## **Abstract**

The yeast knockout collections provide opportunities to perform massively parallel phenotyping of deletion mutants for almost every yeast open reading frame. I used the knockout collection to screen for synthetic lethal partners, defined as alleles that cause lethality when combined but are nonlethal alone, with *CTF4* and *CTF18* and present the results in Chapter 2. I developed procedures for interpreting microarrays designed to compare changes in oligonucleotide TAGs specific to each knockout strain and present those methods in Chapters 3 and 4. These TAG microarrays allow thousands of experiments to screen for synthetic lethality among pairs of null alleles to be accomplished relatively quickly. In Chapter 4, I present 1410 novel predicted synthetic lethal interactions based on 707 currently completed screens. Interpretation of synthetic lethality is presented with a computational approach in Chapter 5, termed the congruence score. High congruence scores associate genes into common pathways, and I use the method to predict that *YLL049W* is a component of the dynein-dynactin nuclear orientation pathway. In Chapter 6, I propose a generalization of the congruence score to any phenotype, such as growth rate in the presence of various compounds, or even non-quantitative phenotypes such as cell morphology. This procedure connects genes based on similarity of multiple phenotypes using an application of information theory to produce a shared information score. Using gene ontology similarity, I show that high scores are associated with similarly annotated genes.

## **Preface**

My interest in biology began with an early introduction to advanced placement biology as a freshman in high school, followed by dual enrollment in biotechnology as a senior. Thanks to my teacher Dr Susan Behel, I performed my first restriction digests and PCRs before high school graduation in 1993. The importance of these early biology courses might be exemplified by the thesis of one of my high-school friends, also a beneficiary of Dr Behel's instruction. Dr Noel Southall is a self-described “expert on water,” which is accurate considering his biophysics dissertation on the hydrophobic effect.

This exposure to molecular biology led me to a position as a student research technician in Dr Ernest Hiebert's plant virology laboratory at the University of Florida Institute for Food and Agricultural Sciences. Dr Hiebert and his postdoctoral scientist Dr Ahmed Abouzid provided opportunities for me to learn various molecular biology techniques, and my summer work with another of Dr Hiebert's postdoctoral researchers, Dr Wayne Hunter, introduced me to electron and fluorescence microscopy.

The experience provided by my work in plant virology was a tremendous opportunity, and Dr George Agrios, the chairman of Plant Pathology, deserves great credit for the funding the department provided during my first year as a student assistant. When I met with my advisor, Dr F. William Zettler, during my first semester at the University of Florida and mentioned that I was interested in finding a job of that scope, he put me in touch with Dr Agrios, who was offering to fund research jobs for undergraduates. Dr Zettler was a great resource for me, and one of the reasons I chose

Plant Pathology as a second major in addition to Microbiology. With only 6 undergraduates in the program when I began, Plant Pathology was my true home department since Microbiology was full of approximately 100 times that many students, many of whom were in the pre-medicine track. While I experienced interesting coursework in the Microbiology department, Plant Pathology's Fifield Hall was where I learned truly applicable lessons.

Another important lesson from early in my undergraduate years was the ease with which seemingly insurmountable difficulties can be overcome when I have the support of my wife. Dr Rachel Wander-Peyser was my girlfriend at the time but she supported me utterly and continues to do so today. I experienced graduate school without her for one year at the University of Pennsylvania, and her absence was evidenced by the letter of academic probation that I received prior to leaving the program. I hope that my return to the University of Florida was helpful to her during veterinary school, but I know that she was essential to my success in graduate school at The Johns Hopkins University.

While my wife was becoming a veterinarian, I continued learning about biology as a senior lab tech and biological scientist in Dr Maureen Goodenow's pediatric HIV pathogenesis laboratory. My later interest in functional genomics began during my interactions with Dr Carter Coberley, who was a graduate student in Dr Goodenow's lab. Dr Coberley studied gene expression changes in cultured human macrophages infected with HIV using Affymetrix *GeneChips*. He and his wife, Dr Sadie Coberley, have been good friends and valuable advocates since then.

During my graduate school career I received significant help from many people,

including those acknowledged in following chapters, but some deserve mention here. My thesis committee members, Dr Geraldine Seydoux, Dr Susan Michaelis, Dr Neil Clarke, Dr David Cutler, and Dr Rafael Irizarry all provided helpful insights. Dr Cutler provided vital help in initiating the congruence score calculation described in Chapter 5, and he prevented huge wastes of time I would have otherwise endured with phenotypic similarity measures described in Chapter 6. Dr Irizarry was delightful to work with in the high-throughput synthetic lethality group, and he provided indispensable biostatistics expertise that made Chapters 3 and 4 possible.

The final committee member, my advisor Dr Forrest Spencer, deserves many thanks. I entered graduate school with more experience than most of my classmates, along with almost an expectation that graduate school would not end before some kind of screaming altercation with my mentor. In fact, Dr Spencer has been completely supportive and I have never been pushed to do undesired experiments or to follow questions that do not enthrall me. No amount of experience can guarantee a graduate student experience as enjoyable as mine has been.

Last, I must thank my son, Rohan Phineas Peyser. Rohan is almost one year old and is the best-behaved baby in the history of mankind. At times he allowed me to write this dissertation while my wife, Rachel, worked late, by playing quietly and looking at his books while the dogs played babysitter. I don't think he actually read any of his books on his own, but he does know the words "Mama," "Dada," and "uh-oh."

