{*,\text{sub}})_{\text{max}}$  are 2-3 times as strong as the mean wind  $u_*$ . There is agreement here with Fig. 7 too: the LES simulation produced peaks (at each gridpoint) of 1.5-2.5 times the mean  $u_*$  when run for one sol with a timestep of 1.5 seconds, equivalent to a critical probability of  $O(10^{-5})$ , which is in line with Fig. 9, for  $k$  values of  $\sim 2.5-4$ .

The values here represent the scaling factor that may be applied to the  $u_*/u_*^t$  field shown in Fig. 4, to account for unresolved turbulent gustiness, and may be compared to those in Fig. 6, which shows the same for unresolved  $z_0$  variability, with a critical probability of 0.001 (representing the change in spatial resolution from  $5^\circ$  to  $\sim \frac{1}{6}^\circ$ ). If a globally homogeneous  $k = 3.0$  is assumed,  $u_*/u_*^t$  is increased, due to gustiness, by around a factor of two at all gridpoints, meaning that in the southern midlatitudes, variability in  $z_0$  and in wind speed could have comparable impacts on dust lifting.

Note that although the Weibull distribution accounts for the full range of wind speed variability within an MGCM gridbox, it cannot fully account for mesoscale structure in the wind field, in particular from slope winds, which are caused by heterogeneity in the surface topography that is seen by neither the MGCM nor the sub-grid scale parameterisation. We return to this point in section 5, but stress that a gustiness parameterisation method of this kind, with a globally homogeneous shape parameter  $k$ , does not provide the complete solution to the problem of unresolved wind variability in an MGCM.

#### 4 Combined impact of sub-grid variabilities on dust lifting

Taken together, the changes to  $u_*/u_*^t$  resulting from the parameterisation of sub-grid scale variability in  $z_0$  and in surface wind speed are substantial, and imply that dust lifting rates are very different, both in magnitude and in spatial distribution, than those which are produced by calculation at MGCM spatial resolution. We now explore quantitatively the possible impact of these sub-grid scale variabilities, by returning to the MCD data introduced in section 2.

655 Sub-grid scale variability is modelled stochastically, by drawing random numbers to construct pdfs for each of  $z_0$  and near-surface wind speed. For surface roughness, values are distributed log-normally about the gridbox mean, using either a prescribed, spatially uniform geometric standard deviation  $\sigma_g(z_0)$  (ranging from 1.0, resulting in no variability, to 2.0), or a heterogeneous  $\sigma_g(z_0)$  660 calculated from the high-resolution  $z_0$  map (as in section 3.1; see also Supplementary Information, Fig. S2). For gustiness, a Weibull distribution is used for  $u(z_1)_{\text{sub}}$  (rather than  $u_{*,\text{sub}}$  which, due to the heterogeneous  $z_0$  used in conversion from  $u(z_1)_{\text{sub}}$ , will now in general not follow a Weibull distribution), with the ambient wind speed  $u(z_1)$  as the scale parameter and a spatially homogeneous 665 shape parameter  $k$  in the range 2.5–3.5, and these wind speeds are then converted to drag velocities  $u_{*,\text{sub}}$  using the heterogeneous  $z_0$  values from the generated pdf. Finally, for both variables, a critical probability is chosen to define the cut-off point for the tails of the distributions. Physically, if expressed as a fraction of the gridbox area, this parameter represents the smallest scale 670 of variability that is considered in calculation of the lifted dust flux for the gridbox. Using this approach, arrays of  $u_{*,\text{sub}}$  and  $u_{*,\text{sub}}^t$  are calculated in each gridbox for each 30-minute timestep in a typical model year. Further details on these calculations are given in the Supplementary Information.

Saltation fluxes can then be calculated, using the common saltation flux ( $H$ ) formula from White [1979], which has

$$H(u_*, u_*^t) \propto \frac{\rho}{g} (u_*^t)^3 \left( \frac{u_*}{u_*^t} - 1 \right) \left( \frac{u_*}{u_*^t} + 1 \right)^2. \quad (6)$$

Fluxes with and without sub-grid scale variability are therefore, respectively,

$$H_{\text{sub}} = \frac{1}{N} \sum_{i=1}^N H(u_{*,\text{sub}}, u_{*,\text{sub}}^t)_i \quad \text{and} \quad H_{\text{mean}} = H(u_*, u_*^t),$$

where  $N$  is the number of sub-grid boxes being used. Dust lifting rate (vertical flux) is generally taken to be proportional to  $H$ , with a proportionality constant, the ‘lifting efficiency’, that is dependent on the particle size distribution present at the surface, as well as other factors, and the value of which is extremely poorly known for Mars (more complex schemes for the relationship between horizontal and vertical flux exist, but exhibit very large uncertainty at present [Kang et al., 2011]). Saltation fluxes, when shown in this section, are normalised, and as a result can equivalently be interpreted as normalised dust lifting rates.

