Abstract: Gender studies report a male advantage in several visuospatial abilities. Only few studies however, have evaluated differences in visuospatial planning behavior with regard to gender. This study was aimed at exploring whether gender may affect the choice of cognitive strategies in a visuospatial planning task and, if oculomotor measures could assist in disentangling the cognitive processes involved. A computerized task based on the Travelling Salesperson Problem paradigm, the Maps Test, was used to investigate these issues. Participants were required to optimize time and space of a path travelling among a set of subgoals in a spatially constrained environment. Behavioural results suggest that there are no gender differences in the initial visual processing of the stimuli, but rather during the execution of the plan, with males showing a shorter execution time and a higher path length optimization than females. Males often showed changes of heuristics during the execution while females seemed to prefer a constant strategy. Moreover, a better performance in behavioral and oculomotor measures seemed to suggest that males are more able than females in either the optimization of spatial features or the realization of the planned scheme. Despite inconclusive findings, the results support previous research and provide insight into the level of cognitive processing involved in navigation and planning tasks, with regard to the influence of gender.

1 **Introduction**

2 Literature on spatial cognition often reports gender differences [1, 2]. Males
3 typically perform better in tasks involving mental rotation, three-
4 dimensional figures, spatial orientation and maze navigation [3, 4], whereas
5 females are better at episodic memory tasks such as object location [5].

6 Many factors have been proposed for the gender differences found in
7 visuospatial processing including behavioural, neuroanatomical substrates,
8 hormonal and environmental [2, 6–9]. Despite these reasons, cognitive
9 processes sensitive to gender are restricted mainly to visuospatial or
10 linguistic features [10].

11 One aspect of gender differences not yet investigated in detail concerns
12 visuospatial planning. Planning is a fundamental cognitive function
13 frequently employed in common daily activities such as preparing meals,
14 housekeeping, managing financial matters and so on. It requires the
15 cooperation between several cognitive processes including strategy
16 formation, coordination of mental functions, recognition of goal attainment
17 and storage of representations. These guide movement from the “initial
18 state” to the “end state” of a desired goal. When circumstances demand an
19 immediate solution, pressure and speed can be associated with this and can
20 be overcome with rational planning, in which spatial orientation and
21 optimisation strategies are essential for obtaining the best solution. Many
22 studies [11] have shown that flexible coordination between mean-ends

23 analysis and cognitive abilities can favour the emergence of an
24 “opportunistic behavioural” approach, referred to as an “accuracy–effort
25 trade-off” [12] between competing decision-making strategies.
26 Planning seems to be based on the principle of “cognitive saving”, inducing
27 people to employ simple schemes to minimize the cognitive resources
28 required to achieve the result. According to this principle, several studies
29 [11, 13, 14] have shown that human planning is based on cognitive
30 heuristics. These are defined as behavioural schemas that can approximate
31 the correct solution, thereby requiring less cognitive resources than a
32 complete algorithmic process. Planning behaviour, by means of heuristics,
33 generates a strategy, which is a determined series of actions that guides the
34 subject through realisation to the solution of the problem [15]. The
35 application of a heuristic is not intended to be an exclusively automatic
36 process; rather people evaluate the efficiency of an action by comparing the
37 actual and future states of being, as performed by a feed forward process
38 [16]. Visuospatial planning tasks represent a subset of planning problems, in
39 which the items to be organised are described by visuospatial properties
40 such as position, whereas other characteristics (nature, attractiveness,
41 information) are irrelevant to the task. Examples of planning tasks in which
42 the visuospatial component is secondary (or not required at all) for
43 accomplishing the task are meal preparation [17], the towers of Hanoi and
44 London (in which items must be shifted to pass from an initial state to a goal

45 state) [18] and puzzles such as the missionaries and cannibals puzzle [19].
46 An example of visuospatial planning exists in maze-like tasks, in which
47 people have to organise a path through a series of locations. This is heavily
48 determined by the spatial relationships between the targets.
49 Previous studies on maze navigation have reported contradictory data on the
50 type of navigation strategy employed by females and males. For example,
51 Saucier and colleagues reported that females rely predominantly on
52 landmark cues, whereas males use both geometric and landmark cues [20].
53 Lawton and Kallai [21] later found that females show a greater tendency to
54 use landmarks and relative directions, whereas males use more cardinal
55 directions and distances, a pattern that has been replicated cross-culturally.
56 Recently, Mueller and colleagues suggested that women employ a strategy
57 based on memory, whereas males use spatial relationships [22]. Besides
58 these few studies, little attention has been paid to identifying how
59 performance and strategy might be qualitatively different between males
60 and females.
61 Gender differences in the optimisation and selection of spatial strategies
62 lead to different behavioural performances. The problem lies in finding a
63 suitable task that allows for these processes to be measured. One potential
64 solution might be to evaluate the involvement of visuospatial planning
65 abilities in a simulated environment using the Maps test, which is thought to
66 represent an abstract version of an everyday task. The computerised Maps

