Authors' final version of manuscript, in press, *J Behav Addict*, 2016

ABSTRACT

Background and aims: Previous analyses have highlighted significant associations between GD/subsyndromal GD and increased rates of anxiety symptoms and anxiety disorders relative to the general population. However less is known about how anxiety symptoms influence the clinical presentation of gambling problems. The objective of the current study was to evaluate the association between anxiety symptoms, gambling activity and neurocognition across the spectrum of gambling behavior.

Methods: The sample consisted of 143 non-treatment-seeking young adults (aged 18 to 29). Sixty-three individuals (44.1%) were classified as recreational gamblers, 47 (32.9%) as having subsyndromal GD, and 33 (23.1%) met criteria for GD.

Results: The main findings were: 1) there was a positive correlation between anxiety severity and gambling severity measured by number of DSM 5 GD criteria met; 2) there was a positive correlation between anxiety severity and attentional impulsiveness; 3) subjects with

suicidality presented higher levels of anxiety; and 4) the severity of anxiety symptoms was negatively correlated with quality of life.

Conclusions: This study suggests that anxiety may be associated with relevant clinical variables in the broad spectrum of gambling activity. Therefore, proper management of anxiety symptoms might improve the clinical presentation of gamblers in different areas.

KEYWORDS: Gambling disorder; subsyndromal gambling; problem gambling; anxiety; neurocognition.

1. INTRODUCTION

Gambling disorder (GD) is associated with high rates of depression, substance-use disorders, and suicidality; as well as occupational and legal problems (Bland et al., 1993; Cunningham-Williams et al., 1998; Petry and Kiluk, 2002; Muelleman et al., 2002; Toce-Gerstein et al., 2003, Petry et al., 2005). The annual cost of GD is approximately 5 billion US dollars within the United States alone (National Gambling Impact Study Commission; 1999). Subsyndromal gambling is also a notable concern, and is defined as significant gambling activity that does not meet full DSM-5 criteria for GD (Grant et al., 2014). Subsyndromal gamblers also show high rates of depression, anxiety disorders, substance-use disorders, financial, legal, family and professional problems (Cunningham-Williams et al., 1998; Gerstein et al., 1999; Shaffer and Korn, 2002; Welte et al., 2001; Desai et al., 2004; Potenza et al., 2006; Grall-Bronnec et al., 2012). Therefore, it is likely that gambling symptoms present on a continuum, and that symptoms should be assessed across the spectrum of gambling behavior (Cunningham-Williams

et al., 1998; Gerstein et al., 1999; Shaffer et al., 1999; Slutske et al., 2000; Welte et al., 2001; Eisen et al., 2001; Shaffer and Korn, 2002; Toce-Gerstein et al., 2003; Grant et al., 2014).

Previous analyses have highlighted significant associations between GD/subsyndromal GD and increased rates of anxiety symptoms and anxiety disorders relative to the general population (Bland et al., 1993; Black and Moyer, 1998; Cunningham-Williams et al., 1998; Petry et al., 2005; Desai and Potenza, 2008). One large epidemiological study found a lifetime prevalence of anxiety disorders of 41.3% among disordered gamblers (Petry et al., 2005). A systematic review of epidemiological studies corroborated these findings, with 37% of gamblers reporting a history of a comorbid anxiety disorder (Lorains et al., 2011). In another analysis, Desai and Potenza (2008) also found a high prevalence of panic disorder, generalized anxiety and social phobia in subsyndromal GD.

Although anxiety symptoms are common in gamblers, less is known about how anxiety symptoms influence the clinical presentation of gambling problems. Various lines of research suggest that anxiety could be a powerful contributor to gambling behavior. First, research in other addictions (alcohol-use disorder and substance-use disorder) suggests that the behavior may be a way to cope anxiety (Sher et al., 1994). The relief of the anxiety, however, tends to be short-lived, and the symptoms may often reappear more intensely. As a result, a harmful cycle is created, and the anxious individual may therefore present with a more frequent and severe form of the addictive behavior. Second, attentional bias toward threatening elements is a well characterized phenomenon in anxious individuals and, as a result of this, other non-threatening elements tend to be less perceived (MacLeod et al., 1986; Mogg & Bradley; 1998, Bishop et al., 2004; Koster et al., 2004; Koster et al., 2006, Bar-Haim et al., 2007, Schofield et al., 2012). Therefore, an anxious individual who gambles may have a reduced focus on the gambling

behavior (i.e. how to bet, how much to bet). This attentional deficit may be another factor leading to a worse severity of GD. Finally, anxiety symptoms decrease some dimensions of quality of life (Spitzer et al., 1995). In this context, the increased emotional suffering and the lower level of life satisfaction could also increase the risk of suicide.