With both gustiness and  $z_0$  variability included, the situation shown in Fig. 8 must now be updated to include a spatially varying lifting threshold. The interaction of the two pdfs, of  $u(z_1)_{\text{sub}}$  and  $u(z_1)_{\text{sub}}^t$ , is illustrated in the diagram in Fig. 10, in which the orange shaded area represents a collection of dust lifting hotspots within the gridbox. Also shown in Fig. 10 is an example of the stochastic sampling approach, where lifting at several hotspots can be seen for a sub-threshold mean wind speed. At this hypothetical gridpoint, mean  $z_0$  is 0.5 cm with  $\sigma_g(z_0) = 1.5$ , and sub-grid wind speeds follow a Weibull distribution with  $k = 2.5$ . The mean wind speed at  $z_1$  is set to half the threshold value. Despite this, dust lifting occurs at multiple sites within the gridbox: primarily those at which strong gusts occur, with some weighting towards low values of  $z_0$ .

The sensitivity of dust lifting rates to the parameters  $k$  and  $\sigma_g(z_0)$ , which control the magnitudes of each of the two types of variability, is explored below; first, results from the most plausible pair of parameters — a gustiness shape parameter of  $k = 3.0$  and  $\sigma_g(z_0)$  calculated from the high-resolution  $z_0$  map — are shown. Fig. 11 shows peak  $u_{*,\text{sub}}/u_{*,\text{sub}}^t$  resulting from the inclusion of

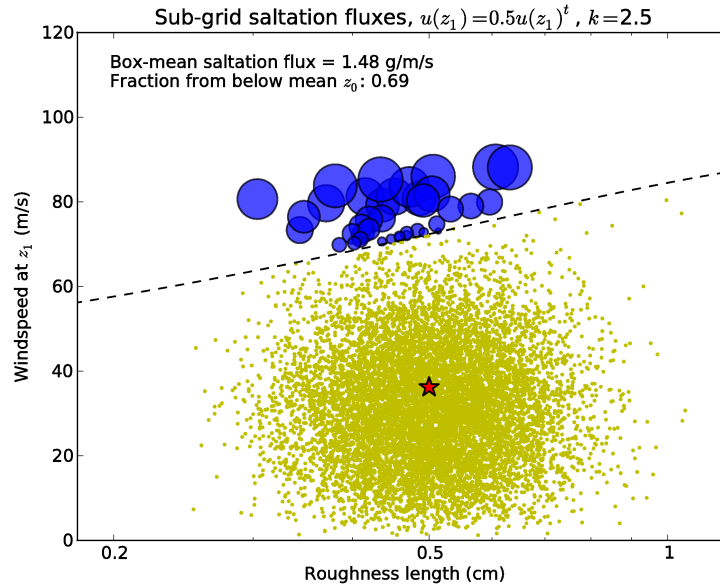

Fig. 10. (Top) Diagram (an extension of Fig. 8, with Weibull distributions used for wind speed rather than drag velocity) illustrating how pdfs for  $u(z_1)_{\text{sub}}$  (blue) and  $u(z_1)_{\text{sub}}^t$  (green) can interact to produce dust lifting in a portion of the gridbox (note that the  $u(z_1)_{\text{sub}}^t$  distribution is in reality more complex than the normal distribution drawn here). (Bottom) Saltation fluxes (from (6)) at 10,000 points (i.e. assuming a critical probability of 0.0001) sampled in the  $(u(z_1)_{\text{sub}}, z_{0,\text{sub}})$  domain, within a gridbox with  $z_0 = 0.5$  cm,  $\sigma_g(z_0) = 1.5$ ,  $k = 2.5$  and  $u(z_1) = 0.5u(z_1)^t$ . The red star marks the mean values of wind speed and roughness length. The dashed line marks the threshold for lifting,  $u(z_1)_{\text{sub}}^t$ . Points at which dust lifting occurs are plotted as blue circles, with sizes proportional to the local dust flux; points at which no lifting occurs are plotted as yellow dots.