## **Chapter 1.**

### **Introduction**

A significant advance in our ability to understand the biological pathways required for life was made by the introduction of the yeast knockout (YKO) collections (Giaever et al. 2002). These collections of *Saccharomyces cerevisiae* deletion mutants contain strains with defined null alleles for > 95% of predicted open reading frames (ORFs) in the yeast genome. Strains were created in haploid *MATa* or *MATα* backgrounds, *MATa/MATα* diploids (*ykoΔ/ykoΔ*), or as heterozygous diploids (*YKO/ykoΔ*). Each mutant was created by homologous recombination with selectable marker KanMX4, consisting of a constitutive promoter from *Eremothecium gossypii* (*Ashbya gossypii*) fused to *nptI*, the kanamycin resistance gene.

The KanMX4 module was amplified in a polymerase chain reaction (PCR) using 74–75 bp oligonucleotide primers designed specifically for each deletion mutant. The primers contained, from 5' to 3', 18 or 19 nucleotides of homology to KanMX4 (U2 or D2), a 20 base TAG sequence particular to the targeted ORF, an 18 base universal priming site (U1 or D1), then 18 bases of sequence homologous to the 18 bp immediately up- or downstream of the predicted ORF. A second PCR was performed with the first product as template, using primers with homology to the 45 bp immediately up- or downstream of the ORF. This second PCR resulted in a construct with (from 5' to 3'): 45 bp of homology to sequence immediately upstream of an ATG start codon, an 18 bp universal primer sequence (U1), a 20 bp “barcode” sequence (UPTAG) specific to the deletion mutant, the KanMX4 module, a 20 bp DNTAG, another 18 bp universal primer (D1), then 45 bp of homology to the genomic sequence immediately downstream of the stop codon (Winzeler and Shoemaker et al. 1999; Giaever et al. 2002; <http://www->

[sequence.stanford.edu/group/yeast\\_deletion\\_project/deletions3.html](http://sequence.stanford.edu/group/yeast_deletion_project/deletions3.html)). The end result was a collection of YKO strains with specific ORFs precisely deleted, each marked with oligonucleotide TAGs and the KanMX4 G418-resistance cassette.

Fewer than 20% of these deleted ORFs are required for survival on rich glucose medium. While the essential genes provide important functions, a large majority of ORFs encode proteins that are not required for growth under any standard laboratory condition. This suggests that many yeast genes are evolutionarily retained for their ability to buffer genetic variation in other genes (Hartman et al. 2001).

Alleles that are lethal in combination but individually nonessential are termed “synthetic lethal” (Dobzhansky 1946). Sometimes this occurs when a point mutation in a component of an essential protein complex is combined with a point mutation from another component of that same complex (Potenza et al. 1992; Appling 1999). The combination of point mutations results in failure to organize the essential complex and therefore, death of the cell. When considering null mutations, dispensable genes may be buffered by another pathway, which results in lethality when components of the buffering pathway are removed (see Guarente 1993).

This genetic buffering due to parallel pathways is the current focus of study due to introduction of the YKO collections. Multiple studies have been performed using the entire set of viable deletion mutants to screen for synthetic lethality. Some of these studies use arrays of individual YKOs combined with a query mutation and score genetic interaction based on direct measurement of colony size (Tong et al. 2001; Tong et al. 2004; Tong and Boone 2006). This method is termed synthetic genetic array (SGA) or

epistatic miniarray profile (E-MAP) for a subset approach to SGA (Schuldiner et al. 2005; Collins et al. 2006; Schuldiner et al. 2006; Collins et al. 2007). Other approaches estimate growth defects by microarray hybridization of the oligonucleotide TAGs from samples grown competitively in a pool, known as synthetic lethality analyzed by microarray (SLAM) (Ooi et al. 2003), or diploid-based SLAM (dSLAM) (Pan et al. 2004; Pan et al. 2007).

The rapidity of SLAM provides an opportunity to create all ~25 million double mutant combinations and probe their growth rates using microarrays. We have begun this process and have currently completed about 1/7 of the genome (see Chapter 4). With genome-wide synthetic lethality information, pathways responsible for growth can be deduced based on the pattern of interactions (see Chapter 5). The null alleles provided by the YKO collections exhibit synthetic lethality between genes in separate, related, parallel pathways (Guarente 1993).

Other experiments have assigned genes to common pathways based on similarity of expression patterns (see Hughes and Marton et al. 2000 for a landmark study of this kind). However, this approach simply finds common transcription modules, which is not the same as common pathways. Genes that function in the same pathway often share transcription control mechanisms, for example, the *lac* operon in *Escherichia coli*. Comparison with data from functional profiling of the YKO collections shows that genes up-regulated in response to specific treatments are rarely included among those genes required for optimal growth in those same conditions (Giaever et al. 2002; Birrell et al. 2002). This argues for use of YKO phenotypes rather than expression patterns to assign

pathway membership, and in Chapter 6 I present a calculation that uses a collection of these phenotypes to align genes into common pathways.

## **Chapter 2.**

### **Examining the functions of CTF4 and CTF18 with global synthetic lethality screens**

This work contributed to the publication:

Warren CD, Eckley DM, Lee MS, Hanna JS, Hughes A, Peyser B, Jie C, Irizarry R, Spencer, F. 2004. S phase checkpoint genes safeguard high fidelity sister chromatid cohesion. *Mol Biol Cell* 15:1724–35.