In light of this background, the objective of the current study was to evaluate the association between anxiety symptoms, gambling activity and neurocognition across the spectrum of gambling behavior (recreational gamblers, subsyndromal GD and GD) in a non-treatment seeking sample. We assessed the current severity of anxiety symptoms and associations between anxiety symptom severity, gambling symptoms, impulsiveness, and neurocognition. We predicted that anxiety symptoms would be associated with 1) worse overall severity of GD, measured by increased gambling activity and more losses due to gambling, and 2) higher impulsivity measured with clinical and neurocognitive tasks. Additionally, we expected that anxiety would be correlated with 3) worse clinical and neurocognitive attentional performance, 4) lower quality of life and 5) higher levels of suicidality. If our hypotheses are correct, anxiety symptoms would be associated with variables correlated with poor prognosis and poor overall functioning. Therefore, proper management of anxiety should receive greater attention in clinical practice since it could improve the clinical presentation of gamblers in multiple domains. If our hypotheses are not supported, constant assessment and treatment of anxiety would be a secondary approach in the management of GD.

2. METHODS

2.1 Sample

The sample consisted of 143 non-treatment-seeking young adults (aged 18 to 29) [n=75 (52.1%) male; mean age 24.8 (\pm 2.9) yrs] with varying levels of gambling severity. Participants were recruited through media advertising (“have you ever gambled?”), and had gambled at least five times during the past year. Sixty-three individuals (44.1%) were classified as recreational gamblers (see later for definitions), 47 (32.9%) as having subsyndromal GD, and 33 (23.1%) met criteria for GD.

2.2 Procedures

All assessments were completed as a part of an ongoing study of gambling behavior in young adults. Participants were compensated with a US\$50 gift card to a local department store. Subjects were recruited in Chicago/IL and Minneapolis/MN metropolitan areas. Exclusion criteria included inability to complete study procedures, inability/unwillingness to provide voluntary written informed consent, and gambling frequency of less than five times in the past year. No medications were administered as part of this study. Subjects taking medications were allowed to take part in the research.

2.3 Measurements

2.3.1 *Demographics*

Age, gender, marital status, educational status, professional status, ethnicity and sexual orientation were recorded.

2.3.2 *Severity of anxiety symptoms*

The Hamilton Anxiety Scale (HAM-A) is a valid and reliable instrument that assesses cross-sectional severity of anxiety symptoms (Hamilton, 1969; Snaith et al., 1982; Maier et al.,

1988). The HAM-A consists of 14 items (score range 0 to 56) that evaluate a variety of anxiety symptoms (Beck and Steer, 1991). HAM-A total score presents an intraclass coefficient of 0.74 and a concurrent validity between 0.63 and 0.75 (Maier et al., 1988). The HAM-A has shown good internal consistency [Cronbach's alpha = 0.893] (Kummer et al., 2010). It is probably the most used and accepted scale to evaluate anxiety symptoms.

2.2.3 Clinical variables

a) Gambling behavior: We evaluated the age at start of regular gambling, the amount of money lost with gambling in the last year and the average gambling frequency (times per week).

b) Overall Severity of GD: we assessed the total number of DSM-5 GD criteria using the Structured Clinical Interview for Gambling Disorder [SCI-PG] (Grant et al., 2004). SCI-PG was first validated using the criteria of the Fourth Edition of the Diagnostic and Statistical Manual of Mental Disorders [DSM-4]. Test-retest reliability on the number of GD criteria endorsed showed $r = 0.97$ [$p = .006$] (Grant et al., 2004). We retrospectively processed the electronic saved DSM 4 criteria for a proper adaptation to DSM-5. This procedure was performed deleting the criterion “committed illegal acts such as forgery, fraud, theft, or embezzlement to finance gambling regarding illegal acts”, which was present in previous manual, DSM-4. Moreover, we lowered the diagnostic threshold from five to four, consistent with DSM-5. Remaining criteria were unchanged. Severity was divided in three categories: recreational gambling (meets 0 DSM-5 criteria), subsyndromal GD (meets 1 to 3 DSM-5 criteria) and GD (meets 4 or more DSM-5 criteria).