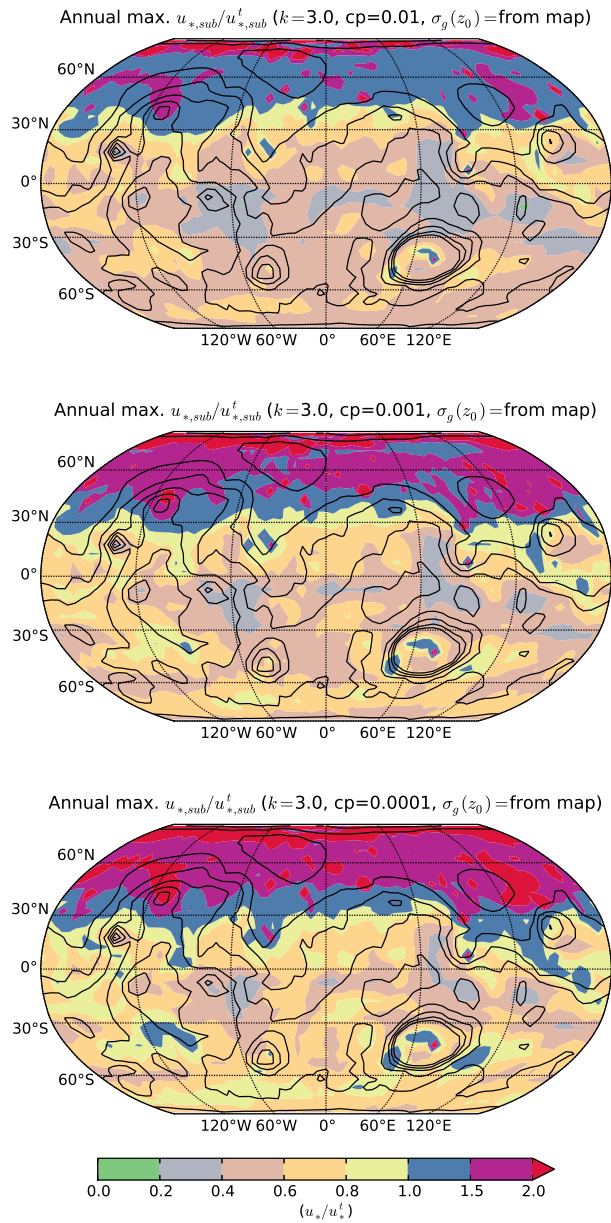

Fig. 11. Annual maximum  $u_{*,sub}/u_{*,sub}^t$  from the MCD, as in Fig. 4, when sampling sub-grid scale variability in  $z_0$ , using geometric standard deviations taken from the high-resolution map, and in wind speed, using a Weibull distribution with shape parameter  $k = 3.0$  and scale parameter  $u(z_1)$ . Critical probabilities of 0.01 (top), 0.001 (middle) and 0.0001 (bottom) are shown.

700 both types of sub-grid scale variability, where now the value for a gridbox is  
the maximum of any of the sub-grid areas within that gridbox. It is seen that  
even with a relatively low critical probability of 0.01, substantial increases over  
the mean-fields case, shown in Fig. 4, are produced: the combined impacts of  
the two types of variability cause the annual maximum  $u_{*,\text{sub}}/u_{*,\text{sub}}^t$  to ex-  
705 ceed unity throughout the northern mid- and high-latitudes, and dust lifting  
also becomes possible, at least briefly, at a greater number of points in the  
southern hemisphere, on the western and northeastern slopes of Hellas. With  
a critical probability of 0.001, further southern midlatitude dust lifting sites  
are activated, at Solis Planum and east of Hellas. Furthermore, large areas  
710 of the southern hemisphere now show peak drag velocities not far below the  
local threshold. It is possible that some of these areas may become viable for  
dust lifting during a major dust storm, when surface stresses are elevated due  
to the strengthened global circulation [Haberle et al., 1982, Montabone et al.,  
2005]. The activation of secondary lifting sites may in fact be a crucial part  
715 of the development of some major dust storms [Strausberg et al., 2005]. With  
a critical probability of 0.0001 — still very plausible, at least with respect to  
gustiness, according to Fig. 7 — further southern hemisphere areas reach or  
come close to reaching the threshold at some point during the year, including  
the south polar region, where cap-edge dust storms have been observed [e.g.,  
720 Imamura and Ito, 2011]. The percentages of gridpoints at which the threshold  
is reached in the three cases described are 30%, 34% and 38% respectively.

