## **Abstract**

Ecological forecasting is difficult but essential, because reactive management results in corrective actions that are often too late to avert significant environmental damage. Here, we appraise different forecasting methods, concluding that simple extrapolation of current trends in state is often inadequate because environmental drivers change in intensity over time and new drivers emerge. However, statistical models incorporating relationships with drivers simply offset the prediction problem, requiring us to forecast how the drivers will themselves change over time. Some authors approach this problem by focusing in detail on a single driver, whilst others use ‘storyline’ scenarios, which consider projected changes in a wide range of different drivers. We explain why both approaches are problematic and identify a compromise to model key drivers and interactions along with possible response options to help inform environmental management. We also highlight the crucial role of validation of forecasts using independent data. Although these issues are relevant for all types of ecological forecasting, we provide examples based on forecasts for populations of UK butterflies. We show how a high goodness-of-fit for models used to calibrate data is not sufficient for good forecasting. Long-term biological recording schemes rather than experiment will often provide data for ecological forecasting and validation because these schemes allow capture of landscape-scale land use effects and their interactions with other drivers.

Prediction – predictive modelling - environmental drivers - weather - density dependence – butterfly monitoring

## Why attempt to forecast?

*“Two very different masters teach [man] his lesson: experience and foresight. Experience teaches efficiently but brutally.....I should prefer, in so far as possible, to replace this rude teacher with a more gentle one: foresight” Frédéric Bastiat, 1848*

Predicting the future is notoriously difficult. Many great thinkers have tried, and spectacularly failed. For example, in 1895, Lord Kelvin, a Scottish mathematician and physicist is famous to have forthrightly stated to have “not the smallest molecule of faith” in aerial flight beyond ballooning, just eight years before the Wright brothers put together the first successful fixed wing aeroplane. Similarly, in a 1961 interview T.A.M. Craven the US Federal Communications commissioner of the time famously predicted: “*There is practically no chance communications space satellites will be used to provide better telephone, telegraph, television or radio service inside the United States*”. Only a few years later, satellites were in space performing all the above services. So perhaps it is best to keep our heads below the parapet and not make predictions which, in retrospect, appear foolhardy?

In many fields of research, however forecasting- prediction of future states based on past events, is essential. Forecasts allow us to alter our behaviours in response to likely realisations of future events in order to reduce costs or maximise benefits. In the environmental sciences, for example, weather forecasts, which have improved greatly in recent decades, provide huge overall benefit to society. In the longer term, climatological forecasts provide critical guidance to help steer our socioeconomic systems away from unsustainable and self-destructive pathways. There are still many dangers of ‘getting it wrong’ (as UK weather forecaster Michael Fish famously did in 1987 when he told people not to worry about a hurricane just hours before winds reaching 122 mph hit the Southern England). However, hiding away from making forecasts is often not an option, because it leads to greater overall costs than making predictions that are occasionally wrong.

In ecological science, forecasting is also essential. It forms part of a set of tools, including horizon scanning (Roy et al., 2014; Sutherland et al., 2008) and risk assessments (Mace et al., 2008; Thomas

et al., 2011), that enable us to anticipate future changes and respond appropriately. Reactive responses to new environmental impacts caused through changes in socioeconomic systems (e.g. adoption of new technologies), may often be too late to avert significant environmental damage. For example, the pesticide DDT caused substantial losses to bird populations before it was finally banned (Pimentel, 2005; US Environmental Protection Agency, 1975). In Europe, agricultural subsidies, paid to farmers to increase food production and security, have led increased to loss of natural or semi-natural habitats, which have been a primary cause of European biodiversity decline (Inger et al., 2014; UK NEA, 2011; Van Swaay et al., 2010). The responses to mitigate these environmental impacts and others have mostly been reactive, in that they occurred only when damage had begun. In contrast, risk assessments based on experimental evidence of pesticide toxicity along with ecological modelling to predict potential impacts on species populations at larger spatial scales could have enabled proactive preventative measures to be taken.