Additionally, we investigated the overall gambling severity with the Pathological Gambling Yale-Brown Obsessive-Compulsive Scale (PG-YBOCS). It is a 10-item scale that showed high validity [$r = .895$] and reliability [Cronbach's $\alpha = .970$] (Pallanti et al., 2005). This

scale provides a total score (overall severity) as well as scores in 2 subscales (urges subscale and behavior subscale).

c) Impulsiveness: evaluated by the Barratt Impulsiveness Scale, version 11 [BIS- 11] (Patton et al., 1995), a scale that has been largely used to investigate impulsiveness (Steinberg et al., 2013). This scale has shown good internal consistency [Cronbach α between 0.79 and 0.83] (Patton et al., 1995). BIS-11 provides scores in three different dimensions, based on previous factor analyses: [attentional impulsiveness], [motor impulsiveness] and [Non-planning impulsiveness] (Patton et al., 1995).

d) Prevalence of illegal acts: the commitment of illegal acts to finance gambling activity has been associated with higher severity of GD (Toce-Gerstein, 2003; Strong and Kahler, 2007; Granero et al., 2014). It was evaluated using an open question using previous DSM-4 criteria: “Have you committed illegal acts such as forgery, fraud, theft or embezzlement to finance gambling?”

e) Suicidality and psychiatric comorbidity: evaluated by the Mini International Neuropsychiatric Interview [MINI] - (Sheeran et al., 1998).

f) Quality of life (Quality of life inventory): a 17-item scale that evaluates subject’s overall quality of life (Frisch, 1994). Alpha coefficients and test-retest correlations for this questionnaire have ranged, respectively, from 0.77 to 0.89 and from 0.80 to 0.91 (Mendlowicz and Stein, 2014).

g) Use of nicotine: assessed by a 20-cigarettes pack per day equivalent.

2.3.4 Neurocognitive testing

Individuals with GD tend to present with several neurocognitive deficits such as poorer response inhibition, low cognitive flexibility, worse decision-making and problems with sustained attention and executive functioning (Clark, 2010; Van Holst et al., 2010). This study evaluated whether anxiety symptoms affected any of these neuropsychological variables. In this context, participants undertook selected tests from the computerized Cambridge Neuropsychological Test Automated Battery [CANTABeclipse, version 3, Cambridge Cognition Ltd, Cambridge, UK] (Cambridge Cognition, 2015). Task order was fixed and the total duration of cognitive testing was approximately 50 min.

a) Response inhibition: assessed by the Stop-signal task, which assesses the subject's ability to inhibit/suppress motor responses. Individuals react to an arrow stimulus, by touching either a left- or right-key depending on the direction in which the arrow points. When an audio tone occurs, the participant attempts to suppress their motor response for the particular trial (Morein-Zanir, 2010). The outcome measure of interest is the stop-signal reaction time, an index of the time taken for the person's brain to stop a response that would normally be made.

b) Cognitive flexibility: investigated with the Intra-Dimensional /Extra-Dimensional set shifting test, which evaluates rule learning, reversal, and shifting of attentional focus across stimulus dimensions. The test uses visual stimuli (colorful shapes and white lines) and gives feedback to the individual so that they are able to learn an underlying 'rule' about which stimulus is correct, based on trial and error. The underlining rule that determines what is "correct" and incorrect" changes several times and assesses the individual's ability to respond flexibility (Cambridge Cognition, 2015). The adjusted total number of errors is an overall score of performance.

c) Decision making: assessed using the Cambridge Gamble Task, a test that assesses decision-making and risk-taking (Deakin et al., 2004; Lawrence et al., 2009, Cambridge cognition, 2015).