67 test [23], which represents an open version of the travelling salesperson
68 problem (TSP) [24], has been used to assess visuospatial planning.
69 Participants are required to minimize the total travel time and distance
70 among a number of locations [25, 26]. The TSP has been considered a
71 reliable tool for investigating planning behaviour because it requires
72 subjects to spontaneously generate a strategy, optimising the order of
73 locations with the aim of extracting a satisfactory path in a modelling space
74 without any spatial constraints [27]. In turn, the Maps task requires a
75 considerable and strong relationship between central and peripheral
76 processes, promoting a fundamental interaction of perceptual,
77 representational and executive components in the achievement of the final
78 goal [28]. These properties allow both genders to adopt, spontaneously (but
79 differently), several cognitive heuristics to optimise the path length. From
80 previous data obtained by visuospatial TSP-based tasks, such as the Maps
81 test and the City Map test [29–31], behavioural data indicated the presence
82 of three distinct spatially-based heuristics generating solving strategies and
83 showed that subjects often change heuristics when executing the plan [29].
84 The Maps paradigm has also been applied to explore differences between
85 genders. Bisiacchi and colleagues [32], for example, considered only the
86 execution time and pure length of the trajectories, finding that both males
87 and females achieved all sub-goals using a limited number of moves, with
88 males faster in programming and executing the task.

89 Other tests attempting to investigate planning processes are the Multiple
90 Errands [33, 34] and Virtual Errands tests [35]. In these, participants are
91 faced with a list of tasks to be accomplished in a local shopping centre. The
92 task consists of finding an efficient route by considering both spatial and
93 timing constraints. Although these tests examined the impairment of single
94 mechanisms of planning, they were not used to investigate gender
95 differences within the executive functioning context. Our intention was to
96 reduce the gap between gender studies and visuospatial planning analysis by
97 increasing knowledge and improving understanding in both fields of study.
98 Moreover, the investigation of oculomotor variables during the “plan
99 execution” process can provide insight into gender differences in the area of
100 planning behaviour. Eye tracking, for example, allows the investigation of
101 different visual scanning paths when males and females attend to a task by
102 computing vertical and horizontal movements during saccades or during the
103 evaluation of a region of interest within a fixation. It is well known that eye
104 movement behaviour changes according to the level of mental activity in
105 which an individual is engaged [36]. Moreover, eye movements are related
106 to the amount of actively processed material and represent a physiological
107 index of cognitive resource, memory and task demand [37, 38]. A recent
108 study by Mueller and colleagues [22] attempted to specify the visual
109 correlates underlying gender differences in spatial navigation using eye
110 tracking methodology. These researchers examined eye movements and

111 physiological correlates of memory to compare visual scanning of spatial
112 orientation using a virtual analogue of the Morris Water Maze task.
113 Although the behavioural data replicated previous findings of an improved
114 spatial performance for males, they also found that males consistently
115 explored more space earlier than females. These findings were also
116 supported by the fact that for females a significant positive correlation
117 emerged between pupil diameter (indicative of higher working memory
118 load) and performance efficiency despite the longer fixation durations
119 associated with poorer performance in both genders. Combining the Maps
120 Test with an eye movement tracking device while measuring the mental
121 workload required by males and females and disentangling the cognitive
122 strategies used in the accomplishment of the task could contribute to the
123 literature.

124 This study aimed to explore: (1) the level of cognitive processing at which
125 gender differences in visuospatial navigation occur; (2) whether eye
126 movements add further insight into the explanation of gender differences;
127 and (3) whether gender differences influence the choice of cognitive
128 strategies and the employment of “opportunistic behaviour”. The data
129 collected will help describe planning process characteristics for genders,
130 thereby increasing knowledge about the way males and females deal with
131 2D maps.
132

133 **Methods**

134 Performance times, qualitative measure of strategies and eye movement
135 behaviour (namely fixation number (NFix) and the fixation ratio (FR)) were
136 used to investigate both behavioural and oculomotor variables. On the basis
137 of Hayes-Roth and Hayes-Roth heterarchical architecture [11], it is
138 reasonable to expect that both genders employ an “opportunistic planning
139 behaviour”, in which they modify their ongoing plans with online
140 adjustments. According to previous research, people produce incomplete
141 plans at the beginning of a route and continuously make decisions along the
142 trajectory of task execution. In turn, with time and length constraints, gender
143 differences in visuospatial planning might be associated with using different
144 cognitive strategies during the task. Moreover, men enjoy a partial
145 advantage over women in performance execution and optimisation ability
146 when priority is given to the length path despite similar preplanning times.
147 This been widely found in literature, but the reasons behind this result are
148 still a matter of debate. The analysis of eye movements can provide
149 significant information on the visual exploration of an environment
150 represented from a survey point of view. If males exhibit an advantage in
151 behavioural performance and strategy selection, they are also expected to
152 produce less eye movements than females. This result implies that males
153 need less information to produce a representation/elaboration of the scene,
154 which also explains why males produce lower execution times than females.