In many cases, due to slow decision making and policy implementation, significant damage is done before ameliorative actions are in place. The slow progress to develop co-operative global actions to halt climate change may turn out to be another such example, with potentially very large consequences for the environment and society (IPCC, 2014). In other cases, policy responses may be rapidly formulated based on hastily gathered evidence. In both situations there are strong benefits of early evidence gathering, ecological modelling and risk assessment to inform timely and evidence-based policy decisions. It should be recognised, however, that it will never be possible to foresee all ecological problems and some environmental management will have to be reactive.

In understanding the chain of events leading to environmental impacts, the ‘DPSIR’ (driver, pressure, state, impact, response) framework can be useful and is widely used (Figure 1; European Environment Agency, 2007; United States Environmental Protection Agency, 2014). This framework illustrates the causal links between the ultimate drivers of environmental degradation (e.g. population growth), the proximate pressures (e.g. food production) on the state of the environment (e.g. biodiversity) and their final impacts on humans (e.g. loss of well-being through degradation of ecosystem services which are underpinned by biodiversity). Societal responses may then be put in

place to ameliorate these impacts. These may tackle the ultimate drivers (e.g. campaigns to educate on the environmental impacts of population growth) or proximate pressures (e.g. sustainable food production) or try to address the state of the environment directly without addressing drivers and pressures (e.g. improving the quality of semi-natural habitats that are known to support a high diversity of specialised species). However, the key problem with the DPSIR framework is that following it sequentially, as described above, amounts to reactive management practices which are often too late to avert significant environmental damage. It would be far better, as the quotation at the start of this article suggests, to be able to look forwards and predict possible impacts so that they can be averted. Thus, there is great need to forecast the impact of environmental drivers and pressures on the state of the environment.

### **Extrapolation of trends- the simplest way to forecast**

By far the most straightforward way of predicting future states of the environment is to identify past trends in state over time and extrapolate these forwards using some kind of statistical model. For example the Global Biodiversity Outlook 4 report (GBO-4; Secretariat of the Convention on Biological Diversity, 2014) includes indicator-based extrapolations of recent and current trends to 2020. The report states “The assessment of progress towards the Aichi Biodiversity Targets in GBO-4 is informed by recent trends in 55 biodiversity-related indicators and their statistical extrapolation to 2020”. Extrapolation can sometimes work well. For example, as shown in Figure 2 (panels a and b) for the butterfly species *Aphantopus hyperantus*, a linear trend fitted to a national population index from 1980-2000 does a reasonable job at predicting abundances for the subsequent 13 years (mean absolute error = 0.076). In other cases, extrapolation does a poor job at predicting the future state of an environmental variable. This might be due to several reasons: 1) there is substantial error in our measurement of the system state, 2) our statistical model is inadequate (e.g. fitting a linear trend when there is significant curvature), 3) there is a high degree of short-term variability in the system state about some trend (sometimes called ‘stochasticity’), or 4) the ‘rules’ that govern the system state change over time (i.e. the drivers and pressures change). Examples of unsuccessful extrapolations are

shown for the butterfly species *Euphydryas aurinia* (Figure 2c and d; mean absolute error = 0.217) and *Hesperia comma* (Figure 2e and f; mean absolute error = 0.421). In these cases, neither linear models, nor second or third order polynomials, fitted to 1980-2000 data are able to adequately predict population indices in the subsequent 13 years.

Why are extrapolations so poor for these species? The population indices are collated from a reasonably large number of sites (mean number of sites per year for each species  $\pm$  standard error: *A. hyperantus* =  $324.7 \pm 32.3$ ; *E. Aurinia* =  $62.5 \pm 5.24$ ; *Hesperia comma* =  $25.8 \pm 1.9$ ) and so any measurement errors should cancel each other out and have negligible effect. With regards to the statistical model, for each species three different models were compared (linear and second and third order polynomials) and in both cases the linear model was the best fit to the 1980-2000 data. In the case of *E. aurinia* (Figure 2c & d), the interannual population variability is very large, and although the linear model is a better fit compared to the models with curvature, the predicted values of the population index are often poor estimates. This may be problematic if accurate annual predictions are necessary; for example, if we were aiming to predict the abundance of a pest species in order to inform prophylactic pesticide application. It may be possible to predict some of the interannual variability in population abundances with models incorporating the factors that drive population dynamics (see next section), but there will often remain variation left over that we are unable to explain (e.g. resulting from demographic stochasticity). Despite this, it is notable that errors in our predictions do not necessarily get markedly worse the further on in time a prediction is made (e.g. Figure 2d; regression of absolute error by year:  $F_{1,11}: 0.42$   $p = 0.53$ ). Therefore, if accurate annual predictions are not so important, but we are rather more interested in broad forecasts of future population trends, e.g. to allocate conservation funding appropriately, then large interannual population variability may not be such an issue (Roy et al., 2001). The exception here would be for special cases where stochasticity itself changes over time (e.g. changing environmentally-induced stochasticity as populations move towards- or away- from the edge of their fundamental niche space as the climate changes; Oliver et al., 2012a; Oliver et al., 2014)