Similar plots for separate inclusions of each effect (with critical probability  
0.001) are provided in Supplementary Information, Fig. S4. For these param-  
eter choices, the impacts of the two forms of variability are comparable in  
725 some locations, but gustiness has the bigger impact overall (12% of gridpoints

exceed the threshold in the  $z_0$ -only case, while 29% do so in the gustiness-  
 only case, compared to 4% for the mean fields case (Fig. 4). Increases in  
 peak  $u_{*,\text{sub}}/u_{*,\text{sub}}^t$  (compared to  $u_*/u_*^t$ ) due to gustiness occur globally homo-  
 geneously, since a uniform  $k$  is used, whereas increases due to  $z_0$  variability  
 730 are greatest at 30–60°S and virtually absent in the plains at 0–20°N (compare  
 with Fig. 4), due to the sensitivity (insensitivity) of the lifting threshold to  $z_0$   
 in rough (smooth) regions. Roughness length variability increases in impor-  
 tance, relative to gustiness, as the critical probability is decreased (see also  
 Fig. 12), as additional southern hemisphere gridpoints become activated via  
 735 substantially lowered thresholds. The relative importance of the two variabili-  
 ties ultimately depends on the critical probabilities, which need not necessarily  
 be the same for each in reality.

The sensitivity of global dust lifting rates to the various sub-grid scale param-  
 eters used is shown in Fig. 12. Total lifting rates increase with decreasing  $k$   
 740 and increasing  $\sigma_g(z_0)$ . Gustiness dominates in these results, though this could  
 be partly due to the handling of  $z_{0,\text{sub}}$  at large mean roughness lengths —  
 $z_{0,\text{sub}}$  values greater than 2 cm can be generated by the sampling method, but  
 no lifting is allowed to occur from these sub-grid points, in order not to move  
 beyond the applicable range of the  $f_{\text{eff}}$  function used (and with the expecta-  
 745 tion that lifting rates ultimately become negligible at large  $z_0$ ). If instead an  
 upper limit is placed on the  $z_{0,\text{sub}}$  values that can be stochastically generated,  
 resulting global mean lifting rates increase more substantially with increas-  
 ing  $\sigma_g(z_0)$ , but the variation due to gustiness remains the larger of the two  
 sensitivities, for the parameter ranges considered.

750 The sensitivity to both types of sub-grid variability increases as the critical  
 probability is reduced, as the tails of the generated pdfs become more thor-

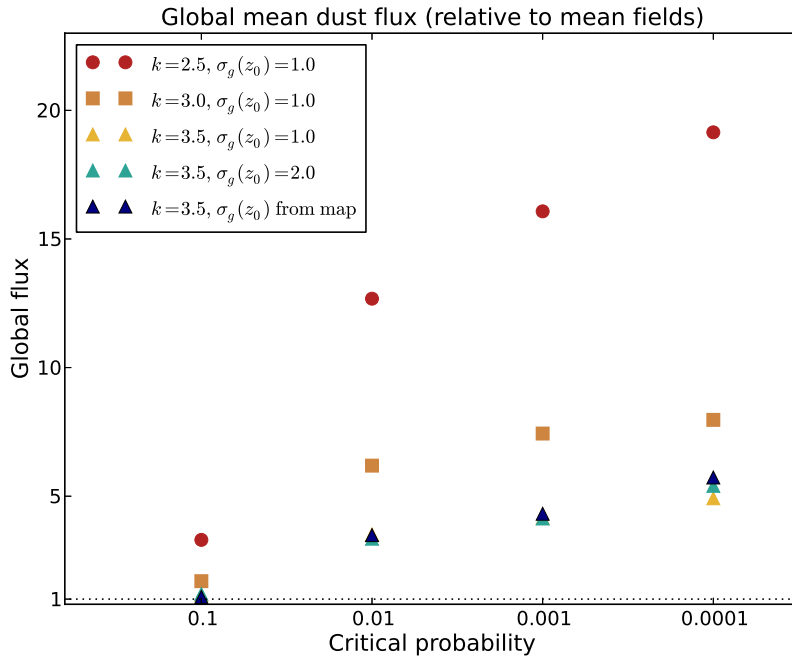

Fig. 12. A summary of global mean dust fluxes (lifting rates) for various combinations of sub-grid variability parameters, allowing lifting only at ice-free gridpoints, with roughness lengths no larger than 2 cm. Lifting rates are expressed relative to the value obtained using mean fields; i.e.  $H_{\text{sub}}/H_{\text{mean}}$  is plotted, with the mean field baseline  $H_{\text{mean}}$  represented by the dotted line at a value of 1.

