Abstract

Background

We have previously shown that the selective serotonergic re-uptake inhibitor, citalopram, reduces the neural response to reward and aversion in healthy volunteers. We suggest that this inhibitory effect might underlie the emotional blunting reported by patients on these medications. Bupropion is a dopaminergic and noradrenergic re-uptake inhibitor and has been suggested to have more therapeutic effects on reward-related deficits. However, how bupropion affects the neural responses to reward and aversion is unclear.

Methods

17 healthy volunteers (9 female, 8 male) received 7 days of bupropion (150 mg/day) and 7 days of placebo treatment, in a double-blind crossover design. Our functional Magnetic Resonance Imaging task consisted of 3 phases; an anticipatory phase (pleasant or unpleasant cue), an effort phase (button presses to achieve a pleasant taste or to avoid an unpleasant taste) and a consummatory phase (pleasant or unpleasant tastes). Volunteers also rated wanting, pleasantness and intensity of the tastes.

Results

Relative to placebo, bupropion increased activity during the anticipation phase in the ventral medial prefrontal cortex (vmPFC) and caudate. During the effort phase, bupropion increased activity in the vmPFC, striatum, dorsal anterior cingulate cortex and primary motor cortex. Bupropion also increased medial orbitofrontal cortex, amygdala and ventral striatum activity during the consummatory phase.

Conclusions

Our results are the first to show that bupropion can increase neural responses during the anticipation, effort and consummation of rewarding and aversive stimuli. This supports the notion that bupropion might be beneficial for depressed patients with reward-related deficits and blunted affect.

Introduction

Defined as the inability to experience pleasure from normally rewarding stimuli, anhedonia is one of the two main diagnostic criteria for depression. Studies examining the effects of the current antidepressant treatments, selective serotonin reuptake inhibitors (SSRI), have found that the symptom of anhedonia is not effectively treated, which in turn predicts a longer time to recovery and fewer depression-free days (Shelton and Tomarken, 2001, Spijker *et al.*, 2001). Further, there are reports that SSRIs can in fact contribute to emotional blunting in patients, where experiences, both positive and negative, are flattened (Price *et al.*, 2009). It has therefore been suggested that different pharmacological targets might be needed to adequately treat anhedonia and apathy in depression (Dunlop and Nemeroff, 2007, McCabe *et al.*, 2009a, Nutt *et al.*, 2007)

Anhedonia is multi-dimensional, with the anticipatory (appetitive/wanting) and consummatory (hedonic/liking) dimensions being the most widely examined in depression (Frey *et al.*, 2015, McCabe, 2014, Nutt *et al.*, 2007). Affective neuroscience studies of reward ‘wanting’ and ‘liking’ have suggested that these psychological processes map onto distinct brain reward systems. For example, studies of pleasure identify hedonic impact in the ventral pallidum, nucleus accumbens and orbitofrontal cortex (OFC) (Berridge and Kringelbach, 2008, Peciña, 2008, Peciña and Berridge, 2005, Peciña *et al.*, 2006, Smith and Berridge, 2005, Wheeler and Carelli, 2006), whereas “wanting” or incentive salience is mediated by neural systems that include mesolimbic dopamine projections from the ventral tegmental area to the ventral striatum (Berridge, 2007, Berridge *et al.*, 2009). Further, dopamine has been shown to be involved in the learning about rewards in prefrontal cortical regions, such as the anterior cingulate cortex and the OFC (Dayan and Balleine, 2002).

Examining the neural correlates of anhedonia in depression, studies have found reduced anticipatory and consummatory responses to reward in the ventral and dorsal striatum and the anterior cingulate (Epstein *et al.*, 2006, Forbes *et al.*, 2009, Pizzagalli *et al.*, 2009a, Smoski *et al.*, 2009, Ubl *et al.*, 2015, Zhang *et al.*, 2013), with increased activity to the anticipation of gains in the anterior cingulate (Knutson *et al.*, 2008). Unfortunately few studies investigate the separate dimensions of anhedonia within the same task, which may account for overlapping regions activated across studies in depression (Treadway and Zald, 2011, Zhang *et al.*, 2013). Recent behavioural evidence suggests impairments in the amount of effort expended for rewards

in depressed patients (Sherdell *et al.*, 2012, Treadway *et al.*, 2012, Yang *et al.*, 2014), suggesting another possible conceptual dimension of anhedonia needing further investigation. How effort expenditure might map onto neural processes in depression is as yet unclear.