## **Introduction**

In budding yeast, *CTF4* and *CTF18* are required for robust sister chromatid cohesion (Hanna et al. 2001). This cohesion is carried out by the essential Cohesin complex, consisting of Scc1p, Scc3p, Smc1p, and Smc3p (reviewed in Nasmyth 2001). Sister chromatids are produced and cohesion is established during S phase (Skibbens et al., 1999; Toth et al., 1999). The association of sister chromatids must be maintained until anaphase, when sister chromatids are split resulting in one of each chromosome in the daughter nucleus.

When cells are arrested at metaphase by depolymerization of microtubules, cohesion failure occurs rarely in wild-type yeast, but *ctf4* $\Delta$  and *ctf18* $\Delta$  mutants exhibit failure in ~30% of cells, a significant increase (Hanna et al. 2001; Mayer et al. 2001). When *ctf4* $\Delta$  and *ctf18* $\Delta$  alleles are combined in the same cell, yeast are unable to survive (Miles and Formosa 1992; Formosa and Nittis 1999). This genetic interaction is termed synthetic lethality, and provides information about what functions are required in the absence of some other nonessential function. In order to more fully understand the roles of *CTF4* and *CTF18* in contributing to sister chromatid cohesion, we searched for other synthetic genetic interactions using a genome-wide screen.

## **Materials and Methods**

### **Random Spore Analysis**

A set of candidate synthetic lethal interactions produced by J. Hanna using a haploid synthetic lethality analyzed by microarray (SLAM) method (Ooi et al. 2003) prior to my

involvement was tested against both *ctf4Δ* and *ctf18Δ* using random spore analysis. Candidate *MATa* deletion mutants (*ykoΔ::KanMX*, *yko* represents yeast knockout) from the YKO collection (Giaever et al. 2002) were mated to strains YJH96 (*MATa ctf4Δ::NatMX can1::MFA1pr-HIS3*) and YJH97 (*MATa ctf18Δ::NatMX can1::MFA1pr-HIS3*) on solid yeast extract, peptone, dextrose media (YPD), and diploids were selected on solid YPD +200 μg/ml G418 (Cellgro, Herndon VA) +100 μg/ml clonNAT (Hans-Knöll Institute für Naturstoff-Forschung, Jena Germany). The resulting heterozygous diploids were replica-plated onto solid sporulation media and grown at 25 °C for 5 d. Following sporulation, a swatch of cells was transferred into 500 μl of sterile dH<sub>2</sub>O and briefly sonicated to break apart cell clumps, then 10, 20, or 40 μl were plated on solid haploid selection media (synthetic complete –His –Arg +50 μg/ml canavanine [Sigma-Aldrich, St Louis MO]) to select all *MATa* spores, +200 μg/ml G418 to select single mutants, or +200 μg/ml G418 +100 μg/ml clonNAT to select double mutants, respectively. Monosodium glutamic acid (1 g/l) replaced ammonium sulfate in synthetic media when G418 or clonNAT selections were applied. Growth of double mutant colonies was compared to single mutants after 42 h at 30 °C, and double mutants that failed to grow or grew more slowly were scored as synthetic lethal or fitness defect.

### **Synthetic Lethality Screen**

Screens for synthetic lethal mutants were repeated using an early diploid-based SLAM (dSLAM) method (Pan 2007). Heterozygous diploid yeast knockout (YKO) strains (Research Genetics) were pooled, then modified by introducing *can1Δ::MFA1pr-HIS3*, a *MATa* haploid selection marker (Tong et al. 2001), by transformation *en masse*

with the targeting construct (gift of X. Pan, Baltimore). This haploid-convertible pool was transformed with a PCR construct consisting of ~2 kb genomic sequence surrounding *CTF4* on either side of the *NatMX* nourseothricin resistance cassette. In parallel, transformations were performed with *ura3Δ::NatMX* to serve as a control. Approximately  $5 \times 10^5$  transformants were selected on solid YPD + 200 μg/ml G418 +100 μg/ml clonNAT. These double mutant heterozygous diploids were scraped into a pool of  $\sim 2 \times 10^8$  cells and cultured in liquid sporulation media for 7 d. The cells were checked for asci to verify sporulation, then cultured on solid SC –His –Arg +50 μg/ml canavanine +G418 +clonNAT to select for  $\sim 10^6$  *MATa* haploid double mutants. Each experiment was performed in duplicate.

### **Tag Microarray Hybridization**

Haploid double mutants were collected and  $\sim 2 \times 10^8$  cells were used to prepare genomic DNA. Biotin-labeled UPTAGs and DNTAGs were generated from each sample using ~200 ng genomic DNA as template in a PCR with biotinylated primers as previously described (Giaever et al. 2002). PCR products were separated from unincorporated primers using Microcon YM-10 columns. These labeled UPTAGs and DNTAGs were combined and hybridized to Tag3 arrays (Affymetrix) as described (Giaever et al. 2002).