Our third example (*Hesperia comma*; Figure 2e and f), is also a poor forecast from extrapolation, but in this case the interannual population variability is relatively low (Bennie et al., 2013). Instead, the linear trend, which is a good fit to the population indices between 1980 and 2000, is a poor fit to the data from 2001 onwards, with the predictions getting noticeably worse the further ahead we try to predict (Figure 2f; regression of absolute error by year:  $F_{1,11}: 18.2$   $p = 0.001$ ). The population trajectory has changed direction, presumably because density dependent processes are beginning to operate or the primary drivers which affect populations (e.g. climate, habitat quality, habitat extent) have changed over the duration of the monitoring period. This is a critical problem for extrapolation methods, because by using data only on the system state we cannot account for changes in drivers. Instead, they are assumed to be constant; an assumption that is very often contravened. For example, Mason *et al.* (this volume) consider rates of distribution change (northern range margin shift) in four different animal groups over two time intervals (from 1970-2010) and find that rates of change in the first time interval are poor predictors of rates of change in the subsequent time interval. What are these changes in drivers that underlie species' responses?

The UK National Ecosystem Assessment (UK NEA, 2011) was the first comprehensive review of drivers of change in biodiversity and other ecosystem services. It assessed the historic impact of drivers, but also their expected future impact. It is notable that the magnitude of drivers often changes over time. For example, habitat loss and pollution have been the primary causes of biodiversity loss in the UK over the last century, but the impacts of these drivers are expected to lessen, with climate change and invasive species becoming the major new drivers of change (UK NEA, 2011). Similar patterns are likely to be occurring across other heavily modified temperate landscapes. For example, Carvalheiro *et al.* (2013) suggest that pollinator declines in a number of northwest European countries may have slowed, probably due to a peak in the conversion of land use to intensive agriculture. In addition to changes in the magnitude of existing drivers, new drivers may emerge with the advent of new technologies (August, this volume). For example, a recent horizon scanning exercise by Sutherland *et al.* (2008) identified nanotechnology and geoengineering as fields with a large potential to impact biodiversity. Finally, drivers of change also interact in their environmental impacts, leading

to non-linearity in responses (Brook, Sodhi & Bradshaw, 2008). For example, climate and land use change can interact on biodiversity through a wide range of mechanisms affecting processes from demography to metapopulation structure and community interactions (Oliver & Morecroft, 2014). All these changes in drivers mean that simple extrapolations of system state are often a poor method of forecasting, especially over longer timescales. Instead, statistical models are needed which can incorporate the impact of drivers and how these may change in the future.

### **Forecasting changes in drivers and pressures**

In order to incorporate the impact of pressures on the state of environmental systems we need to understand their functional relationships (e.g. what is the relationship between weather variables and a species' population size), and also anticipate how pressures are likely to change in the future (e.g. what will future weather be like under climate change). Effects may be direct (e.g. weather impacts on demographic rates) or indirect (e.g. mediated through impacts on other species which interact with the focal species). The former task of understanding causal relationships can be achieved through experimentation (e.g. Tilman et al., 1994) or through observation of 'natural experiments' (i.e. using long term monitoring of system state and relating this to naturally occurring changes in drivers and pressures; Baker et al., 2012; Eglington & Pearce-Higgins, 2012; Roy et al., 2001). Both these methods are costly and time consuming, but the experimental designs (e.g. split-plot field experiments, long term monitoring networks) and statistical analysis techniques needed (e.g. multivariate regressions, hierarchical mixed modelling and structural equation modelling) are well versed in the ecological sciences. In contrast, the latter task of anticipating future changes in drivers and pressures is more difficult and less practiced. One technique would be to use extrapolative techniques to predict how drivers and pressures may change based on past temporal trends. For example the GBO-4 report (Secretariat of the Convention on Biological Diversity, 2014) uses extrapolations of trends in human population size, gross domestic product, intensity of resource use, agricultural subsidies and surplus nitrogen in the environment. However, the problems with extrapolation of the state of the environment outlined above also hold true for extrapolation of