The task simulates gambling activity but uses points for bets, rather than ‘real’ rewards. The main outcome measures in this test are: quality of decision-making, proportion of points gambled and risk adjustment.

d) Sustained attention: evaluated by the Rapid Visual Information Processing paradigm. This task investigates the ability to detect unpredictable target sequences over prolonged periods of time (Sarter et al., 2001). The task consists of a white box in the center of the computer screen, inside which numbers, from 2 to 9, show up in a pseudo-random manner, at the frequency of 100 digits/minute. *A’ prime* was used as measure of sustained attention.

e) Executive functioning: assessed using the One touch stockings of Cambridge task. This test, a variant of a variation of the Tower of London (Owen et al., 1995), investigates goal-directed planning (Cambridge Cognition, 2015). The task presents visual problems to the subject and evaluates the individual’s ability to plan a solution and answer these problems.

2.4 Statistical analysis

We analyzed the association between severity of anxiety symptoms and demographic, clinical and neurocognitive variables of the participants using Spearman’s coefficients for continuous elements and Mann-Whitney tests for categorical variables.

To control for multiple comparisons, we divided the usual level of significance ($p = .05$) by the number of variables evaluated in each group of assessments (i.e. [clinical variables] and [neurocognitive testing]). Consequently, significance was defined as $p \leq .004$ ($0.05/13 = 0.004$) for [clinical variables]; $p \leq .007$ ($0.05/7 = 0.007$) [neurocognitive variables].

In order to reduce the likelihood of confounding variables contributing to the above analyses, we controlled for current major depressive disorder, alcohol-use disorder, substance-use disorder, and nicotine use. These controls were included, as all four variables have

demonstrated significant overlap with anxiety symptoms and several clinical/neurocognitive variables investigated in this study, in prior work (Maier et al., 1988; Clark, 2010).

2.5 Ethics

This research was approved by the Institutional Review Boards of the University of Chicago and the University of Minnesota. Study procedures were explained to participants prior to providing consent, and all participants were given time to ask questions. All participants provided written informed consent.

3. RESULTS

Table 1 describes the demographics and main clinical variables of our sample.

TABLE 1 HERE

There was a significant positive correlation between the severity of anxiety symptoms and the number of current DSM 5 GD criteria. Additionally, quality of life was negatively correlated with the severity of anxiety symptoms. The presence of suicidality in gamblers was also associated with significantly higher scores on HAM-A, even after controlling for major depression, alcohol use-disorders, substance-use disorder, and use of nicotine (see also findings using ANOVA, Figure 1). The analysis also showed a direct correlation between anxiety symptoms in gamblers and higher scores on the attentional impulsivity dimension of BIS [i.e. higher attentional impulsiveness] (see table 2).

TABLE 2 HERE

We did not find significant correlations between neurocognitive variables and anxiety symptoms (see table 3).

TABLE 3 HERE

4. DISCUSSION

The current study analyzed the association of anxiety symptoms, gambling clinical variables and neurocognitive variables in non-treatment seeking gamblers. We evaluated subjects with a wide range of gambling severity (individuals who meet 0 to 9 DSM 5 GD criteria) and with different levels of anxiety (HAM-A scores from 0 to 28). The use of a non-treatment seeking sample was important in order to achieve this spread of disease severities, to maximize ability to detect relationships between variables. Treatment-seeking gamblers tend to be more severe than gamblers in the general population (Petry et al., 2005) and therefore, the range of different levels of gambling activity is narrower in treatment-seeking samples. Additionally, treatment-seeking gamblers may present a significant selection bias. Therefore, the use of a non-treatment seeking sample enabled us to assess the association between anxiety, gambling and neurocognition throughout a broad spectrum of gambling and anxiety levels.

This study found that the severity of anxiety symptoms was associated with several important clinical variables, even when controlling for major depression, alcohol use disorder, substance-use disorder and use of nicotine. There was a positive correlation between anxiety severity and gambling severity measured by number of DSM 5 GD criteria met. There was also a positive correlation between anxiety severity and attentional impulsiveness. Participants with suicidality presented with higher levels of anxiety. Finally, the severity of anxiety symptoms was negatively correlated with quality of life.