### **Microarray Analysis**

Signal intensities were read from Affymetrix “.cel” files into R (Ihaka and Gentleman 1996) and analyzed using the Bioconductor *affy* package (Gautier et al. 2004) and custom script. Perfect match and complement perfect match signal values were

averaged, then  $\log_2$ -transformed. Mismatch probes were not used. TAGs from all essential genes and TAGs that had signal intensities lower than 97% of all essential genes on both URA3 control chips were removed from the data separately for UPTAG and DNTAG. Remaining UP- and DNTAGs were then quantile normalized (Bolstad et al. 2003). All pairwise  $\log_2$  ratios were generated between experiment and control chips ( $\log_2[ura3a/ctf4a]$ ,  $\log_2[ura3a/ctf4b]$ ,  $\log_2[ura3b/ctf4a]$ , and  $\log_2[ura3b/ctf4b]$ ), and then averaged. For comparisons of known synthetic lethal/fitness defect results with genes tested with no interaction, the UP- and DNTAG  $\log_2$  ratios were averaged. When one of the TAGs was filtered, the other value was used. For candidate interactions the larger of UP- or DNTAG  $\log_2$  ratio was used, and any YKO with a log ratio  $\geq 1.1$  and  $|\log_2(ura3a/ura3b)| \leq 0.75$  was chosen.

## Results

The combined function of *CTF4* and *CTF18* is not optional for viability in yeast. This suggests that each gene provides some similar function in parallel, either one of which is nonessential. Using random spore analysis, we examined synthetic lethal or fitness defect interactions in both *ctf4* $\Delta$  and *ctf18* $\Delta$  backgrounds to examine the requirements of each mutant. Selection of *MATa* haploid spores with varying marker requirements was made possible by *MFAlpr-HIS3* and *canI<sup>R</sup>* (Tong et al. 2001). Random spore analysis displayed differences in growth rate between single and double mutants as smaller colonies under double selection. We tested 84 potential interactions with both *ctf4* $\Delta$  and *ctf18* $\Delta$  and an additional 18 interactions with *ctf4* $\Delta$  alone. Interactions were scored without knowledge of the identity of each mutant, and given a score of 0 (no

interaction), 1 (slight fitness defect), 2 (fitness defect), or 3 (lethal). Figure 1 shows examples for each level of fitness defect. This random spore analysis revealed synthetic fitness defects with *ctf4*Δ for 31 of the 102 genes (Table 1). Of these, only *ctf18*Δ (*chl12*Δ) had been previously reported (Formosa and Nittis 1999). We also found 13 genetic interactions with *ctf18*Δ. Among the 15 interactions exhibited by *ctf4*Δ for which we have information on *ctf18*Δ, 12 also interacted with *ctf18*Δ. The shared interactions suggest that *CTF4* and *CTF18* provide similar functions—loss of either one is lethal in cells lacking *CLB2*, *FUR4*, or *HPR5*.

We performed a microarray-based synthetic lethal screen (see Ooi et al. 2003 and Methods) to search for additional nonessential genes that require *CTF4*. This technique examines the relative abundance of “barcode” TAGs uniquely marking each deletion mutant (Shoemaker et al. 1996) in two populations of pooled yeast knockout strains (Giaever et al. 2002). A pool of 5916 *YKO/yko*Δ::*KanMX* mutants was transformed *en masse* with a *ctf4*Δ::*NatMX* deletion construct, to generate a heterozygous pool of double mutants. Replacement of *ura3*Δ0 with *ura3*Δ::*NatMX* was performed in parallel to serve as a control. Haploid *MATa* double mutants were selected from each pool and the relative representation of each *yko*Δ::*KanMX* mutant was compared between *ura3*Δ::*NatMX* and *ctf4*Δ::*NatMX* (control:experiment). For those mutants unable to grow in the presence of *ctf4*Δ, we expect to find a large control:experiment ratio.

Microarray results for *ctf4*Δ suggested synthetic lethal interactions for many of the known genes as well as some new potential interactions (see Table 2, pursued in Warren et al. 2004). The average log<sub>2</sub> ratio was significantly correlated for the known mutants

(Figure 2). The Spearman correlation coefficient was 0.57 for mean  $\log_2$  ratio versus interaction score, with  $P < 0.001$ . The  $\log_2$  ratios were significantly higher for known synthetic lethal compared to known healthy ( $P = 5 \times 10^{-7}$ ), for known synthetic fitness defect versus known healthy ( $P = 1 \times 10^{-7}$ ), and synthetic lethal pairs displayed higher ratios than synthetic fitness defect pairs ( $P = 0.03$ ) by the Wilcoxon rank sum test. The median and interquartile ranges were 1.01 and 0.71 to 1.55, 0.57 and 0.26 to 0.74,  $-0.03$  and  $-0.24$  to 0.17 for known synthetic lethal, synthetic fitness defect, and known healthy, respectively.

## Discussion

We discovered 30 novel synthetic genetic interactions with *ctf4* $\Delta$ . These interactions provided interesting targets for analysis of sister chromatid cohesion (Warren et al. 2004). One interesting result is the lethal phenotype observed in *ctf4* $\Delta$  *fur4* $\Delta$  double mutants (Table 1). *FUR4* encodes uracil permease, providing a route for entry of uracil in the culture medium into the cell. The *ctf4* $\Delta$  strains we used were Ura<sup>+</sup>, without which *fur4* $\Delta$  cells would not survive on synthetic media. However, even in a Ura<sup>+</sup> cell, loss of the ability to take up uracil could affect the levels of UMP, and therefore UTP and CTP, due to decreased flux through the salvage pathways of pyrimidine ribonucleotides. Rather than generating UMP from uracil through the salvage pathway, *fur4* mutants must utilize the de novo biosynthesis pathway. This could impact levels of PRPP and reduce the availability of purines and deoxyribonucleotides as well. Since *CTF4* is involved in DNA replication, it is possible that stress to the availability of deoxyribonucleotides during DNA synthesis may cause DNA damage that requires *CTF4* for proper resolution.