pressures affecting system state – the pressures themselves are affected by multiple other factors (drivers) which may have non-linear trends over time. These more proximate drivers are themselves affected by other drivers, and so on. For example, nitrogen deposition is affected by both the cost of petrochemical fertilisers and price of crops in the world market, these factors themselves are affected by other more ultimate drivers such as population growth and development of alternative resource extraction and food production technologies. Suddenly we are faced with an enormous task: to forecast how a given pressure might change we need to understand the whole chain of causality affecting that pressure (the ‘infinite regress of drivers’ dilemma). Much ecological science, and indeed science in general, has tended to be reductionist in its approach, focussing on specific causal relationships, but more systematic ways of thinking are evident in ancient eastern world views (e.g. the Buddhist concept of ‘Pratītyasamutpāda’) which strongly emphasises the interdependency of entities and multiple causal linkages between them, and also feature in ‘systems ecology’ approaches (Odum, 1983; Schellnhuber, 1999; Evans et al., 2013). Yet, there are clear practical limitations to understanding changes to specific pressures by tracing causal links across the entire socio-ecological-economic system; effectively, this relies on a statistical model of the entire world!

At this point, one might be tempted to throw in the towel and give up trying to forecast future environmental states. However, returning to our original reason for attempting forecasting – that without it we rely on reactive management which is often too late to avert significant environmental damage – we are reminded that forecasting, although difficult, is very necessary. What is needed is a practical way forward that still remains as rigorous as possible. Pragmatic approaches to the problem so far have tended to either focus on one specific chain of causality affecting the environmental state (e.g. how climate change will affect local temperatures and how these will affect species populations; Thomas et al., 2004), or to adopt a ‘storyline’ scenario approach where various possible socio-economic scenarios are described and then a deliberative approach used to translate how changes in more ultimate drivers (such as population size, climate, new technologies) will impact on proximate pressures that affect environmental states. This latter approach is adopted by the Millennium Ecosystem Assessment (2005) and also in UK National Ecosystem Assessment

(2011) in order to explore how different socioeconomic scenarios might affect the state of the environment and the ecosystem services it provides. Both approaches have advantages but also some key problems.

The first approach which focuses on a single ‘chain’ of causality can afford more detailed quantitative analysis, but because this approach is more reductionist it ignores the importance of other interacting drivers and pressures on the system state. This may be warranted where there is good evidence for an overwhelmingly strong influence of one driver, which explains a large proportion of variance in the system state. For example, figure 3 illustrates predictive correlative models for the abundance of three butterfly species, whose population dynamics are driven by annual weather and density dependence to varying extents. The first species, *Melanargia galathea* (panels a and b), shows a reasonably good fit between predicted and observed abundance in the model calibration period ( $R^2 = 0.68$  with density dependence effects incorporated in models,  $R^2 = 0.53$  without), and also in the model validation (mean absolute error [MAE] = 0.14-0.15) and the ‘forecasting’ periods (MAE = 0.10-0.11). In contrast, for the species *Celastrina argiolus* (panels c and d) even though goodness-of-fit for the model incorporating density dependence is greater than the one without ( $R^2 = 0.72$  compared with 0.54) and there is little apparent difference in model fit in the validation period (MAE = 0.21 compared with 0.17), it turns out that the simpler model without density dependence performs slightly better in the forecasting period (MAE = 0.29 compared with 0.4). Interestingly, this is a species in which the population dynamics are anecdotally thought to be driven by parasitoids causing to be what look like 6-8 year cycles (Revels, 2006). In fact, panel d shows that a model with just three weather variables (spring rainfall in the current year, and autumn temperatures in the two previous years) can predict the population dynamics reasonably well. In other cases, it may be much less easy to predict abundances using weather variables. This can be despite an apparent good fit of models in the calibration period. For example, the species *Lasiommata megara* (panels e and f) has a model with a high goodness-of-fit between predicted and observed abundance in the model calibration period ( $R^2 = 0.83$  for the model also incorporating density dependence effects; panel e), yet forecasts are very poor (actually predicting local extinction by 2004). In this case, it would be clear from validation that