155

156 ***Participants***

157 Thirty subjects (15 males, mean age = 24.40, SD = 3.34), students from the

158 University of Padua, participated in the experiment in return for course

159 credits. Participants were found to be strongly right-handed according to the

160 Edinburgh Handedness Inventory [39]. All had normal or corrected to

161 normal vision with no history of neurological or psychiatric disease.

162 Because of errors in eye movement data collection, three subjects were

163 excluded from analysis, thereby obtaining an overall sample of 27

164 participants (13 males, mean age = 24.18, SD = 2.89). Informed consent was

165 obtained from all participants. The experiment was approved by the ethics

166 committee of the Department of General Psychology of the University of

167 Padua.

168

169 ***Apparatus***

170 ***The Maps test***

171 ----- Place Figure 1 around here -----

172 Each trial of the Maps task presented a fictitious map of a number of

173 buildings blocks set out on a grid of seven vertical and five horizontal roads

174 (see Figure 1). The Maps test was composed of 30 visuospatial problem-

175 solving tasks; each of these situations was composed of seven sub-goals

176 (green-coloured circles placed at different intersections between the roads)

177 plus the final goal. Moreover, a blue square at the top left-hand corner
178 indicated the starting point and a red square at the bottom right-hand corner
179 represented the final goal. Starting at the top-left corner, subjects were asked
180 to move the silhouette (by pressing the arrow keys) to pass over each sub-
181 goal to reach the final goal located at the bottom-right corner. Subjects were
182 instructed to find the shortest route in the shortest time. A blue line showed
183 the step made at every movement of the silhouette, resulting in a feedback
184 of the followed trajectory.

185 A reaction time task was administered as an additional task of the Maps test
186 to calculate the planning index (PI; see further details on behavioural testing
187 section). A sequence of 25 stimuli measured the individual ability in the
188 pressing of the four possible arrow keys (4-choice RT). A sound with a
189 duration of 150 ms and frequency of 432 Hz was followed by a pre-stimulus
190 consisting of a human silhouette that appeared in the middle of the screen
191 within an interval between 200 and 1000 ms. A green circle would then
192 appear in one of four positions (up, down, left or right), displaced five
193 ocular degrees with respect to the silhouette. Subjects had to press the arrow
194 key as fast as possible to move the silhouette to get to the circle.

195

196 *Eye movement tracking*

197 Eye position and movements were measured in real time using an infrared
198 video-based system (Viewpoint™ Eye Tracker, Arrington Research, Inc).

199 Gaze position was determined by analysing eye position (collected at a
200 sampling frequency of 30 Hz). The system recorded horizontal (x) and
201 vertical (y) pupil positions with a monocular eye tracker camera. Calibration
202 and drift correction of the position signal were defined before starting the
203 experimental session and repeated during the experiment as necessary.

204

205 *Procedure*

206 The study was performed in a quiet and windowless room with the lights off
207 during behavioural testing. Subjects sat on a comfortable chair in front of a
208 PC screen positioned at 45 cm from their eyes. Subjects were tested in one
209 session lasting approximately 30 minutes. First, the sequence of 4-choice
210 RT was presented. Task instructions for the Maps test were then displayed
211 on the screen, and two practice maps were presented to let participants
212 familiarise themselves with the task. Participants were then prompted to
213 begin, and a randomised sequence of 30 Maps was presented separated by a
214 10 s inter-trial interval.

215

216 *Behavioural testing*

217 The computerised test automatically recorded information about the timing
218 and the sequence of errands achieved by the subject. For each trial of the
219 Maps test, the following measures were collected: preplanning time,
220 execution time, each intermediate time and number of key presses between

221 every couple of sub-goals (eight couples, originating the independent
222 variable location) and sub-goals achievement order.

223 Preplanning time is the time between the appearance of the sub-goals and
224 the subject's first movement. It can be considered the time that subjects use
225 to collect information on the situation and begin solving the task by
226 preparing a provisional plan. Execution time is the time taken for the subject
227 to execute the task, that is, between the first movement made and the
228 attainment of the final sub-goal (execution time excludes preplanning time).

229 Given that movements in the Maps test are segmented into steps (where
230 each step corresponds to an arrow key press), a modification of the
231 optimisation index proposed by Graham and collaborators [40] was used.