The importance of *CTF4* in relation to DNA damage is reinforced by the synthetic lethal phenotypes with *hpr5* $\Delta$  and *mrc1* $\Delta$ . *HPR5* (*RADH/SRS2*) is a helicase involved in DNA repair (Aboussekhra et al. 1989; Rong and Klein 1993), and *MRC1* activates the S-phase checkpoint in response to DNA damage (Alcasabas et al. 2001). These interactions suggest that *CTF4* can provide an alternative DNA damage response, or that *CTF4* is required to properly replicate chromosomes in the face of increased DNA damage.

## **Abstract**

*Saccharomyces cerevisiae* knockout collection TAG microarrays are an emergent platform for rapid, genome-wide functional characterization of yeast genes. TAG arrays report abundance of unique oligonucleotide ‘TAG’ sequences incorporated into each deletion mutation of the yeast knockout collection, allowing measurement of relative strain representation across experimental conditions for all knockout mutants simultaneously. One application of TAG arrays is to perform genome-wide synthetic lethality screens, known as synthetic lethality analyzed by microarray (SLAM). We designed a fully defined spike-in pool to resemble typical SLAM experiments and performed TAG microarray hybridizations. We describe a method for analyzing two-color array data to efficiently measure the differential knockout strain representation across two experimental conditions, and use the spike-in pool to show that the sensitivity and specificity of this method exceed typical current approaches.

## **Introduction**

Introduction of the yeast knockout collections, containing arrayed strains harboring deletion mutations for > 95% of predicted open reading frames (ORF), allows systematic genome-wide screens for various phenotypes to be readily accomplished (Winzeler and Shoemaker et al. 1999; Tong et al. 2001; Giaever et al. 2002). One aspect of the knockout collections that facilitates rapid screens is the pair of unique 20 nucleotide TAGs within each deletion mutation (Shoemaker et al. 1996). A gene in each yeast knockout strain (YKO) is replaced with a selectable marker flanked by two TAGs, termed UPTAG and

DNTAG. All UPTAGS or all DNTAGs in a sample can be amplified in a PCR reaction using universal primers. Individual YKO representation is subsequently interrogated by hybridizing labeled TAGs to microarrays and observing changes in signal intensity between experimental conditions. This approach has been applied to genome-wide screens for mutant phenotypes (Ooi et al. 2001; Giaever et al. 2002), synthetic genetic interactions (Ooi et al. 2003; Warren et al. 2004; Lee and Spencer, 2004; Arevalo-Rodriguez et al. 2004; Pan et al. 2004) and synthetic-chemical-genetic interactions (Pan et al. 2004). TAG microarray approaches are rapid and comprehensive, but systematic optimization of analysis methods is lacking. We address this need here.

The most common application of TAG arrays is comparison of YKO representation in two samples. Typically, samples are co-hybridized on one array using complementary fluorescent labels (Cy5 and Cy3). Various general approaches for two-color arrays have been proposed for quality assessment, background adjustment (Kooperberg et al. 2002; Yang et al. 2002) and normalization (Kerr et al. 2000; Dudoit et al. 2002; Huber et al. 2002). However, in analysis of TAG arrays, each YKO has UPTAG and DNTAG probes; four measurements corresponding to each YKO are obtained. Finding the best way to summarize this information in one quantity reflecting differential YKO representation is not trivial (Irizarry et al. 2003). Here we demonstrate the utility of a spike-in experiment by evaluating a simple quality assessment procedure and a novel strategy for combining the UPTAG and DNTAG information in a way that is robust to problematic TAGs. Our results show that implementing these two data procedures can greatly improve the utility of TAG arrays.

## **Materials and methods**

Preparation of spike-in pools. Heterozygous YKO (Research Genetics) were grown on solid media and combined, with the exception of YKO from plate 259 which were separately mixed in subpools, as shown in Figure 1, before incorporation into pool A or B at appropriate representation levels. Genomic DNA was extracted from samples of each spike-in pool using the Masterpure Yeast DNA kit (Epicentre). Pool A and B TAGs were labeled with Cy3 and Cy5, respectively, and TAG microarrays were hybridized, washed and scanned as described (Yuan et al. 2005).

Analyses were performed using custom scripts written in R, an open-source statistical language (Ihaka and Gentleman 1996). GenePix local background intensities were not used for correction because, as suggested by Yang et al. (2002), subtracting these severely increases noise (data not shown). Normalization was performed using a procedure similar to the one previously proposed (Dudoit et al. 2002). Alternate normalization methods did not impact results (data not shown).

The GEO accession number for microarray data is GSE2832. Data and code necessary to reproduce all the results and figures are available upon request.