the model without density dependence is actually a better predictor (MAE = 0.39 compared to 3.96) despite the markedly lower goodness-of-fit in the calibration period ( $R^2 = 0.13$ ). This might be because density dependent processes are changing over time (e.g. due to changes in the parasites or pathogens that drive density dependence). Importantly, in ‘free running’ predictions (where abundance is sequentially estimated as a function of abundance the previous year) any errors in modelled density dependence relationships quickly accumulate, leading to very large prediction errors in just a few years.

These examples highlight the inherent difficulties of ecological forecasting. A good fit of models in calibration periods is not a sufficient indicator of good predictive ability, and only after successful validation should models be used for prediction. In practice, prediction errors would be larger than shown here because true forecasts would be based on estimates of weather from downscaled climate models, rather than the observed weather variables used here. Even with observed weather data and even though ectothermic butterflies tend to be highly responsive to weather, these correlative statistical models based on large datasets still only had limited predictive ability. Relationships with density and weather could change over time (e.g. due to changes in the factors causing density dependence, such as the aggregation of natural enemies, and due to evolutionary adaptation of populations to changes in climate). In addition, other drivers beyond climate are likely to be important in driving population changes (e.g. habitat quality).

The second ‘storyline’ scenario approach to predicting the impacts of environmental change has the advantage of considering many different interacting drivers and pressures. The scenarios generated are not necessarily taken as predictions of the future but, rather, delineate a wide range of possible outcomes in the parameter space of multiple drivers and pressures. The major disadvantage of this approach, however, is that the large number of causal relationships between multiple drivers and environmental state, including interaction effects, means that predictive models are nearly impossible to parameterise empirically; instead, these rely on expert opinion, or a combination of both such as Bayesian belief networks (Haines-Young et al., 2011). The other key problem is that the models are so complex that any resulting differences in environmental state between scenarios are

difficult to attribute back to specific drivers. For example, the UK National Ecosystem Assessment includes various storyline scenarios such as ‘Nature at Work’ and the ‘National Security’ that differ greatly in predicted ecosystem services (Haines-Young et al., 2011; Bateman et al., 2011). However, it is impossible to say whether this is due to differences in protected area coverage, the extent of several different cover types, or due to varying impacts of climate change, which all differ between the scenarios.

For successful ecological forecasting, it is necessary to find a practical compromise between the two extremes of quantitative reductionism (which ignores multiple interacting drivers) and a fully systemic approach (which is too complex to parameterise and to attribute final changes in environment state). Below we suggest a practical middle ground which may potentially reconcile these extreme approaches.

### **Key driver and response-test scenarios**

One possible middle ground solution for ecological forecasting lies in identifying the minimum number of key drivers or pressures that are demonstrated (through empirical analysis or expert opinion) to strongly influence an environmental state variable over the time frame of interest. This avoids the excessive complexity of considering all drivers in models, but also extends beyond the simplistic view of considering change in one driver in isolation. The suite of drivers considered may already be operating or they may be potential new drivers. In addition, interactions between drivers should also be considered where relevant. In order to make our ecological forecast models of applied use, we should also consider alternative possible ‘response’ options (i.e. management solutions). For example, in considering the possible impact of climate change on populations of a species we might consider a range of land use scenarios which, through the existence of land-use climate interactions, potentially allow the amelioration of climate change impacts (i.e. ‘adaptation’ measures).