oughly sampled. Lifting rates increase with decreasing critical probability, as does the sensitivity to  $\sigma_g(z_0)$ , as greater numbers of low- $z_0$  sub-grid points (with low  $u_*^t$ ) are sampled. Increases to total dust lifting rates are substantial, for most plausible choices of parameters, even for relatively high critical probabilities.

Fig. 13 shows the global distribution of annual mean dust lifting, in the form of the saltation flux normalised by the largest value on the planet. With  $k = 3.0$ , a critical probability of 0.001 and  $z_0$  variability based on the high-resolution map, the figure shows that dust lifting is predicted to occur most frequently in

the northern midlatitudes, particularly around Acidalia Planitia ( $\sim 90\text{--}0^\circ\text{W}$ ,  $50\text{--}70^\circ\text{N}$ ), from where flushing storms have been seen to originate most regularly [e.g., Hinson et al., 2012, Wang et al., 2013]. In fact, near Alba Patera, the threshold is exceeded on as many as half of the days of the year, suggest-  
765 ing a near-constant supply of atmospheric dust in this region during parts of the year — provided, that is, that dust remains available at the surface. Lifting rarely occurs, by contrast, in the low-thermal-inertia regions at  $0\text{--}20^\circ\text{N}$ , which Ruff and Christensen [2002] found to possess a relatively thick surface dust layer. This supports an interpretation of these areas as present-day net  
770 dust sinks, from which emission is unlikely. The majority of wind stress dust lifting occurs in midlatitudes (around 90% of the total occurs between  $35^\circ$  and  $55^\circ$ ), for any level of  $z_0$  variability assumed, as shown further in Supplementary Information, Fig. S5, where it is also seen that although increasing  $\sigma_g(z_0)$  increases annual-mean lifting rates globally, rates are decreased at  $15\text{--}$   
775  $45^\circ\text{N}$ , where gridbox-mean lifting conditions are relatively favourable, as a consequence of the  $1/f_{\text{eff}}$  threshold dependence.

A number of southern midlatitude gridpoints — including those near the Hellas and Argyre basins and in other regions where dust storms have been observed [e.g., Martin, 1974, Wang et al., 2013] — are also predicted to produce  
780 dust lifting on multiple occasions during the year. Although the large thresholds in these regions do make simulated dust lifting events rarer than they are in the northern hemisphere, it should be noted that the  $u_*^3$  dependence in the saltation flux formula (equation (6)) means that when the threshold is exceeded at a gridpoint with large  $z_0$  (requiring a large  $u_*$ ), saltation tends  
785 to occur with greater intensity, and so it may be that lifting events in the southern midlatitudes have a greater chance of growing into local or regional

Normalised annual mean saltation flux ( $k=3.0$ ,  $cp=0.001$ ,  $\sigma_g(z_0)=\text{from map}$ )

Fig. 13. Saltation flux (to which dust lifting rate is often set proportional), normalised by the largest value on the map, as calculated from the MCD Climatology scenario, using  $k = 3.0$ , a critical probability of 0.001 and  $z_0$  variability calculated from the high-resolution map. Saltation and dust lifting are permitted to occur only at gridpoints without surface ice cover.

dust storms than the more common but typically less intense northern hemisphere events. (This increase of dust flux with increasing wind speed can be seen in Fig. 10, and in Supplementary Information, Fig. S6.) Also, the ratio of events in the southern to northern hemispheres is seen to increase as the critical probability is decreased, due in particular to the influence of roughness length variability, which is felt more strongly in the southern hemisphere than the northern hemisphere.

The map of predicted dust emission events bears a reasonable resemblance to the map of observed storms shown in Fig. 1, at least in the northern hemisphere. A notable discrepancy is the absence in Fig. 13 of dust lifting in the

southern mid-to-high latitudes at levels comparable to the northern equivalent latitudes. However, these are areas that can become activated by the choice of a lower critical probability, as seen in Fig. 11. Remaining underestimation  
 800 of south polar dust storm frequency may result from an under-resolving of the temperature gradient at the ice cap edge, and therefore of the strength of the baroclinic and sea-breeze flows that are crucial to the generation of these storms.