## **Results**

To evaluate statistical procedures for TAG microarray data, we tailored defined spike-in pools to resemble expected results in a typical synthetic lethality analyzed by microarray (SLAM) experiment (Ooi et al. 2003). Synthetic lethality is defined as inviability of cells containing two mutations which are individually not required for

growth. In a SLAM experiment, viable YKOs in pooled form are compared under two conditions: absence versus presence of a specific second mutation (the ‘query’). The average number of genetic interactions expected in a genome-wide screen has been estimated to be ~35, although several query mutations with interactions exceeding 100 have been analyzed (Pan et al. 2004; Tong et al. 2004). Therefore, we designed a pair of pools (‘A’ and ‘B’) with 5758 YKOs at equivalent representation, and a set of 94 YKOs with known differential representation ranging from 1:2<sup>1/5</sup> to 1:2<sup>5</sup> and 1:infinity (Figure 1 and Supplementary Table 1). Additionally, certain YKOs grow slowly, and representation of these in the control SLAM sample is expected to be lower than YKOs with wild-type growth rate. To examine our ability to address these mutants, we designed three representation levels in the control (B) pool: high (about equal to all other strains), medium (8-fold dilute) and low (64-fold dilute). TAGs from pools A and B were amplified with Cy3- and Cy5-labeled primers, respectively. These samples were mixed at equal ratio, such that most TAGs should exhibit equal hybridization, while Cy5: Cy3 ratios that deviate from one are expected for the few differentially represented TAGs. This design allows discovery of the best method to produce a measure of differential representation from hybridization results.

Before addressing differential representation, we document the utility of two filtering steps in data pre-processing. First, we noted TAG-specific hybridization artifacts evident in self-self hybridizations performed to examine the noise distribution. Pool A DNA served as template for preparation of labeled TAGs with both Cy5 and Cy3. Thus, all TAGs were present at equal amounts between channels. Figure 2a shows a scatterplot

of normalized  $\log_2$  Cy5: Cy3 ratios for corresponding UPTAG and DNTAG probes. Because all these values should be zero plus measurement error, we expect these to be uncorrelated and centered at zero. Figure 2a confirms this except for a few YKOs with extreme values for one TAG. These outliers may have a negative impact on specificity. They are likely to be due to individual tag templates that enter the labeling PCR as contaminants, which are detectable even at very low levels (Yuan et al. 2005).

We determined that these artifacts are consistent across experiments performed with a single batch of labeled primer, but not between different primer batches (Supplementary Figure 1). To create a useful filter, we assumed that the data follow a bivariate normal distribution and defined outliers as TAGs with log ratios three SDs away from zero, using a robust estimate of the SD. If the log ratio data follow a normal distribution, excluding outliers, we expect to inappropriately remove only ~0.5% of the data (32 TAGs). We applied this filter (Figure 2a, red lines) independently to UP- and DNTAGs. Fortunately, the YKOs were designed with two TAGs per gene (except for 192 strains lacking DNTAGs), greatly improving chances that at least one TAG performs adequately. Because non-outlier UP/DNTAGs appear to provide independent measurements, the chance of inappropriately removing both TAGs for the same YKO is less than 0.000 01. Using this procedure we defined 193 DNTAGs (purple circles) and 244 UPTAGs (blue circles) as primer-batch specific outliers. Six YKOs had both UP and DN ratios filtered (orange circles).

Next, we considered the effect of TAG-specific hybridization behavior resulting from the presence of nucleotide mutations found in some of the TAGs and universal

priming sites (Eason et al. 2004). This is important because sensitivity will be markedly affected when TAGs fail to provide a meaningful measure of strain representation. Histograms of  $\log_2$  signal intensity display a bimodal distribution (Figure 2b and data not shown) for UP- and DNTAGs whether Cy3 or Cy5 labeling is used. The lower peak is close to background intensities and contains nonfunctional TAGs with absent or inefficient hybridization. While TAG sequence discrepancies have been characterized (Eason et al. 2004), knowledge of the presence and nature of mutations was insufficient to fully predict hybridization behavior (Yuan et al. 2005; Eason et al. 2004).

The naïve approach to summarizing UP- and DNTAG information is to average their observed log ratios. This solution will yield suboptimal measures when one of the TAGs is non-functional. We propose a procedure exploiting the bimodal distribution of TAG intensities to improve on simple averaging. To determine if a TAG is non-functional we fit a mixture model, as in Irizarry et al. (2003), to the log intensity data for the control sample. The model fits two normal distributions to the Cy5 data, one for the lower mode and one for the upper mode. The ‘blank’ (YQL) features (Yuan et al. 2005) define the location and width (mean and SD) of the lower distribution. With this fitted model in place, we can predict the probability that each TAG is ‘present’ (Figure 2b). We consider a DN/UPTAG non-functional when it is predicted absent while the complementary UP/DNTAG is present. We define a weighted average =  $w * UP + (1 - w) * DN$ , where  $w = 0.5 + [P(UP \text{ present}) - P(DN \text{ present})]/2$ . Thus, when UP is present ( $P_{UP} = 1$ ) and DN is absent ( $P_{DN} = 0$ ),  $w = 1$  and only UPTAG is used (Figure 2c). We describe a less complex procedure in Supplementary Note 1 that uses binary absent or

present values ( $P = 0$  or  $1$ ) and performs similarly (data not shown). Researchers using unsophisticated analysis software such as spreadsheet applications may prefer the simple procedure.