Studies examining the neural response to aversive stimuli in depression are less consistent, with some finding increased responses in regions such as the amygdala (Knutson and Greer, 2008, Sheline *et al.*, 2001, Surguladze *et al.*, 2004), whilst others find reduced/blunted responses in the amygdala and lateral OFC (Bylsma *et al.*, 2008, Luking *et al.*, 2015, McCabe *et al.*, 2009a). However, blunted responses to both reward and aversion fits with the theory of Emotion Context Insensitivity in depression, whereby patients exhibit reduced reactivity to all emotional stimuli (Rottenberg, 2007, Rottenberg *et al.*, 2005).

To assess the neural response to both reward and aversion, we have developed an experimental model that utilizes pleasant and unpleasant sights and tastes. We have previously shown that the SSRI, citalopram, reduced the neural response to the anticipation of reward in the ventral striatum, medial OFC and ventral medial prefrontal cortex (vmPFC) and in the ventral striatum to the taste of the reward (consummatory) (McCabe *et al.*, 2010). Citalopram also reduced the neural activation to the anticipation of aversion in the insula and lateral OFC and to the aversive taste in the insula (consummatory) (McCabe *et al.*, 2010). We suggested that this general inhibitory effect might underlie the emotional dampening associated with SSRIs and their alleged inability to effectively treat reward-related deficits in depression (Kumar *et al.*, 2008, Opbroek *et al.*, 2002, Price *et al.*, 2009, Shelton and Tomarken, 2001).

It has been suggested, however, that catecholamine antidepressants like bupropion (dopamine and noradrenaline reuptake inhibitor, DNRI) (Dwoskin *et al.*, 2006, Stahl *et al.*, 2004) might be more efficacious at improving reward-related deficits and apathy in depression and less likely to cause the negative side-effects of sexual dysfunction seen with SSRIs (Argyropoulos and Nutt, 2013, M Pereira *et al.*, 2014, Nutt *et al.*, 2007, Shelton and Tomarken, 2001). In fact a recent study examining the human response to erotic images found increased activity in the posterior midcingulate cortex, mediodorsal thalamus, and extended amygdala under bupropion (Abler *et al.*, 2011). However, how the separate dimensions of neural reward and aversion processing (anticipation, effort and consummation) might be affected by bupropion is unknown and is therefore the aim of the current study. To do this we included in our task an anticipatory phase (pleasant or unpleasant cue), an effort phase (button presses to achieve a pleasant taste or to avoid an unpleasant taste) and a consummatory phase (pleasant or unpleasant tastes). We hypothesized that, unlike our previous results

with citalopram, bupropion would increase neural responses during anticipation in areas such as the striatum and anterior cingulate cortex. Further, we expected that during the effort phase bupropion would increase the neural activation in regions such as the striatum and prefrontal cortex, as these regions have recently been shown to be activated when working for rewards and avoiding aversion (Delgado *et al.*, 2009, Wiers *et al.*, 2014). Additionally, we hypothesized that bupropion would increase neural responses in the striatum and medial OFC during the consummatory phase, given their involvement in hedonic processing. Finally, as with our previous work on the effects of 7 day treatments with antidepressants in healthy volunteers, we expected to find no observable behavioural effects on effort or subjective ratings for each of the stimuli (Harmer *et al.*, 2009, McCabe *et al.*, 2010).

Materials and Methods

Participants

17 healthy right-handed and Caucasian volunteers (mean 24 years, nine female), were randomized to receive 7 days oral treatment with bupropion (150 mg/day) and 7 days oral treatment with placebo separated by a 2-week washout phase in a double-blind between-groups design. Our previous fMRI study indicated an effect size of $d = 0.4$ with a mean standard deviation of 0.25 (McCabe *et al.*, 2009b), demonstrating that a sample size of 15 would be required to achieve 80% power at an alpha level of 5%. The study was located at the Centre for Neuroscience and Neurodynamics (CINN) in the Department of Psychology at the University of Reading. Volunteers were recruited via advertisement and, after reading study information, provided written consent prior to screening. Ethical approval was obtained from the University of Reading.