The number of DSM 5 criteria endorsed showed a positive correlation with anxiety levels. There was no significant correlation, however, between gambling severity, as measured by PG-YBOCS, and anxiety. The DSM-5 criteria assess symptoms over the past year whereas

the the PG-YBOCS was designed to evaluate severity during the past 7 days. Given that anxiety is often a chronic condition, the DSM-5 criteria may more accurately capture the impact of these symptoms on gambling behavior.

A large epidemiological study suggested that anxiety disorders usually precede GD and appear to trigger gambling problems (Kessler et., 2008). The longitudinal relationship between anxiety symptoms and gambling activity, after gambling has started, remain unclear. In this context, important questions remain: do gamblers have a more harmful gambling activity due to higher anxiety levels? Or, does having severe gambling problems and, therefore more negative consequences, make gamblers feel more anxious? Future longitudinal studies should address this point.

The finding that anxiety levels were positively correlated with gambling severity is clinically important, and proper management of anxiety may improve treatment outcomes in gambling problems. Psychological therapies should address anxiety while identifying reasons for gambling or for worsening of bets. Relaxation techniques and alternative ways to deal with anxiety (other than gambling) might be useful. Pharmacological approaches, such as the use of selective serotonin re-uptake inhibitors, may also enhance the control of anxiety. Grant and Potenza (2006) found that the use of escitalopram in a sample of disordered gamblers with co-occurring anxiety significantly improved gambling and anxiety symptoms. Future clinical trials looking specifically at anxious gamblers are needed.

This study observed a positive correlation between attentional impulsiveness as indexed by the Barratt questionnaire, and severity of anxiety symptoms; and between worse sustained attention on a computerized task, and severity of anxiety symptoms. Attentional impulsiveness has been described as an inability to keep attention/concentration (Stanford et al., 2009). When

the BIS was first developed, attentional impulsiveness was believed to be an isolated dimension together with motor impulsiveness and lack of planning (Barrant, 1959). Later research suggested that it is an underlying construct that interacts with motor impulsiveness and lack of planning (Patton, 1995). Therefore, attentional impulsiveness may be considered a dimension that is correlated with impulsiveness in several levels (Patton, 1995).

Attentional bias is a well characterized phenomenon in anxious individuals, who preferably allocate attention/focus on threatening stimuli rather than on neutral stimuli (MacLeod et al., 1986; Mogg & Bradley, 1998; Bar-Haim et al., 2007). This attentional bias to threat also leads to slower disengagement from threatening elements and, as a result of this, other non-threatening elements tend to be less perceived (Bishop et al., 2004; Koster et al., 2004; Koster et al., 2006, Schofield et al., 2012). Therefore, an anxious individual who gambles may have a reduced focus on the gambling behavior (i.e. how to bet, how much to bet). Future studies might further investigate how the attentional bias interferes in gambling activity and could, particularly, look at possible threatening stimuli that are over-perceived during gambling behavior.

This study also observed that severity of anxiety symptoms was positively associated with the presence of suicidality (Figure 1).

FIGURE 1 HERE

This is an important finding for several reasons. First, suicide has a huge economic impact in the United States. For example, in 2010, the financial losses associated with suicide were estimated in 44 billion American dollars/year (American Foundation for Suicide Prevention, 2010). Second, suicide is a top 2 leading cause of death in the United States for

subjects aged 15-34 (Centers for Disease Control and Prevention, 2011), the population evaluated by this study. Third, GD and subsyndromal GD has been associated with higher rates of suicide ideation/attempts (Bland et al., 1993; Hodgins et al., 2006; Newman and Thompson, 2007). Therefore, young gamblers appear to have a substantially elevated risk for suicide (age + gambling activity).

Unlike the current research, the majority of previous studies that assessed suicide/risk of suicide in gamblers did not report a significant correlation between anxiety and suicidality. Two facts may explain this: a) some studies failed to assess the relationship between anxiety symptoms/anxiety disorders and suicide (see Hodgins et al., 2006); b) the current study evaluated only young adults (aged 18 to 29), a group with higher anxiety symptoms and higher suicidality (Martin, 2003; Centers for Disease Control and Prevention, 2011). Therefore, anxiety symptoms may present a higher impact on suicidality in young gamblers and c) we evaluated a broad spectrum of gambling activity.