Fig. 14. Global dust lifting rates at  $30^\circ L_s$  intervals, normalised by the annual totals (left axis), for mean-field (grey) and sub-grid variability (critical probability 0.001) cases ( $k = 2.5$ , red;  $k = 3.5$ , yellow;  $k = 3.5$  with  $z_0$  variability from the high-res map, blue). The dotted line shows the global-mean visible dust opacity, taken from the MCD Climatology scenario, scaled by an arbitrary factor (right axis).

Finally, the seasonal variation in dust lifting activity and its sensitivity to the  
 805 various sub-grid scale parameters is shown in Fig. 14. As expected, in all cases

the global mean vertical dust flux is largest in southern spring/summer; however, in the mean fields case (i.e. when no sub-grid scale variability is considered), the dust lifting in this part of the year is concentrated in a narrow window in southern spring. By contrast, the simulations with sub-grid variability  
810 produce lifting throughout the spring and summer seasons. A double-peaked structure is present in each of these curves over  $L_s = 180\text{--}360^\circ$ , which is consistent with the ‘solstitial pause’ that has been observed to occur in flushing dust storms originating in the northern midlatitudes [Wang et al., 2005] (although the second of these peaks is not detectable in the global-mean opacity  
815 of the MCD dust scenario). Northern midlatitude storms occur with greatest frequency during  $L_s = 220\text{--}250^\circ$  and  $L_s = 320\text{--}330^\circ$  [Wang et al., 2013], and this situation is best reproduced by the strong gustiness case ( $k = 2.5$ ).

However, it is not possible to properly discriminate between the various cases using observed dust loading time series, due to the uncertain component of  
820 this atmospheric dust that is provided by dust devils, not explicitly simulated here. The absence of dust devils is very likely the main reason for the apparent underestimation of dust lifting/loading during northern spring and summer ( $L_s = 30\text{--}150^\circ$ ). Dust flux is increased during this period (as well as in the annual mean) with the inclusion of sub-grid variability, however, suggesting that as well as small-scale ‘conventional’ wind stress lifting events, dust  
825 devil lifting becomes partially captured by the probabilistic representation of the high wind speeds that form in the walls of convective vortices (though a statistical wind speed distribution may not be able to fully account for convective lifting, if the efficiency of the process is enhanced by updrafts in the  
830 core of a vortex [Greeley et al., 2003]). The impact of critical probability on the seasonal cycle (not shown) appears to be small.

To summarise, the inclusion of two forms of sub-grid scale variability in calculations of dust lifting rates increase global mean dust lifting rates substantially — by an order of magnitude, for plausible parameter values — and increase dramatically the number of gridpoints at which the lifting threshold is reached during a typical year. The seasonal distribution of global-mean dust flux is also modified by sub-grid variability, and the resulting patterns of annual mean flux show agreement with known regions of strong dust storm activity.

## 5 Discussion

Several areas of uncertainty remain in the analysis presented here. Firstly, the range of curves presented in Fig. 2 indicates that a degree of uncertainty exists over the variation of the drag partition function with  $z_0$ . While there is good reason to adopt the Raupach et al. [1993] form, the change in lifting thresholds at  $z_0 \sim 1$  cm that would result if  $f_{\text{eff}}$  were altered by only  $\sim 0.1$  could have a significant impact on southern hemisphere dust lifting rates. From the point of view of parameterised MGCM dust lifting, the Raupach/Wooding form as used throughout this paper represents a dependence of lifting rates on  $z_0$  that is large compared to other possible  $f_{\text{eff}}$  forms. As a result, the correction of errors in this form seems likely to shift results in the direction of those obtained with  $\sigma_g(z_0) = 1$ , in which  $z_0$  sub-grid variability had no effect on lifting rates. As Fig. 12 shows, large increases in global dust fluxes over the mean-field case are still present in this scenario, due to the sub-grid scale gustiness that remains, and in fact lifting at more than one site in the southern hemisphere is possible without sub-grid  $z_0$  variability for a critical probability as large as 0.001 (Supplementary Information, Fig. S4). Less variable  $f_{\text{eff}}$  functions

cannot be ruled out on the basis of model lifting rates at present, since  $k$  and critical probability are only loosely constrained.