### **Which statistical method to use?**

Thus far, we have broadly considered ecological forecasting methods in terms of the merits of trend extrapolation techniques versus multivariate models which incorporate changes in drivers and pressures. The latter method is recommended with a pragmatic approach to selecting key drivers and incorporating response options. However, we have so far discussed specific statistical methods only fleetingly. A wide range of statistical methods are relevant to this problem, ranging from simple correlative models to highly complex individual based ‘process’ models. Table 1 gives examples of a range of methods which span a continuum of complexity and input data requirements (also see Sutherland, 2006). Ecological modellers often specialise on some part of this model continuum. For example, fitting correlative models across many species (macroecology) versus developing detailed individual based models for specific species (process-based modelling). Neither approach is right or wrong and each has its advantages and disadvantages. Detailed process-based models are often highly complex, aiming to incorporate many biological processes (e.g. demographic parameters which vary in different environments, interspecific interactions and evolutionary processes). As such, they are more biologically realistic representations with the potential for more accurate predictions. However, the cost of this complexity is that many more parameters need to be estimated, requiring significantly more data to calibrate models. When one considers the total numbers of species that one could potentially be interested in for conservation ecology (e.g. c. 70,000 in the UK, which is a relatively species-poor country; UK Species Inventory, 2014; Gurney et al., in press), then it becomes clear that such data-hungry models are impractical, unless they can be shown to produce general responses that are representative of many other species. At the other end of the spectrum, extrapolative techniques or simple correlative models, which consider species’ responses to a single driver, may be too simplistic and ignore key interactions between drivers. This lack of mechanistic understanding behind species responses can mean that predictions are inaccurate if drivers change in non-linear ways over time. To identify a practical way forward, again, the theory of the ‘middle way’ may help up to reconcile these extremes. Methods are needed which balance the complexity needed to make robust predictions with the feasibility of model parameterisation given data availability. The methods in the middle rows of Table 1 are most likely to achieve this balance and produce reliable forecasts of environmental change

for many species in order to inform conservation responses. These include phenomenological models and mechanistic models. In practice, successful models may contain a combination of both the above approaches, with well known biological processes specified by mechanistic relationships but with flexibility for unknown relationships to be estimated from the observed data (Dormann et al., 2012).

### **Rigour in predictive modelling**

In addition to selecting the most appropriate statistical modelling framework, the modelling approach must be as rigorous as possible, in order to ensure accurate predictions. This is especially important if our forecasts are used as evidence to implement prophylactic management to avert environmental damage. Such management options may have substantial costs and therefore need to be well evidenced. For example, setting aside semi-natural habitats to maintain pollinating insects under climate change has costs in terms of reduced land for cropping and so strong evidence is needed to convince stakeholders of the best land management solution.

To select the most appropriate statistical model, the goodness-of-fit to historic data of alternative models is usually assessed. But this criterion alone can lead to over-parameterised models that are poor at predicting future environmental states. Instead, model validation is necessary using data independent of that used for model fitting. For example, Figure 3 shows how 20 years of historic monitoring data can be split into 15 years for model fitting (of abundance changes in relation to weather variables) and five for model testing. This can prevent overfitting and allow better predictions of subsequent abundance (demonstrated here by hindcasting to the most recent 13 years of data). In the absence of time series data, space-for-time substitutions are the next best option to validate models; for example, using the model fitted to data in one area to predict environmental state in a different area. There can be problems with this approach, however, as a number of different correlated variables may change across spatial gradients (Isaac et al., 2010; White & Kerr, 2006).

Despite the importance of validation, yet because of its difficulty, a number of current modelling frameworks are being used to predict future environmental states with limited validation of the models. This is especially evident in the recently emerging field of ecosystem service modelling (e.g.

Bateman et al., 2013; Nelson et al., 2009; Nelson et al., 2010; UK NEA, 2011). There is clearly a danger in implementing management options with limited evidence. Under such circumstances an adaptive management approach is highly appropriate, where the management actions predicted as most suitable are taken but with regular monitoring to assess their effectiveness. Past environmental policies have often tended to be inflexible, however, leading to ‘lock-in’ to a set of options with little consideration of adaptive management. For example, agri-environment schemes put in place in the UK to prevent biodiversity declines in agricultural landscapes were based on synthesis of the evidence base for the effectiveness of different management options. Over £400M per year is spent on these schemes in England (Natural England, 2009), yet the budget to monitor the effectiveness of these schemes (and validate the predictions of their effectiveness) is a very small percentage of this (less than 1%). With this and many other environmental policies, when seen in the context of ecological forecasting and its validation, there is a strong argument for rebalancing spending on action versus monitoring and analysis.