The exclusion criteria included current/previous psychiatric disorder (including alcohol or drug dependency) using the DSM-IV Structured Clinical Interview [SCID (Spitzer *et al.*, 2004)], pregnancy and any contraindications to MRI and bupropion (including family history of bipolar disorder and seizures/epilepsy). Volunteers were medication-free for the past 3 months (excluding the contraceptive pill) before starting the study and underwent a physical examination. Volunteers had a healthy BMI and their liking and craving for chocolate was measured using a questionnaire (Rolls and McCabe, 2007). Eleven volunteers were non-smokers, four smoked < 1 cigarette a week, one smoked 5 cigarettes per week and one smoked 1-2 cigarettes a day on average. Baseline measures of mood and anhedonia were taken using the Beck Depression Inventory (Beck *et al.*, 1961), Snaith-Hamilton Pleasure Scale (Snaith *et al.*, 1995), Fawcett-Clarke Pleasure Capacity Scale (Fawcett *et al.*, 1983), Temporal Experience of Positive Mood (Gard *et al.*, 2007) and Behavioral Inhibition/Activation Scales (Carver and White, 1994). Given that we use taste stimuli, including chocolate, volunteers also completed the Eating Attitudes Questionnaire (Garner *et al.*, 1982) to assess eating attitudes.

Experimental design

The study used a double blind, within-subjects, counterbalanced, crossover design. Volunteers received 7 days (1 tablet each morning) of bupropion treatment (150mg/day) and 7 days of placebo treatment,

separated by a 2-week washout phase. Treatment order was randomised, with 9 volunteers receiving bupropion first and 8 receiving placebo first. Volunteers underwent an fMRI scan on the 7th day of each treatment at approx. 3 hrs after last dose. One volunteer had a scan after 6 days treatment (drug) due to experiencing adverse side-effects. Medication was provided by the Oxford Health NHS Foundation Trust and the Royal Free London NHS Foundation Trust. Participants were asked to not consume chocolate for 24 hours prior to scanning and were allowed only one caffeinated drink on the scan morning. Before scans, volunteers completed the Patient Rated Inventory of Side Effects (PRISE: Sequenced Treatment Alternatives to Relieve Depression) to record any adverse side-effects. Mood was measured before and after scans using the *befindlichkeit* scale of mood and energy (von Zerssen *et al.*, 1974) and a mood visual analogue scale (VAS).

The task was adapted from (McCabe *et al.*, 2010) to include an effort phase (Figure S1). The task (40 trials) had 4 conditions based on the trial type (reward/aversive) and its level of difficulty (easy/hard). Trial type was cued by a visual stimulus (chocolate picture or a picture of a mouldy drink, 2 sec, anticipatory phase), which indicated either to work to win the chocolate taste or to avoid the unpleasant taste. Difficulty was determined by the amount of effort required to complete the effort phase (easy = 24, hard = 45 button presses). The effort phase, required volunteers to press a button as fast as possible (< 6 sec) to move a bar towards the pleasant chocolate picture (reward) and away from the unpleasant mouldy picture (aversive), allowing enough time to complete easy trials but not hard. A taste was then delivered (consummatory phase) based on performance. If on reward trials volunteers were successful they received the taste (5 sec delivery and 2 sec swallow cue) of chocolate and if not they received the tasteless solution. If on aversive trials volunteers were successful they received the tasteless solution and if not they received the unpleasant taste. A grey image (2 sec) followed by a tasteless rinse was presented at the end of each trial. Each condition was repeated 10 times, chosen by random permutation. Jitters were used for both interstimulus intervals and inter-trial intervals. To sustain effort, 4 trials (2 reward/2 aversive) were longer at 9 sec each. Volunteers also rated 'wanting', 'pleasantness' (+2 to -2) and 'intensity' (0 to +4) on a VAS on each trial (Figure S1).