232 Accordingly, StepPAO indicates the percentage of steps made by the
233 subjects that are above the minimum number of steps required to execute
234 the tour [29]. In the Maps test, StepPAO is a measure based on the total
235 number of steps needed to complete the tour rather than the total tour length.

236 For each solution X_i made by a participant i of a map X , StepPAO is
237 calculated as follows:

238

$$239 \quad \text{StepPAO}(X) = [\text{Total Steps}(X_i) - \text{Optimal Steps}(X)] / \text{Optimal Steps}(X)$$

240

241 The optimal steps were calculated with an exhaustive search algorithm for
242 each map. The more the StepPAO of a tour X_i approximates to 0, the more

243 the corresponding trajectory is close to the optimal solution. This measure
244 was considered a reliable index of quality of the performance on a TSP-
245 based task in spatial terms (completing the time measures), and has been
246 repeatedly found as very low in humans [41, 42].
247 Furthermore, the PI was considered an estimate of the cognitive effort
248 devoted by the subjects to plan the route step-by-step [28]. This index was
249 created to obtain a succession of measures, each one filtered by the relative
250 distance of the sub-goals in the situation and the subjects' skills in key
251 pressing. It consisted of an array of eight measures calculated as follows.
252 The intermediate time between each sub-goal of the trajectory was divided
253 by the corresponding intermediate number of moves, and was then divided
254 by the 4-choice RT obtained by each subject.
255 The sub-goals achievement order was analysed using a procedure based on
256 the detection of heuristics and strategies (which emerged from the
257 combination of heuristics).
258 To detect the presence of a heuristic, four algorithms were run, each one
259 corresponding to a heuristic. As in a previous study by Basso et al. [29], the
260 analysed heuristics were: (1) a cluster heuristic (all the locations are
261 separated into distinct clusters, then afterwards all locations within the same
262 cluster are achieved before proceeding with the next cluster [43]); (2) a
263 nearest neighbour heuristic (the next location to achieve is the closest one
264 from the actual location [44]); and (3) two directional heuristics

265 corresponding to the vertical and horizontal directions (starting from a
266 border position, the next locations are achieved following an orientation
267 (horizontal or vertical) and a direction (up or down for vertical direction, left
268 or right for horizontal direction) [23]. Other kinds of heuristics could have
269 described the performance of the participants; however, given the spatial
270 constraints of this task (i.e., the regular grid, the limited number of streets)
271 this list was sufficiently appropriate [25] and feasible [23] to represent
272 human performance on the open version of the TSP.

273 For each sub-goal of each path, each algorithm detected whether the criteria
274 for its attribution were satisfied (for a complete description of the algorithms
275 see [28]). If this check returned a positive value for at least three successive
276 sub-goals within the path, then the corresponding heuristic was attributed to
277 that section of the path. Thus, each heuristic could result in one of the three
278 following patterns: (1) attributed to the *whole* path, (2) attributed to only a
279 *part* of it; or (3) *not* attributed at all in that path. All the heuristics could be
280 attributed either to the whole path, or to a part of it, except the cluster
281 heuristic; given that it divides the whole space into sectors, it can only be
282 used for the whole path. A certain part of the path could be representative of
283 more than one heuristic at a time, a case that cannot be avoided because it is
284 usually present in real life.

285 At the end of the mechanism of heuristic attribution, the resulting pattern for
286 each path generated one of these three types of strategy: (1) one or more

287 heuristics were attributed to the whole path (from the beginning to the end
288 of the path: constant strategy); (2) heuristics were used for only a part of the
289 path but covered the whole path when taken together (strategy with changes
290 of heuristic, also named flexible strategy); or (3) the four algorithms did not
291 indicate any heuristic or combination of heuristics which could cover the
292 whole path (no strategy).

293

294 Eye tracking testing

295 Data from the eye tracker was analysed through a custom-made code written
296 in Matlab (Version 7.0). As for the PI, eight measures of NFix, one for each
297 sub-goal, were obtained. An eye movement was considered a fixation when
298 the gaze resided inside a 1.5 degree field for a time greater than 170 msec.
299 First, we evaluated the relative vertical and horizontal gaze movement
300 vectors for each sampling point by selecting x and y positions at $time = n$
301 and $time = n + 1$. By summing eye position vectors, we obtained the eye
302 shift between each sampling point. To avoid eye movement effects related
303 to speed in visuospatial processing, we calculated the FR. As for the PI, the
304 FR was calculated for each sub-goal and was the ratio between the time
305 spent on fixations divided by the steps needed to move between a sub-goal
306 and the next one. Compared with NFix, the FR was not influenced by
307 individual differences in either the quality of execution or optimisation
308 level. Trials, containing either blinking or eye movements, occurring off

309 screen [45] as well as data 60 ms before and 60 ms after such an artefact
310 were also discarded (overall mean = 15%).