Secondly, the true sub-grid scale variability of  $z_0$  is not yet known with certainty, due in part to possible satellite artefacts present in the map presented  
860 above. It has been seen that lifting rates in the northern midlatitudes can vary by a factor of two depending on the values for  $\sigma_g(z_0)$  assumed in this region, and southern midlatitudes could likewise see higher lifting rates if larger  $\sigma_g(z_0)$  are present. Also, the true variability in roughness length below the resolution of the map ( $\frac{1}{8}^\circ$ ) and its possible impact on dust lifting on larger scales are  
865 unknown at present.

Some uncertainty remains over the value of  $u_{*s}^t$ , due to the possibility that direct detachment of low-density dust aggregates makes a significant or even dominant contribution to dust fluxes. However, a reduction to  $u_{*s}^t$  of around 30% (as could result if direct detachment were in fact the mechanism respon-  
870 sible for wind stress dust lifting) does not dramatically change the results presented here, as the reduction applies uniformly over the planet (as far as is known currently, at least), and lifting remains extremely rare in the southern hemisphere without sub-grid scale parameterisations (see Fig. 4).

Also, a further limitation of the method, as noted earlier, is that slope winds  
875 and other mesoscale circulations are unaccounted for, except in a globally averaged sense through the Weibull distribution with fixed shape parameter. Both the slope winds themselves and their possible modification of boundary layer turbulence are important processes for dust lifting [Rafkin and Michaels, 2003], but it remains to be determined how, or even if, mesoscale topographic  
880 variation can be adequately represented in a lower-resolution global model.

## 6 Conclusions

We have shown that when aerodynamic roughness lengths are included in the calculation of the threshold for wind stress dust lifting, parameterisation of sub-grid scale variability becomes essential to simulate lifting realistically in an MGCM. If the drag partition function of Raupach et al. [1993] is used,  
885 dust lifting is particularly impaired in the southern midlatitudes, despite this being a well-known source of dust storms of all sizes, from local to global. This shortfall in MGCM wind speeds occurs even with the use of a new surface layer calculation that accounts for varying stability conditions.

890 However, with parameterised sub-grid scale variability, model dust lifting rates can be increased dramatically over the values obtained when using large-scale wind and  $z_0$  fields. A combination of mesoscale and/or turbulent variability in  $z_0$  and near-surface gustiness — each of which contribute significantly — leads to the formation of emission hotspots: small areas in which the majority of dust  
895 lifting activity tends to occur. Capturing the spatial distribution and frequency of occurrence of these hotspots will very likely be crucial for an accurate simulation of Martian dust storms originating in the southern hemisphere, where the effect of sub-grid  $z_0$  variability is felt particularly strongly. Lifting rates are enhanced significantly throughout the year, meaning that sub-grid  
900 scale emission could play an important role in maintaining the background low-opacity haze as well.

The obvious next step is to implement parameterisations for these two sub-grid scale effects in the MGCM, to investigate the effect on dust lifting rates in an interactive simulation in which the important positive radiative feedback on

905 lifting [Newman et al., 2002b] is active. Such methods are increasingly used  
in terrestrial models [e.g., Zender et al., 2003, Cakmur et al., 2004, Menut  
et al., 2013], but may in fact be even more crucial on Mars due to the greater  
temporal variability in emission from key dust sources. To avoid the need  
for stochastic methods as employed here, analytic forms of the probability  
910 distributions used (one of which is the well-known Weibull distribution) should  
be sought, and the saltation flux can then be calculated by integrating under  
the curves, with limits determined by the minimum probability chosen (which  
essentially represents the extent of the increase in spatial resolution that is  
simulated by the parameterisation).

915 In all of the calculations presented, the gustiness shape parameter  $k$  has as-  
sumed a spatially uniform value, yet it has been seen that variation of this pa-  
rameter within its range of possible values can strongly affect lifting rates (Fig.  
12). While values of around 2.5–3.0 are likely to be appropriate for the daytime  
boundary layer in an average sense, gustiness undoubtedly varies both spa-  
920 tially and seasonally. Information on this variation can be obtained from the  
MCD, data for which was produced by an MGCM that includes the thermal  
plume model of Colaitis et al. [2013], which provides estimation of boundary  
layer quantities, namely PBL height and convective updraft velocity, that are  
reliable proxies for turbulent gustiness. Broadly speaking, gustiness (shown,  
925 in the form of convective updraft velocity, in Supplementary Information, Fig.  
S7) is strongest in the summer hemisphere, peaking in the subtropics. In the  
southern hemisphere, the summer maximum stretches right around the 15–  
45° band, and is slightly stronger than the corresponding northern hemisphere  
maximum, which is somewhat confined to the low-albedo, high-topography ar-  
930 eas of Northern Tharsis, Arabia Terra and Elysium. Gustiness should therefore