Stimuli

We used a picture of liquid chocolate (reward), a mouldy drink (aversive) and a grey image (control). The rewarding taste was a Belgian chocolate drink and the aversive taste was a combination of the

chocolate drink mixed with beetroot juice, providing a similar texture. The tasteless solution (25×10^{-3} mol/L KCL and 2.5×10^{-3} mol/L NaHCO₃ in distilled H₂O) was also used as a rinse between trials. This was subtracted from the effects of the other taste stimuli to allow somatosensory and mouth movement effects to be removed (de Araujo *et al.*, 2003, O'Doherty *et al.*, 2001). Solutions were delivered through three teflon tubes held together by a plastic mouthpiece and connected by a one-way syringe-activated check valve (Model 14044-5, World Precision Instruments, Inc.), allowing 0.5 mL of solution to be manually delivered.

fMRI Scan

The experimental protocol consisted of an event-related interleaved design. A Siemens Magnetom Trio 3T whole body MRI scanner and a thirty-two-channel head coil were used. Multi-band accelerated pulse sequencing (Version number RO12 Center for Magnetic Resonance Research, University of Minnesota, EPI 2D BOLD/SE/DIFF Sequence) was used with an acceleration factor of 6. T2*-weighted echo planner imaging slices were obtained every 0.7 seconds (TR). Imaging parameters were chosen to reduce distortion artefact in the orbitofrontal cortex (Wilson *et al.*, 2002). 54 Axial slices with in-plane resolution of 2.4 x 2.4mm and between plane spacing of 2.4mm were attained. The matrix size was 96 x 96 and the field of view were 230 x 230mm. Acquisition was performed during task performance, yielding approximately 3500 volumes. An anatomical T1 volume with sagittal plane slice thickness 1mm and in-plane resolution of 1.0×1.0 mm was also acquired.

fMRI analysis

Statistical Parametric Mapping (SPM8: <http://www.fil.ion.ucl.ac.uk/spm/software/spm8/>) was used to analyze the imaging data. The data was pre-processed using realignment, normalization to the Montreal Neurological Institute (MNI) coordinate system and spatial smoothing with a 6-mm full-width-at-half-maximum Gaussian kernel and global scaling (Collins *et al.*, 1994). The time series at each voxel was low-pass filtered with a hemodynamic response kernel. Time series non-sphericity at each voxel was estimated and corrected for (Friston *et al.*, 2002), and a high-pass filter with a cut-off period of 128 sec was applied.

In the single-event design, a general linear model was then applied to the time course of activation in which stimulus onsets were modelled as single impulse response functions and then convolved with the

canonical hemodynamic response function (Friston *et al.*, 1994). Linear contrasts were defined to test specific effects. Time derivatives were included in the basis functions set. Following smoothness estimation (Worsley *et al.*, 1996), linear contrasts of parameter estimates were defined to test the specific effects of each condition (pleasant/unpleasant cue – grey image and pleasant/unpleasant taste – rinse) with each individual dataset. Voxel values for each contrast resulted in a statistical parametric map of the corresponding t statistic, which was then transformed into the unit normal distribution (SPM z). Movement parameters for each person were added as additional regressors in the 1st level analyses.