311

312 *Data analysis*

313 The following variables were used for the analysis. The array of values
314 included the PI (behavioural measures calculated for each sub-goal of each
315 path), NFix (frequencies of eye movements, obtained for each sub-goal of
316 each path) and FR (values of eye movements, calculated for each sub-goal
317 of each path). Single behavioural measures included preplanning time,
318 execution time, StepPAO (the value calculated from comparing to the
319 norm), strategy (given by the combination of heuristics) and four heuristics:
320 direction right (r), direction down (d), cluster (c) and nearest neighbour (n).
321 Given their structure, in analysing the PI, NFix and FR the variable
322 'location' was used to separate the effects of each segment of the path.

323 To test the hypothesis that males and females differ in the use of cognitive
324 strategies, differences in 'gender' were first investigated using a chi-square
325 analysis on the frequency of paths attributed to each 'strategy'. The no-
326 strategy was excluded because it was expected to provide too little data to
327 perform a reliable analysis. Differences in gender in the preference of
328 heuristics were assessed through a series of chi-square tests comparing
329 gender on the frequencies of the values of heuristics (used for the whole
330 path or only for a part of it), either separated for the four heuristics or

331 comparing them. Preplanning time, execution time and StepPAO underwent
332 a mixed ANOVA with gender as a between-subjects variable and type of
333 strategy (two levels: constant and with-changes strategy) as a within-
334 subjects variable. Because the choice of a particular strategy can produce
335 differences in the performance, the PI and eye tracking data were split
336 according to the strategy factor. Thus, a mixed ANOVA analysis was
337 performed with gender as a between-subjects factor (two levels) and
338 strategy and location (2×8 levels) as within-subjects factors on the three
339 dependent measures the PI, NFix and FR. To specifically evaluate the
340 impact of gender and strategy on each measure, we performed additional
341 post-hoc analysis (Bonferroni corrections with the alpha error threshold set
342 at 0.05) on the PI, NFix and FR for each location. Given that these measures
343 are composed of an array of values, a general evaluation was unsuitable for
344 catching the presence of single differences in specific items.
345 According to recent APA norms, partial eta-squared values (indicated with
346 the symbol η^2) were added to each F-value, whereas standard error means
347 were provided for each mean value.

348

349 **Results**

350 *Behavioural tests*

351 The chi-square test showed a relationship between gender and type of
352 strategy ($\chi^2(2) = 14.105, p < 0.001$; see Figure 2). Males employed roughly

353 the same number of constant (51%) and with-changes (46%) strategies
354 despite females prominently using constant strategies (64%) over strategies
355 with changes (33%).

356 ----- Place Figure 2 around here -----

357 The analysis of the heuristics evidenced that the two genders have different
358 preferences in the use of heuristics. Males were likely to choose direction
359 right heuristic ($\chi^2(3) = 51.897; p < 0.001$), whereas females preferred both
360 directional heuristics ($\chi^2(3) = 71.809; p < 0.001$).

361 Chi-square analysis was also applied to evidence distinctions in gender for
362 each heuristic, split for the two strategies. Differences because of gender
363 were noticed only when people used a constant strategy (restricted to cluster
364 and direction right heuristics; see Table 1).

365 ----- Place Table 1 around here -----

366 The mixed ANOVA analysis revealed that preplanning time was not
367 significantly different between males and females ($F_{1,26} = 0.011; \eta^2 < 0.01$;
368 Figure 3a). Conversely, a significant effect of the strategy factor was found
369 on preplanning time ($F_{1,26} = 5.140; p < 0.01; \eta^2 = 0.17$) and showed that the
370 time spent to plan a constant strategy was significantly shorter than the
371 amount of time needed when a subject used a strategy with changes (Table
372 2). No interaction was found between the gender and strategy factors on
373 preplanning time ($F_{2,26} = 3.081; n.s.; \eta^2 = 0.11$). Considering the execution
374 time, a main effect because of both gender ($F_{1,26} = 53.260; p < 0.001; \eta^2 =$

375 0.68) and strategies ($F_{2,26} = 29.400$; $p < 0.001$; $\eta^2 = 0.54$) was found,
376 showing significantly lower values for males than females in the execution
377 of the paths. However, execution time was lower when subjects employed
378 constant strategies. No interaction was found between gender and strategy
379 factors on execution time ($F_{2,26} = 2.031$; n.s; $\eta^2 = 0.08$).