In fact, Grant and colleagues (2014) used a subsyndromal GD sample and found an association between suicidality and anxiety disorders. However, the assessment of suicidality did not control for other mental disorders as the current study did. As the correlation between GD and suicide ideation/attempts has been strongly attributed to co-occurring major depressive disorder and alcohol/substance-use disorders (Crockford and el-Guebaly, 1998; Hodgins et al., 2006), our study strengthens the possible separate association of anxiety symptoms and suicidality in gamblers.

A meta-analysis of 42 studies conducted by Kanwar et al., (2013) suggested that anxiety disorders are associated with higher suicidality (Kanwar et al., 2013). Better assessment of anxiety symptoms, particularly in gamblers with suicidality seems important in clinical practice.

As anxiety symptoms/disorders are considered relatively treatable (Hofmann and Smits, 2008), a more focused management in anxious gamblers may possibly reduce suicide risk.

Our study found that severity of anxiety was negatively correlated with quality of life. This finding is consistent with previous epidemiological and clinical studies that have shown that anxiety disorders and subthreshold forms of anxiety disorders are associated with significantly reduced quality of life (Markowitz et al., 1989; Weissman, 1991; Kessler et al., 1994; Spitzer et al., 1995; Wittchen et al., 2000, Wittchen, 2002; Mendlowicz and Stein, 2014; Zatzick et al., 2014). On the other hand, subsyndromal GD and GD have also been associated with poorer life satisfaction when compared to the general population (Black et al., 2003; Grant and Kim, 2005). Therefore, this study reinforces the negative correlation between anxiety and decreased quality of life in a non-treatment seeking sample of impulsive patients.

Quality of life is a core dimension in psychiatry treatments and, as a result of this, this variable has been increasingly recognized as a main outcome measure in clinical trials (Johnson and Temple, 1985; Group for the Advancement of Psychiatry Committee on Psychopathology, 1994; Spitzer et al., 1995; Wilson and Cleary, 1995; Pietersma et al., 2014). Anxiety may selectively affect some areas of quality of life. Spitzer et al. suggested that patients with anxiety disorders presented decreased scores particularly in role functioning. Further research should look at the effects of anxiety in specific dimensions. Cognitive behavioral therapy focusing in training of social skills may benefit anxious gambling individuals.

This study should be interpreted in light of its limitations. First, this research used a cross-sectional analysis and, therefore, causal relationships cannot be confirmed. However, the analysis provides reliable measures of association. Second, some of the data collected (age at start of recreational gambling; money lost with gambling in the last year) may be subject to

potential recall bias, as it was collected in hindsight. Third, our sample consisted of a convenience sample of young adults (individuals aged 18 to 29). Therefore, caution is needed when generalizing our findings to broader segments of the population. Finally, our study used a low significance level (i.e. 0.004 for [clinical variables] and 0.007 for [neurocognitive variables]). Therefore, we increased the likelihood of committing Type II error. On the other hand, we reduced the risk of finding false-positive results.

This study suggests that anxiety may be associated with relevant clinical variables in the broad spectrum of gambling activity. Therefore, proper management of anxiety symptoms might improve the clinical presentation of gamblers in different areas: 1) reducing overall gambling severity; 2) improving attentional deficits and attempting to reduce attentional impulsiveness; 3) reducing risk/severity of suicidality and 4) improving quality of life.

TABLE 1 – Description of demographics and main clinical variables of non-treatment seeking gamblers (n= 143).

➤ DEMOGRAPHICS	% (n) or mean (SD ^a)
Age	24.8 (±2.9)
Gender	
Male	52.4 (75)
Female	47.6 (68)
Marital status	
With partner	79.7 (114)
Without partner	20.3 (29)
Educational status	
Less than college	53.8 (77)
College or more	46.2 (66)
Occupational status	
Studying or working	81.8 (117)
Unemployed	18.2 (26)
Ethnicity	
Caucasian	43.3 (61)
Non-Caucasian	56.7 (80)
Sexual orientation	
Heterosexual	83.9 (120)
Other	16.1 (23)
➤ CLINICAL VARIABLES	
Anxiety symptoms severity (Hamilton Anxiety Scale)	6.1 (±6.3)
Age at start of regular gambling	18.9 (±3.0)
Money lost with gambling (last year)	2,221 (±4,325)
Average gambling frequency (times per week)	2.9 (±2.9)
Number of DSM 5 ^b gambling disorder criteria	2.0 (±2.6)
PG-YBOCS ^c total score	7.9 (±8.1)

a) SD = standard deviation

b) DSM 5 = Diagnostic and statistical manual of mental disorders – fifth version

c) PG-YBOCS = gambling adaptation of the Yale-Brown Obsessive-Compulsive Scale

TABLE 2 – Association between clinical variables and anxiety levels in non-treatment seeking gamblers (n = 143).