Second-level fMRI analyses first examined simple main effects of task with one-sample t -tests for all scans (Table S1). These results were thresholded at $p=0.05$ uncorrected and whole-brain cluster corrected [$p<0.05$ family-wise error (FWE) for multiple comparisons]. To examine the effect of bupropion, the one-way ANOVA within-participants design implemented in SPM8 was used and all data were reported thresholded at $p=0.05$ uncorrected and whole-brain cluster corrected ($p<0.05$ FWE for multiple comparisons). Regions of interest, for which we had a priori hypotheses based our previous studies using a similar paradigm in healthy controls, were; ventral striatum [10, 12, -6; -6, 12, -4] (McCabe *et al.*, 2010), caudate [-10, 12, 0; -10, 14, 0] (McCabe *et al.*, 2010), medial OFC [2, 32, -24] (McCabe *et al.*, 2010), vmPFC [8, 56, -12; 2, 44, -14] (McCabe *et al.*, 2009b, McCabe *et al.*, 2010) and lateral OFC [46, 34, -6] (McCabe *et al.*, 2010). Peaks within 15mm of these locations and with a cluster threshold of at least 30 contiguous voxels had small volume corrections for multiple comparisons applied (FWE, $p<0.05$). Plots of contrast estimates were extracted with plots tool in SPM8, and WFU Pick Atlas (<http://www.fmri.wfubmc.edu/cms/software>) was used to display neural activation, with error bars representing the standard error of the mean. Activation co-ordinates are listed in the stereotactic space of the MNI ICBM 152 brain (Table 2).

Behavioral Data

Data was analyzed using repeated measures ANOVA and employed the Bonferroni correction for multiple comparisons. Where sphericity was violated, the Greenhouse-Geisser correction was utilized. Not-normally distributed data was transformed and reanalyzed. The reanalyzed data did not differ from raw data analysis and thus results are reported using the original data. Caution, however, might be paid to interpretation of the VAS analysis, because a proportion of the data was not normally distributed.

Results

Demographic Details and Mood Ratings

Demographic data (Table 1) indicated that participants had low depression and anhedonia scores, as measured on range of mood and anhedonia questionnaires. Volunteers also scored low on the EAT and reported a strong liking of chocolate. A repeated-measures ANOVA was performed to examine the effect of treatment (bupropion/placebo) and time (pre/post scan) on mood and affect, as measured by the BFS and VAS (Table S2). Results revealed that there was no significant effect of treatment [$F(1,16)=.483, p=.497$], time [$F(1,16)=.822, p=.378$], treatment by time [$F(1,16)=1.922, p=.185$], treatment by VAS [$F(1,16)=2.472, p=.084$] or treatment by time by VAS interactions [$F(1,16)=.689, p=.545$]. There was also no significant effect of treatment [$F(1,14)=1.61, p=.225$] or treatment by time interaction [$F(1,14)=2.176, p=.162$] on total BFS scores. However, there was a significant main effect of time on overall BFS score [$F(1,14)=5.879, p=.029$].

Adverse effects

Table S3 reports the number of adverse effects experienced on each treatment, as measured on the PRISE. The most commonly reported adverse effects across both treatment phases were headache (N= 5 per treatment), difficulty sleeping (N= 3 per treatment) and fatigue (N= 3 placebo, N= 5 bupropion). Dizziness (N= 4) was the most commonly reported adverse effect in the bupropion condition that was not reported in the placebo condition.

Subjective Ratings of Stimuli

Volunteers rated the chocolate cue and taste as pleasant and the unpleasant picture and taste as unpleasant (Figure S3). Using repeated-measures ANOVA with Ratings as the first factor with three levels (wanting, pleasantness and intensity), Treatment as the second factor with two levels (bupropion and placebo) and Condition as the third factor with two levels (rewarding and aversive), there was no significant main effect of treatment [$F(1,16)=.867, p=.366$] or treatment by condition interaction [$F(1,16)=2.558, p=.129$], treatment by rating interaction [$F(1,16)=.109, p=.802$] or treatment by rating by condition interaction [$F(1,16)=.701, p=.479$].

Behavioral responses

To examine whether there was an effect of treatment on the amount of effort invested into each condition (reward/aversion), repeated-measures ANOVAs were conducted on the average number of button presses made and the average amount of time it took to complete the effort stage (Figure S4). With Treatment (bupropion and placebo) and Condition (reward and aversion) included as factors, it was revealed that volunteers made significantly more button presses on aversive trials ($M=37.69, SE = 0.33$) compared to reward trials ($M=37.37, SE=0.34$) [$F(1,16)=5.736, p=0.029$]. This was independent of treatment, since there was no main effect of treatment [$F(1,16)=.028, p=.869$] or treatment by condition interaction [$F(1,16)=.063, p=.804$]. Furthermore, although volunteers completed aversive trials ($M=5519.33\text{ms}, SE=46.43$) quicker than reward trials ($M=5546.57\text{ms}, SE=45.11$), this was not significant [$F(1,16)=2.106, p=.166$], nor was there a main effect of treatment [$F(1,16)=.023, p=.881$] or treatment by condition interaction [$F(1,16)=1.654, p=.217$].

fMRI responses

Table S1 in the Supplementary Material provides a summary of the results for each contrast across all volunteers to indicate the main effect of task. Table 2 provides a summary of the results of the interaction with Treatment.