380 ----- Place Table 2 around here -----

381 The analyses of StepPAO showed significant differences in both gender
382 ($F_{1,26} = 8.294$; $p < 0.01$; $\eta^2 = 0.25$) and strategies ($F_{2,26} = 5.555$; $p < .05$; $\eta^2 =$
383 0.18) factors (Figure 3b). Males produced shorter paths, whereas females
384 employed a higher number of steps. Moreover, a higher optimisation
385 performance resulted when participants implemented a strategy with
386 changes rather than a constant strategy. A marginally different interaction
387 was found between gender and strategy on StepPAO ($F_{2,26} = 3.913$; $p =$
388 0.06; $\eta^2 = 0.16$). The pairwise post-hoc analysis (Bonferroni corrected for
389 multiple comparisons, alpha threshold = 0.01) revealed a significant
390 difference for females in the optimisation performance when a constant
391 strategy was implemented.

392 The mixed ANOVA with gender, strategy and location as factors revealed a
393 main effect of gender on the PI ($F_{1,26} = 6.649$; $p < 0.05$; $\eta^2 = 0.21$).

394 Specifically, the amount of cognitive resources that females needed to
395 execute the paths was higher than that of males. Moreover, a main effect of
396 both strategy and location on the PI was found ($F_{1,26} = 18.892$; $p < 0.01$; $\eta^2 =$

397 0.43 and $F_{7,26} = 19.494$; $p < 0.01$; $\eta^2 = 0.44$ respectively). PI values were
398 higher for the strategy with changes, whereas both first and last values were
399 lower than the central ones, which were constant. A gender \times strategy
400 interaction was marginally significant ($F_{7,26} = 4.145$; $p = 0.05$; $\eta^2 = 0.14$),
401 whereas gender \times location ($F_{7,26} = 0.364$; $\eta^2 = 0.01$) and three-way gender \times
402 strategy \times location ($F_{7,26} = 0.644$; $\eta^2 = 0.03$) interactions were not. The post-
403 hoc analysis evidenced that gender differences were present only in the
404 second half of the path (Figure 3a).

405

406 *Eye movement results*

407 The mixed ANOVA revealed the significant effect of gender on NFix ($F_{1,26}$
408 $= 22.570$; $p < 0.01$, $\eta^2 = 0.47$). Post-hoc analysis showed that females
409 needed a significantly higher number of fixations than males (1.504 ± 0.050
410 vs. males 1.163 ± 0.052). A main effect of both strategy ($F_{1,26} = 5.534$; $p <$
411 $.05$) and location on NFix ($F_{7,26} = 3.130$; $p < 0.01$) was found, but the low
412 eta-squared values ($\eta^2 = 0.18$ and $\eta^2 = 0.11$ respectively) indicated that the
413 effects were weak. Post-hoc comparisons showed that participants made a
414 higher number of fixations using a strategy with changes rather than a
415 constant strategy (1.283 ± 0.032 vs. 1.383 ± 0.050).

416 The strategy \times location interaction reported a significant effect ($F_{1,26} =$
417 3.730 ; $p < 0.05$, $\eta^2 = 0.13$). The post-hoc comparison showed that, within
418 the constant strategy, only the sixth value was significantly higher than the

419 others, whereas the fifth and sixth values were higher than the last one in the
420 strategy with changes. Interactions between gender and strategy ($F_{1,26} =$
421 $3.125; \eta^2 = 0.11$), gender and location ($F_{7,26} = 0.320; \eta^2 = 0.01$) and gender
422 \times strategy \times location ($F_{1,26} = 1.209; \eta^2 = 0.06$) were not significant.
423 However, planned post-hoc comparisons showed that, in the females sample
424 only, NFix was higher for the strategy with changes (Figure 3b).
425 The results on the FR revealed a main effect because of gender ($F_{1,26} =$
426 $9.735; p < 0.01, \eta^2 = 0.28$). Females (mean = 0.474 ± 0.023) showed higher
427 FR values than males (mean = 0.371 ± 0.024). Moreover, a main effect of
428 location ($F_{7,26} = 27.052; p < 0.01; \eta^2 = 0.52$) but not strategy ($F_{1,26} = 0.006;$
429 $\eta^2 < 0.01$) was observed. The post-hoc comparison on location replicated
430 the pattern shown for the PI, with the first and last values lower than the
431 central ones. Although the other interactions failed to achieve a significant
432 value, the planned post-hoc comparisons showed interesting significant
433 effects. Genders were significantly different in locations 1, 2, 5, 6 and 8
434 (Figure 3c).