We compared the performance of these two strategies and use of UP- or DNTAGs alone with Receiver Operating Characteristic (ROC) curves based on the spike-in experiment. For this analysis, nominal ratios below 2-fold were excluded from the list of True Positives. This choice is appropriate because 2-fold representation difference corresponds to a subtle growth defect at the margin of detection in colony measurement (1.25-fold colony diameter difference is predicted by hemispherical colony volume =  $2\pi r^3/3$ ). Supplementary Figures 2–3 present ROC curves with varying stringencies for inclusion as ‘True Positive’, including every spiked-in YKO (1.26-fold or higher). ROC curves in the range of false positives likely to be acceptable (Figure 3a and Supplementary Figure 2) demonstrate that the artifact filtering process has a significant effect on specificity (Supplementary Figure 4 shows the full ROC curves). Additional filtering of non-functional TAGs by the weighted average improves results further (Figure 3b and Supplementary Figure 3).

The effect of two filters, one which removes the systematic artifacts and a second which removes non-hybridizing TAGs, is demonstrated by ratio-intensity plots. A naïve approach to analysis would average UP and DN log ratio to produce a measure  $M$  for relative strain representation. By filtering systematic artifacts, noise is significantly reduced (Figure 3c and d, open circles and Supplementary Figure 5). Additionally, combining UP and DN selectively provides increased sensitivity for a number of spiked-

in strains (filled shapes).

## **Discussion**

In summary, we present a spike-in pool design that allows evaluation of various methods for generating measures of differential strain representation. Using this experiment, we determined that the largest factor affecting specificity is the presence of primer batch-specific artifacts, evident in control self-self hybridizations. These artifacts may result from extremely low levels of contaminating TAG sequence template introduced before the labeling PCR. Accidental introduction of contaminants may occur at multiple steps, including the high-performance liquid chromatography (HPLC) column purification of Cy5- and Cy3-labeled primers at their manufacture as well as laboratory manipulation of primer batches during initial stock and aliquot preparation. Because the artifacts are consistent only within batches of primer sets, contamination must occur at initial preparation or during manufacture. Yuan et al. (2005) discuss the unusually large dilutions required to prevent contamination in TAG labeling reactions. While the source of these artifacts is uncertain, there are several options for minimizing their effect. The approach we present uses a control hybridization of one DNA sample labeled with both primer sets, such that every TAG is present at equal amounts in the two labeling reactions. Deviations from expected 1:1 ratio can be recognized and filtering is applied.

The methods we describe improve detection of true signal difference between samples; however, they are not perfect. Once primer-batch specific artifacts are removed, noise is increased slightly with the weighted average method compared to averaging (see Supplementary Figure 5d and e). Additionally, the weighted average could cause

decreased sensitivity when cross-hybridization occurs for one TAG from a low represented strain. The TAG that accurately reflects the low representation of the YKO may be discounted while the cross-hybridizing TAG is emphasized. These problems could be minimized by improving the criteria for selecting a TAG as non-hybridizing, perhaps by examining behavior across many microarrays. The advantage of this method is that it requires as few as two microarray hybridizations (self-self and experiment) to perform well. We have tested these methods to provide optimal results from SLAM experiments, where YKOs that decrease in representation from control to experimental samples are sought. However, appropriately applied, other TAG microarray experiments should benefit from the procedures we describe.

**Figure 1.** Design of spike-in pools. Two pools were created ('A' and 'B') such that 94 strains were differentially represented between the two pools. The 94 differentially represented strains were diluted 1:1, 1:8 or 1:64 (High, Medium or Low representation), then added to Pool B. Each strain was then diluted again from 1:2<sup>6</sup> to 1:2<sup>5</sup> and added to Pool A. One set of strains from each representation group was not added to Pool A (dilution 1:2<sup>∞</sup>).

**Figure 2.** Development of TAG filters. (a) Self-self hybridizations. Pool A gDNA was used as template for TAG labeling reactions with each primer set (UP/DNTAG Cy5/Cy3). Median values across three experiments were displayed. Each point represents a single YKO. Red dotted lines are three SDs. Blue circles, artifacts specific to UP ratio; purple circles, artifacts specific to DN ratio; orange circles, artifacts in both TAGs. (b) Histogram of  $\log_2$  UPTAG Cy5 signal values from pool A versus B hybridization. Results from DNTAG and Cy3 are similar. Red line, probability each feature belongs to the upper (righthand) distribution. (c) UPTAG Cy5 versus DNTAG Cy5. Each point represents a single YKO. Therefore, for each point the numbers of UP- and DNTAGs in the sample are identical. Red lines, values at which absent/present probabilities equal 0.5. In the weighted average method, DN ratio was weighted higher for YKOs in the upper left quadrant, and UP ratio was weighted higher for YKOs in the lower right quadrant.

**Figure 3.** Measures of sensitivity/specificity. (a and b) ROC for several methods of calculating relative YKO representation. True Positive is defined as any YKO with known pool B:A ratio  $> 2$ . False Positive is defined as any YKO with known B:A ratio of 1. ROC curves for UP ratio alone (purple line), DN ratio (blue line), Average ratio (green line), Filtered average ratio (red line) and weighted average ratio (black line). (c and d) Ratio-intensity plots using simple averaging of UP and DN ratios or weighted average ratios. Black open circles, YKOs with known B:A ratio of 1; filled circles, high representation YKOs; squares, medium representation YKOs; diamonds, low representation YKOs. Point size is related to known B:A ratio: from small to large,  $2^{1/5}$ ,  $2^{2/5}$ ,  $2^{3/5}$ ,  $2^{4/5}$ ,  $2^{5/5}$  and  $2^\infty$ . Black dotted lines are 0.1, 1, 99 and 99.9 percentiles for YKOs with known B:A ratio = 1.