Table 2. Regions showing significant effect of treatment on each condition.

orbitofrontal cortex; Cing, cingulate

Main Effect of Task

As expected, the chocolate stimuli activated reward-related areas, such as the ventral striatum, the anterior cingulate and the OFC, whereas the unpleasant stimuli activated regions including the amygdala and IOFC. Both the chocolate taste and unpleasant tastes activated the insula (i.e. the primary taste cortex).

Anticipatory Phase

Relative to the placebo condition, the bupropion condition showed increased BOLD activity in the caudate in response to *both* the pleasant and unpleasant cue. To the pleasant cue, the bupropion condition showed more activity in the pgACC/vmPFC (Fig 1) and IOFC, in comparison to placebo. To the unpleasant cue, the bupropion condition showed more BOLD activity in the vmPFC, relative to placebo.

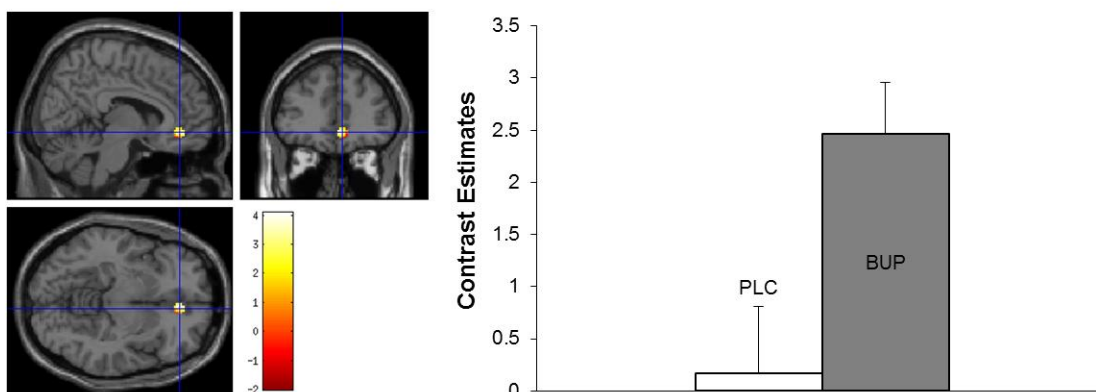

Figure 1. Pleasant cue: *left panel*, axial, sagittal and coronal image of pgACC/vmPFC activation compared to placebo ($Z=3.33$, $p=0.02$ FWE svc for multiple comparisons); *right panel*, contrast estimates for paACC centered at 8, 40, -8. Error bars represent the standard error of the mean.

Effort Phase

For bupropion there was increased BOLD activity in the caudate, vmPFC (Figure 2), dACC/paracingulate gyrus and putamen for the easy chocolate trials compared to hard chocolate trials, in comparison to placebo. Bupropion also increased BOLD activity in the primary motor cortex and ventral

striatum/caudate for the easy unpleasant trials compared to hard unpleasant trials. Bupropion increased BOLD activity in the dorsal anterior cingulate cortex (dACC)/paracingulate gyrus and the superior frontal gyrus for the easy chocolate trials compared to the easy aversive trials, relative to placebo.