435

436 **Discussion**

437 The results of this study have supported previous findings that males tend to
438 have an advantage over women with regard to visuospatial skills [1, 46].
439 Moreover, new insights have been achieved using the several measures
440 collected with the Maps test. The analysis of heuristics and strategies

441 suggests that the difference between genders exists because of the
442 considerable use of flexible strategies by males compared with females, who
443 often employ strategies based on a heuristic that is constantly used
444 throughout the pathway. The general preference for directional heuristics,
445 substantially replicated in both genders, is characterised by the constraint of
446 the 2D environment of the Maps task, which was made of horizontal and
447 vertical streets. Because no statistical gender difference was found in
448 preplanning time, it might be suggested that the difference in strategy
449 selection is unrelated to this phase. The initial processing stage (including
450 representation of the environment and the first sketch of the plan) is unlikely
451 to be different between genders. By contrast, the faster execution times and
452 higher optimisation levels achieved by males strongly imply that the
453 differences found occurred during the execution of the task rather than in
454 the preplanning phase. This pattern of behavioural data points towards a
455 difference between genders because of their differences in the control and
456 management of strategies.

457 Previous literature [29] has suggested that the choice to use more flexible
458 strategies is preferable because it allows a greater number of possibilities in
459 the determination of the trajectory, although the selection and execution of a
460 constant strategy still allows the attainment of a satisfactory solution.

461 According to our results, males seem to be capable of reconsidering and
462 managing their previous choices and, consequently, can change their

463 heuristic when the current one is no longer suitable for achieving the desired
464 goal. Conversely, females tend not to change the initial plan. They instead
465 apply a schema of a resolution chosen from a set of candidates – the one
466 which best fits from a perceptual basis. We might consider female
467 navigation as egocentric navigation [47, 48], which is probably based on the
468 detection of anchor points (i.e., landmarks), as suggested by Sandstrom and
469 colleagues [49]. In the case of the Maps task, the concept of “egocentric
470 perspective” should not be intended as the correspondence between the
471 position of the actor in the real space and his/her representation on a map.
472 However, according to Witkin [50], a continuum exists between egocentric
473 and heterocentric perspectives. An egocentric strategy concerns the
474 assumption of an internal reference, minimizing the attention to external
475 stimuli. By contrast, a heterocentred strategy is based on an interaction
476 between internal aims and elements retrieved from the environment.
477 Females' general preference for egocentric strategies has recently been
478 found by Chen and colleagues [51] using a terrestrial/2D task (similar to the
479 one used in this study) where participants had to find a specific object
480 located at the bottom of a virtual aquarium. The performance of the female
481 sample in the you-are-here (YAH) condition was poor compared with males
482 in the same condition, and compared with their own performance in the
483 guide sign condition.

484 On the basis of these findings, it can be hypothesised that females are likely
485 to perform worse than males in spatial orientation because they tend not to
486 prefer configurational strategies, or because they cannot easily switch their
487 strategy according to the information retrieved from the environment. These
488 differences might concern components such as the “actual navigation or
489 imagined map scanning”, which Coluccia and Louse state are “less efficient
490 during an orientation task” [2].

491 We further hypothesised that gender differences in the PI and eye
492 movements could be explained by the different planning methods employed
493 by the two genders. The results obtained from the PI and FR supported this
494 hypothesis. The two measures (which are higher in women for most of the
495 pathway) suggest that gender differences influence the whole path
496 implementation until the final goal is achieved. The examination of eye
497 movements evidenced a reciprocal confirmation: the number of fixations
498 follows the same trend as the PI. Furthermore, the FR result provides
499 substantial proof of the reliability of the PI. Given that the PI and the ocular
500 measures are considered indices of cognitive effort, higher values in each
501 measure for females strongly suggest they need more cognitive resources to
502 solve the task.

503 The higher NFix in females could be because of poorer performance during
504 execution. Thus, it is reasonable to expect on average more fixations in
505 females than in males. Even though this might be a plausible assumption,

506 analysis of the FR denies this possibility. Because the FR was specifically
507 developed to be insensitive to the intermediate steps the difference between
508 genders is likely to be caused by different planning abilities.

509 Although the optimisation level is different for the two genders, females'
510 StepPAO values demonstrate they are capable of performing well.

511 Furthermore, when females used strategies with switches between heuristics
512 there were no gender differences in the optimisation level. This result
513 suggests that the difference in female performance completely exclude
514 explanations based on a lack of knowledge or use of heuristics. The low
515 performance of females might be because of either a lower ability to create
516 optimised plans (including switches and combinations of heuristics) or
517 realise the plan, as compared to males. However, this experiment did not
518 distinguish between the contribution of planning and more general executive
519 processes and it remains an area in need of further exploration. Nonetheless,
520 considering the trade-off between performance and cost, females appear to
521 be more conservative (aiming to reduce costs), whereas males tend to
522 maximize gain in both areas.