boost MGCM dust lifting most in the southern subtropics/midlatitudes during spring and summer. This, along with the asymmetric impact of  $z_0$  variability deriving from the  $1/f_{\text{eff}}$  dependence, helps to explain how dust lifting can occur commonly in the southern midlatitudes even in the presence of broadly large  
935 roughness lengths (the contrasting situations in the northern and southern hemispheres are highlighted in Supplementary Information, Fig. S6).

A full sub-grid scale dust lifting parameterisation should include a variable gustiness intensity [as noted by Michaels, 2006], perhaps using a  $k$  parameter diagnosed from boundary layer quantities such as updraft velocity, similar to  
940 the work of Cakmur et al. [2004]. The separation of dust devil and wind stress lifting mechanisms in MGCMs may complicate matters here, as this measure of gustiness, used for wind stress lifting, comes from a parameterisation that is based on LES simulations in which dust devils are partially resolved. Care must be taken to apportion the correct amount of diagnosed gustiness to each  
945 of the wind stress and dust devil mechanisms. Further attention should also be given to better representing gustiness in conditions of strong ambient winds, when a Weibull distribution may not be appropriate [Fenton and Michaels, 2010].

Accurately predicting the wind speed at which dust lifting begins is of crucial  
950 importance for MGCMs, since — at large scale — wind stress dust lifting is subject to a strong positive radiative feedback, such that one synoptic wind event in excess of the threshold can initiate an ultimately substantial dust storm. Capturing the activation point for lifting becomes even more important when considering the hysteresis idea of Kok [2010], which implies that only  
955 a brief excursion of drag velocity beyond the local threshold is needed to maintain saltation and lifting over a significant period of time, so long as the

wind remains above a certain lower threshold, estimated to be as little as 10% of the original activation velocity. There is now observational evidence for the occurrence of this hysteresis in sand mobility on Mars [Yizhaq et al., 2014]. In this context, the LES result seen in Fig. 7 may describe a domain that, integrated over the course of day, is a very active source of dust, even if the ambient wind speed is significantly below the lifting threshold. The peak  $u_*$  values shown typically occur at some point during the afternoon, and the hysteresis effect then suggests that saltation is likely to continue at each of those (numerous) sites throughout the afternoon and into the evening, until the boundary layer stabilises and near-surface winds weaken dramatically. The saltation hysteresis can theoretically apply on a very small spatial scale (Dupont et al. [2013] recently simulated saltation structures a few metres in length), potentially resulting in a steady supply of dust to the atmosphere from several hotspots within a given area, provided that surface dust continues to be available at those sites.

What is less clear is whether or not localised emission such as this is capable of triggering emission from neighbouring areas, via a smaller-scale positive radiative feedback than the one mentioned above [Rafkin, 2009, Spiga et al., 2013], or whether the negative feedback typical of dust devil lifting — in which radiative heating of suspended dust warms and stabilises the boundary layer, inhibiting further lifting — takes precedence at this scale. In any case, without an explicit parameterisation of this feedback (positive or negative), dust storm expansion will apply only at and above the GCM gridbox scale. Even if dust lifting from hotspots does not routinely lead to the growth of dust storms larger than a GCM gridbox, it may be the case that smaller-scale emissions are vital — probably in combination with lifting by dust devils — to

maintaining the background dust haze. MGCMs have in general relied upon parameterised dust devil lifting to provide this dust loading, as modelled wind stress lifting has been much more sporadic and focused only on larger events,  
985 but the use of a sub-grid scale parameterisation has the potential to enable low levels of lifting in places from which no lifting previously occurred, increasing the background dust opacity, while retaining the potential for — under the right conditions — explosive dust storm growth.

## 990 **Acknowledgements**

The authors thank Benjamin Lemonnier, whose internship work provided useful insights into the global-scale dust lifting issues addressed in section 2. We thank Scot Rafkin and an anonymous reviewer for their helpful and constructive comments, which have improved this paper.