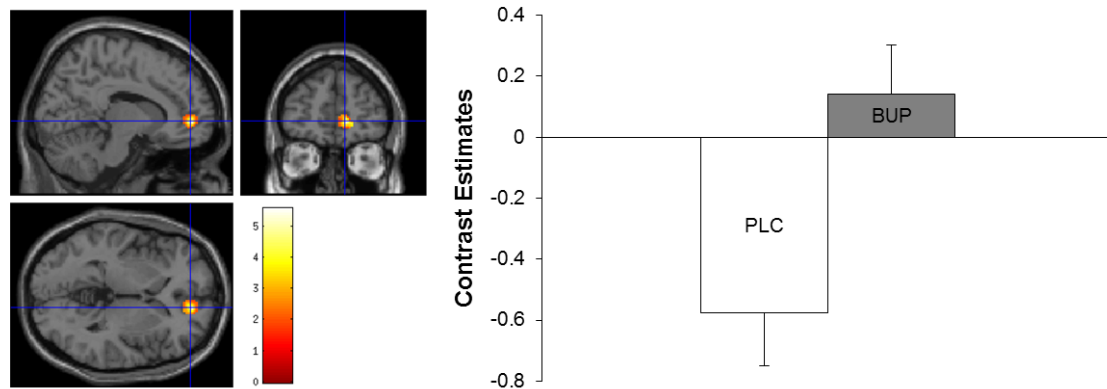

Figure 2. Easy effort chocolate – hard effort chocolate: *left panel*, axial, sagittal and coronal image of vmPFC activation compared to placebo ($Z=4.09$, $p<0.001$ FWE whole brain cluster corrected for multiple comparisons); *right panel*, contrast estimates for vmPFC centered at 12, 50, 0. Error bars represent the standard error of the mean.

Consummatory Phase

Bupropion increased BOLD activity in the mOFC to *both* the pleasant (Figure 3) and unpleasant tastes. Bupropion increased BOLD activity in the amygdala (Figure 4) and ventral striatum for the unpleasant taste relative to the placebo condition. Bupropion also reduced BOLD activity for the pleasant taste in the caudate, relative to the placebo condition.

Figure 3. Chocolate taste: *left panel*, axial, sagittal and coronal image of mOFC activation compared to placebo ($Z=3.67$, $p=0.005$ FWE svc for multiple comparisons); *right panel*, contrast estimates for mOFC centered at 45, -2, 28. Error bars represent the standard error of the mean.

Figure 4. Unpleasant taste: *left panel*, axial, sagittal and coronal image of amygdala activation compared to placebo ($Z=3.26$, $p=0.014$ FWE whole brain cluster corrected for multiple comparisons); *right panel*, contrast estimates for amygdala centered at 28,-2,-26. Error bars represent the standard error of the mean.

Discussion

The aim of this study was to examine the effects of 7 days treatment with bupropion on the neural response to three phases of reward and aversion processing (anticipation, effort and consummation) in healthy volunteers. We found that bupropion increased neural responses during the anticipation, effort to achieve/avoid and the consummation of rewarding and aversive tastes. The effects on reward are consistent with the proposal that bupropion may significantly improve outcomes for depressed patients with predominant symptoms of decreased pleasure, interest and energy (Corcoran *et al.*, 2004, Nutt *et al.*, 2007). Further, bupropions ability to increase neural responses during anticipation, avoidance and consummation of aversive stimuli may be additionally beneficial for patients experiencing blunted affect in depression whereby reduced reactivity to positive and negative stimuli is predominant (Rottenberg, 2007, Rottenberg *et al.*, 2005).

Specifically we found that bupropion increased activity during the anticipation phase (pleasant and unpleasant cues) in the vmPFC and the caudate, with increased lateral OFC to the pleasant cue. These regions are recruited during anticipation of reward (Kim *et al.*, 2010, Sescousse *et al.*, 2013) and found *blunted* to the anticipation of reward in patients with depression (McCabe *et al.*, 2009a, Price and Drevets, 2009). We also found that the caudate was increased during the anticipation phase (pleasant and unpleasant cues) in the bupropion group compared to placebo. The caudate, which has been previously shown to be activated during the anticipation of pleasant and unpleasant stimuli in healthy volunteers (Knutson *et al.*, 2001; Greenberg *et al.*, 2015) has been found hypoactive during the anticipation of reward in people with depression (Forbes *et al.*, 2009, Smoski *et al.*, 2009, Zhang *et al.*, 2013). Thus bupropions ability to modulate activation in these regions during anticipation of reward and aversion might be a mechanism by which catecholaminergic medications are less likely to cause emotional blunting in depression compared to SSRI medications (Argyropoulos and Nutt, 2013, Bylsma *et al.*, 2008, Nutt *et al.*, 2007, Shelton and Tomarken, 2001).