523 This proposes another possibility when considering gender differences in
524 risk-taking behaviour [52]. Males of various ages have been generally found
525 to take more risks than females in several activities. In particular, females
526 are less confident in assuming risks, and this led them to show higher results
527 in the Iowa Gambling task and the Betting task, as assessed by d'Acremont

528 and Van der Linden [53]. Given that the preference for a constant strategy
529 can be indicative of conservative behaviour (because the change of
530 heuristics implies abandoning the previous plan for a new one) a common
531 process might underlie both risk-taking behaviour and strategy choice. The
532 assumption could seem speculative, but the similarities between the two
533 aspects of decision-making behaviour have been hypothesised to originate
534 from an evolutionary system of self-protection [54] or a stronger
535 psychophysiological reaction to emotional stimuli [55].

536 Confusion remains as to whether gender differences occur in risk-taking
537 behaviour or because of a lower tendency to create complex plans (as well
538 as in the motor implementation or in the processing of visual stimuli). A
539 deeper exploration of both the perceptual properties of the environment and
540 the instructions of the task would be helpful to disentangle what “cognitive
541 effort” means in this case, that is, whether gender differences during the
542 execution of the plan are because of different representations of the
543 environment/task, the efficacy of the control process or the inhibitory
544 process that allows switching between heuristics. In fact, the strong route-
545 perspective provided by the Maps task might have strengthened the notion
546 that the difference is down to gender. The level of abstraction required to
547 take the first-person perspective [56], adopting the human silhouette as the
548 “me” moving into an environment, is strictly related to the means of
549 representing the locations into the egocentric/allocentric continuum [57].

550 Research using the YAH maps has shown how the presence of landmarks
551 can be modulated by the alignment of the map to the observer [58]. Thus,
552 genders can manipulate differently the perceptual data provided by the 2D
553 representation of the environment and the ability to easily control the frame
554 of reference. This could be a crucial factor in the emergence of a difference
555 in performance between males and females. This hypothesis has been
556 recently verified by Chen and collaborators [51] in their research
557 investigating way-finding tasks. Males (using more allocentric strategies)
558 showed better navigational performances than females (who used more
559 egocentric strategies). But when females were supplied with the appropriate
560 support (i.e., guide signs), gender differences were eliminated.

561 In conclusion, this research is the first attempt to explore gender differences
562 in the field of errand-planning behaviour by using the Maps test in
563 conjunction with oculomotor measures. Our findings confirm that a trade-
564 off between execution time and optimisation exists because of the human
565 tendency towards an opportunistic planning approach. Gender differences
566 modulate this concept. Our results confirm that a continuous planning
567 process is spontaneously implemented by both genders, but males are more
568 able to make adjustments to the initial plan. According to Mueller and
569 colleagues [22], the investigation of oculometric correlates underlying
570 differential male and female performances in spatial tasks has provided
571 substantial confirmation of the hypotheses on gender peculiarities in the

572 field of errand-planning behaviour. Although the origins of these differences
573 remain partially unknown, this paper provides additional evidence for the
574 peculiarities of genders in planning behaviour. People dynamically adapt
575 their choices to the environment, but within this visuospatial task males are
576 more skilful in adjusting previously made decisions.

728

729 **Captions**

730

731 Table 1.

732 Number of used heuristics, separated for Strategy (K=constant strategy;
733 wC=strategy with changes) and Gender. On rows are represented the 4 types
734 of heuristics (R=direction right, D=direction down, C=cluster, N=nearest
735 neighbor), while in columns frequencies are separated for the heuristic use
736 in the whole path or only for a part of it. The Chi-square analysis represents
737 the differences between the two genders: asterisks indicate a $p < 0.01$, while
738 plus signs indicate a $p < 0.05$. Cluster heuristic is not present within the
739 flexible strategies, since it can be attributed only to the whole path.

740

741 Table 2.

742 Means (+ S.E.M. in brackets) are represented separately for both genders
743 during Preplanning Time (sec.), Execution Time (sec.) and StepPAO
744 (steps), depending on the two kinds of strategies used by subjects.

745

746 Figure 1.

747 An example taken from the Maps task. The square in the upper left corner
748 represents the starting point, the square in the lower right corner represents
749 the end point, and the light circles represent the subgoals.

750

751 Figure 2.

752 Percentage of each type of strategy used by subjects on the total number of
753 paths presented. The percentages represent the amount of strategies used by
754 the subjects based on the absence of a strategy (light grey bars), based on a
755 constant heuristic (grey bars) and based on changes between heuristics
756 (black bars), with respect to the total number of paths performed by the
757 participants.

758

759 Figure 3.

760 In each of the graphs, data from the male group is represented by light lines
761 and data from the female group by dark lines. Mean values (+S.E.M.) are
762 separated for Gender (males: black colored lines; females: grey colored
763 lines) and for Strategy (constant strategy: solid lines; flexible strategy:
764 dotted lines), representing the three following measures:
765 a) Planning Index (PI); b) Number of fixations (Nfix); and c) Fixation Ratio
766 (FR).