### **Data for predictive models and the importance of biological recording**

As discussed above, a wide range of environmental drivers can impact species. Models of these causal relationships (and the potential interactions between drivers) will necessarily have several estimated parameters, even when reduced to the subset of drivers with the largest impacts. Therefore, substantial datasets on species populations and measured values of drivers are needed for model calibration and validation. These data may come from mesocosm or field experiments, or ‘natural experiments’ comprising the monitoring of natural populations over broad environmental gradients. Mesocosm experiments consider responses to a limited range of manipulated variables under controlled conditions. They are useful for testing theory and stimulating further research (Benton et al., 2007), although the ability of these systems to produce species responses similar to those in the real world is questionable (Carpenter, 1996). Field experiments comprise a selected range of treatments to consider the effects of different drivers but at a larger scale and in more realistic settings subject to ‘noise’ from other unmeasured environmental drivers (Carpenter, 1998). Experimental manipulation

is the ideal way to test ecological theories (including those pertaining to relationships between drivers and population responses), but field experiments are very time consuming and expensive. In addition, even in large-scale experiments, the limited spatial and temporal scale means that patterns operating at large scales may be missed (e.g. Wiens, Rotenberry & Van Horne, 1986). The alternative to designed experiments is to exploit natural environmental gradients and large-scale perturbations (Carpenter, 1990). This requires monitoring of species responses, ideally with high levels of spatial and temporal replication which are necessary to maintain statistical power in the face of combined variability across wide range of environmental variables. Examples of such large-scale monitoring include the collection of biological records (georeferenced records of species presences), such as those held by the Biological Records Centre (Pocock *et al.*, this volume), the broad utility of which are demonstrated by the articles within this issue (Chapman *et al.*, this volume; Gillingham *et al.*, this volume; Mason *et al.*, this volume; Powney *et al.* this volume; Roy, this volume; Roy *et al.*, this volume; Purse and Golding, this volume; Sutherland *et al.*, this volume). Abundance data such as those represented in species monitoring schemes (e.g. the UK Butterfly Monitoring Scheme data used in this paper), are even more useful in allowing forecasts of abundance rather than just species presence, although there is evidence that distribution data can predict abundance to a limited degree (Elmendorf & Moore, 2008; Oliver *et al.*, 2012b; VanDerWal *et al.*, 2009). Monitoring data provide a crucial resource for ecological forecasting because of the large spatial and temporal extent that they can cover. This is facilitated by the use of trained volunteers that help to reduce the total costs of monitoring schemes. Experimental approaches, although much better for well-controlled tests of theory and testing management techniques, are often too limited in their spatial coverage to adequately inform ecological forecasts, at least beyond the location of the experiment. For example, species responses to weather conditions (a major driver of population variation across most species) can be assessed using data from national monitoring schemes (Eglington & Pearce-Higgins, 2012; Roy *et al.*, 2001; WallisDeVries, Baxter & Van Vliet, 2011). In addition, because weather effects are modified by topography and habitat type not just at the local scale but also by the structural composition of surrounding landscapes (Oliver *et al.*, 2010; Oliver, Brereton & Roy, 2012), then it is

necessary to empirically model these effects in order to make general forecasts beyond the responses of a single site. Fortunately, a number of countries have well established species monitoring schemes (e.g. the long history of natural history recording in Britain), and protocols for a number of currently unstudied species groups and new monitoring schemes in other countries are currently under development. International initiatives are also at work to synthesise monitoring data (e.g. the global Biodiversity Observation Network, GEOBON).