CLINICAL VARIABLES	Correlation Coefficient ^a or Mean HAM-A ^b (SD ^c)	p value ^d	Adjusted Correlation Coefficient ^e or Effect size	Adjusted p value ^e
Age started gambling regularly	-.170	.043	-.135	.146
Money lost with gambling (last year)	.222	.008	.122	.186
Average gambling frequency (times per week)	.110	.192	.048	.604
Number of DSM 5 ^f gambling disorder criteria	.374	< .001	.363	< .001
PG-YBOCS ^g total score	.345	< .001	.213	.019
PG-YBOCS urges subscale	.341	< .001	.183	.046
PG-YBOCS gambling behavior subscale	.307	< .001	.229	.012
Barrant Impulsiveness Scale				
Attentional	.328	< .001	.290	.001
Motor	.250	.003	.198	.032
Lack of planning	.236	.005	.088	.344
Legal problems due to gambling (yes/no)	2.5 (±2.1)/ 6.2 (±6.4)	.437	-.036	.439
Suicidality in past month (yes/no)	10.1 (±7.2)/ 4.5 (±5.2)	< .001	.040	< .001
Quality of life (Quality of life inventory)	-.343	< .001	-.292	.001

a) Correlation Coefficient = Spearman's correlation coefficient

b) Hamilton anxiety scale

c) SD = standard deviation

d) Significance was defined as $p \leq .004$ ($0.05/13 = 0.004$) for clinical variables.

e) Adjusted for: current major depression, alcohol-use disorder, substance-use disorder and nicotine use.

f) DSM 5 = Diagnostic and Statistical Manual of Mental Disorders – Fifth Version

g) PG-YBOCS = gambling adaptation of the Yale-Brown Obsessive-Compulsive Scale

TABLE 3 – Association between neurocognitive variables and anxiety level in non-treatment seeking gamblers (n = 143).

NEUROCOGNITIVE VARIABLES	Correlation Coefficient ^a	p value ^b	Adjusted Correlation Coefficient ^c	Adjusted p value ^c
Response inhibition (delay at the stop signal test) ^d	.051	.546	.047	.617
Decision-making (Cambridge gamble task)				
Quality of decision-making	-.093	.273	-.109	.243
Overall proportion bet	.124	.141	.128	.172
Risk adjustment	-.131	.120	-.169	.070
Cognitive flexibility (Intra-extra dimensional set shifting test)	.170	.044	.158	.091
Sustained Attention (rapid visual information processing)	-.235	.005	-.153	.101
Executive functioning (One touch stockings of Cambridge)	-.209	.014	-.102	.274

a) Correlation Coefficient = Spearman's correlation coefficient

b) Significance was defined as $p \leq .007$ ($0.05/7 = 0.007$) for neurocognitive variables.

c) Adjusted for current major depression, alcohol-use disorder, substance-use disorder and nicotine use.

d) The following measures were used: [delay at stop signal test] = stop-signal reaction time (ms); [Intra-extra dimensional set shifting test] = total errors (adjusted); [Rapid visual information processing] = proportion of targets detected; [One touch stockings of Cambridge]: problems solved in minimum possible number of moves.

Figure 1 – Association between severity of anxiety symptoms and level of suicidality in non-treatment seeking gamblers (n=138).

a) P value controlled for major depressive disorder, alcohol-use disorder, substance-use disorder and smoking.

b) The level of suicidality was defined by the MINI-score which assesses the risk of suicide in the past month. Suicidality is considered low (scores between 1 and 8 points), moderate (scores between 9 and 16 points) and high (scores ≥ 17).