During the effort phase, we found that there was more neural activity under hard trials than easy in the placebo group (Figure S2). We found that the activity under easy trials was potentiated by bupropion, in the striatum, vmPFC (Figure 2) and the dACC/motor areas, relative to placebo. Given the previous work showing that these regions are implicated in various processes involved in reward processing including

motor performance (Liljeholm and O’Doherty, 2012, Scholl *et al.*, 2015) and in the avoidance of aversion (Kerr *et al.*, 2012), its perhaps not surprising that bupropion enhanced this neural activity during effort expenditure to achieve reward and avoid aversion.

During the consummatory phase we found that bupropion, compared to placebo, increased neural activity for both pleasant and unpleasant tastes in the mOFC. Our results are consistent with the literature indicating the involvement of the mOFC in hedonic experiences in humans and animals (Kringelbach, 2010, Peters and Buchel, 2010, Scott *et al.*, 2005). Further, our previous study in those recovered from depression found reduced activity to the taste of chocolate (possible trait marker) in a similar subgenual/mOFC region to that enhanced by bupropion in this current study (McCabe *et al.*, 2009a). Of note, a study by Pizzagalli *et al.* (2008) found reduced activations in depressed patients to *both* positive and negative outcomes in the striatum (Pizzagalli *et al.*, 2009b) which is of interest given that we find enhanced striatal activation to the unpleasant taste under bupropion in our task. Taken together our results suggest that bupropion may be beneficial at increasing the neural deficits to both positive and negative consummatory stimuli in depressed patients who report blunted affect.

As expected, there was no significant treatment effect on the amount of effort invested in the task or on the subjective reports of pleasantness, wanting and intensity for each of the stimuli. This is similar to our previous studies with acute pharmacological challenges in healthy volunteers and suggests that enhanced neural processing of reward/aversion after 7 days treatment does not necessarily become the subject of conscious awareness, although it could still presumably influence behavior (Horder *et al.*, McCabe *et al.*, 2010, Tudge *et al.*, 2015). Perhaps there is also a ceiling effect as volunteers are all healthy and do not have deficits in their ability to complete the effort component or to experience the tastes. However, how bupropion might affect these processes in studies with larger sample sizes and in depressed patients remains to be elucidated.

To conclude, we suggest a potential mechanism of beneficial antidepressant drug action of bupropion that consists of enhancing the neural activation to reward and aversion during anticipation, effort and consummation. This profile of activity in turn could promote reward-seeking and aversive-avoidant behaviors in patients with depression, whereby a lack of drive to actively seek and experience rewards is coupled with a lack of drive to actively avoid negative experiences. Our results also support the notion that non-serotonergic antidepressants may play an important role specifically for patients that have a blunted

emotional affect and this fits with the Emotion Context Insensitivity theory of depression (Rottenberg *et al.*, 2005). Future research on the effects of bupropion on anticipation, effort and consummation of reward and aversion processing in depressed patients are encouraged to explore this notion further.

Financial support

This study was supported by the University of Reading start-up fund for Dr. C McCabe.

Conflict of interest

Dr. McCabe has acted as a consultant to P1Vital, Givaudan, GWpharma, the British Broadcasting Company (BBC) and Channel 4. Zola Dean, Dr. Stefanie Horndasch and Dr. Panagiotis Giannopoulos report no biomedical financial interests or potential conflicts of interest.

Ethical standards

The authors assert that all procedures contributing to this work comply with the ethical standards of the relevant national and institutional committees on human experimentation and with the Helsinki Declaration of 1975, as revised in 2008.

Acknowledgments

We thank Dr. Mark Parry, MRCPsych consultant psychiatrist and college tutor at Prospect Park Hospital, NHS Berkshire Trust, Reading, UK for his clinical collaboration.