## **Conclusion**

Overall, this review has highlighted the necessity of ecological forecasting in order to avert environmental damages which would occur under a solely reactive management approach. Extrapolating from historic environmental states will often be unsuccessful because drivers and pressures themselves change in non-linear ways and interact in their impact. New pressures on systems, such as those from emerging technologies, may also arise. The complexity of causal pathways between drivers, pressures and environmental state is effectively endless, so a pragmatic approach is needed to focus on a subset of pathways that have the greatest impact on system state. Additionally, incorporating possible response options in our models will allow us to assess the effectiveness of potential solutions to environmental damage. In terms of modelling techniques, a compromise between complexity (and potential biological realism) and feasibility given data availability will be necessary, but there is also a key importance in validating models to ensure that forecasts can be made with reasonable confidence. Although ecological forecasting is very difficult, it is also highly necessary. Much ecological science has tended to focus on understanding current and historic patterns and trends. However, there is a clear need to step out of our comfort zones and develop ecological forecasts in order to inform environmental management effectively.

## **Acknowledgements**

We are grateful to the UK Butterfly Monitoring Scheme (UKBMS) volunteers and scheme co-ordinators for providing the data used in the forecasting examples in this paper. The UKBMS is funded funding by a multi-agency consortium led by the Department for Environmental Food and Rural Affairs, and including the Natural Resources Wales, Natural England, Forestry Commission, and Scottish Natural Heritage. The Biological Record Centre, of which the UKBMS is part, receives support from the Joint Nature Conservation Committee and the Natural Environment Research Council (via National Capability funding to the Centre for Ecology & Hydrology, project NEC04932). We thank Mike Morecroft and Chris Preston for helpful comments which improved this manuscript.

## Figure legends

**Figure 1**, The ‘DPSIR’ framework with an example of drivers, pressures, state and impacts in capitalised font.

**Figure 2**, Extrapolations of population abundance for three butterfly species: The Ringlet *Aphantopus hyperantus* (panels a & b), Marsh Fritillary *Euphydryas aurinia* (panels c & d) and Silver Spotted Skipper *Hesperia comma* (panels e & f). Left hand panels show the UK national log collated index of abundance with a linear trend fitted to the data from 1980-2000 and used to predict abundance from 2001 onwards (open circles). The right hand panel shows the absolute difference between predicted and observed values.

**Figure 3**, Observed (filled circles) and predicted annual abundance for three butterfly species: *Melanargia galathea* (panels a and b), *Celastrina argiolus* (panels c and d), and *Lasiommata megara* (panels e and f). Left hand panels show multiple regression models fitted to log abundance indices in a model calibration period from 1980-1995. The models include the three most important weather variables for each species (Palmer *et al.*, submitted), and the previous years’ density as explanatory variables. Each model is then used for hindcasting abundances in the calibration period using the observed density the previous year along with the observed weather variables (open circles). The goodness-of-fit ( $R^2$ ) of the model is shown in the top left corner of each panel. Also shown are free running abundance predictions for a validation period from 1995-2000 (open triangles) and a ‘forecasting’ period from 2000-2012 (crosses). The mean absolute error of predictions is given in the top right hand corner of each panel. The right hand panels b,d, and f are similar but the models are fitted to only the three most important weather variables for the species without a density dependence term.

**Table 1,** Different statistical methods for ecological forecasting

<b>Forecasting method</b>	<b>Description</b>	<b>Example</b>
<b>Extrapolation</b>	Descriptive statistical model of trend in system state variable	Predicting species geographic range margins from past rates of change
<b>Simple correlative models</b>	Statistical relationship between driver or pressure variable(s) and system state variable	Predicting species distribution from relationships between occurrence and climate variables
<b>Phenomenological models*</b>	Statistical relationship between driver or pressure and intermediate demographic processes which combine to determine state	Predicting species abundance from climate impacts on population growth, mortality and dispersal
<b>Mechanistic model *</b>	Relationship between driver or pressure and intermediate demographic processes based on prior biological understanding	Predicting species abundance under climate changes based on physiological relationships between development rates and lethal temperatures
<b>Individual-based models</b>	Behavioural rules used to model individual decisions, often in combination with phenomenological components relating to demography	Predicting impacts of climate change on individual movements and how this scales up to species range margin shifts

\*Note that this dichotomy is not strict and some models combine both phenomenological and mechanistic components