## Supplementary note 1

An alternate weighting procedure can be used where  $p$  equals 0 or 1, such that all control (Cy5) TAGs above a threshold are considered ‘present’ ( $p=1$ ) while TAGs below the threshold are ‘absent.’ The threshold value for each array can be calculated using the mean plus three standard deviations for  $\log_2$  Cy5 intensity values of expected ‘blank’ features. On the “Hopkins TAG Array” (GEO accession GPL1444) the ‘YQL’ features can be used for this purpose. On other TAG arrays, researchers could use features representing essential yeast knockout strains (YKOs), if the sample is from a haploid pool. Once the threshold value for a given array is determined, each UPTAG and DNTAG is annotated ‘present’ ( $p=1$ ) or ‘absent’ ( $p=0$ ) based on the control channel intensity, and the corresponding log ratios are averaged for each YKO using  $w * UP + (1 - w) * DN$ , where  $w = 0.5 + (p(UP\ present) - p(DN\ present))/2$ .

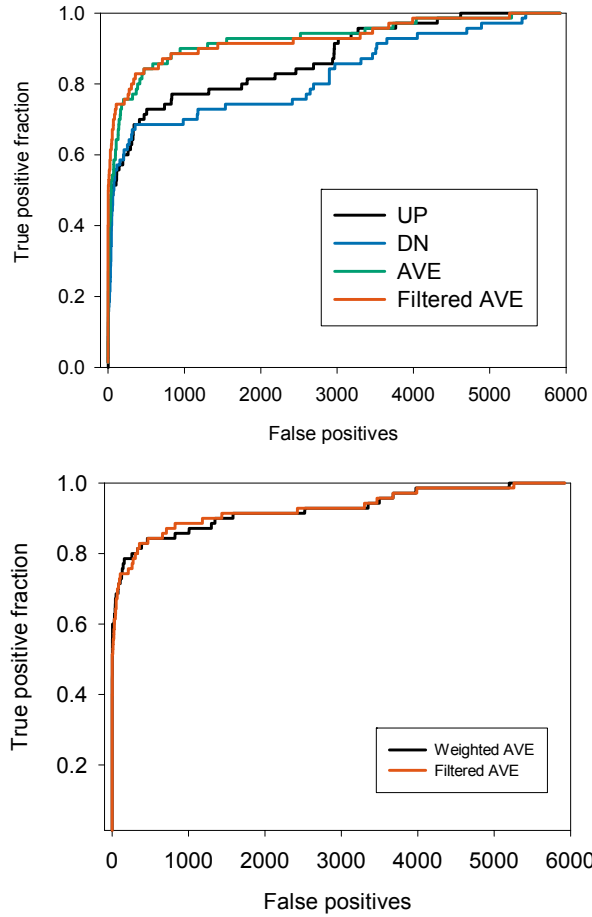

**Supplementary Figure 1.** UPTAG log<sub>2</sub> ratio versus DNTAG log<sub>2</sub> ratio. Three independent self: self hybridizations were performed using the same batch of Cy3/Cy5 labeled primers (a-c). A different batch of primers was used to perform the hybridization in panel d. Each point represents a single yeast knockout strain. Blue circles, UPTAG specific artifacts from Figure 1; purple circles, DNTAG specific artifacts; orange circles, artifacts in both tags. Red lines, three times S.D. Identities of colored points are constant across all panels.

**Supplementary Figure 2.** ROC curves. True positives defined as all knockout strains with  $\log_2$  pool B:A ratio of  $\frac{1}{3}$  and greater (left column), 1 and greater, (middle column), or 3 and greater (right column), and pool B representation level of 1:64 or greater (top row), 1:8 or greater (middle row) or 1:1 (bottom row). False positives defined as all knockout strains present at 1:1 ratio. UP ratio, black lines; DN ratio, blue lines; average ratio, green lines; filtered average ratio, red lines.

**Supplementary Figure 3.** ROC curves. True positives defined as all knockout strains with  $\log_2$  pool B:A ratio of  $\frac{1}{3}$  and greater (left column), 1 and greater, (middle column), or 3 and greater (right column), and pool B representation level of 1:64 or greater (top row), 1:8 or greater (middle row) or 1:1 (bottom row). False positives defined as all knockout strains present at 1:1 ratio. Weighted average ratio, black lines; filtered average ratio, red lines.

**Supplementary Figure 4.** ROC curves for several methods of calculating relative YKO representation. True Positive is defined as all knockout strains with  $\log_2$  pool B:A ratio  $\geq 1$ . False Positive is defined as all knockout strains present at 1:1 ratio. (a) ROC curves for UP ratio alone (black line), DN ratio (blue line), Average ratio (green line), and Filtered AVE ratio (red line). (b) Weighted AVE ratio (black line), and Filtered AVE ratio (red line).

**Supplementary Figure 5.** Detection slopes. Five methods for generating a single log ratio measure of differential pool B/A representation were analyzed by comparing observed ratio to known ratio. Points from High (red points and lines), Medium (blue), and Low (yellow) representation groups were used to generate three linear fits (least squares). Slope of the fitted line is indicated in corresponding color adjacent each line. Dotted lines indicate the noise range of all ratios for known 1:1 knockout strains. Panels a-e: UP ratio alone, DN alone, AVE ratio, AVE ratio with artifacts removed, Weighted AVE ratio with artifacts removed.

## **Chapter 4.**

# **Synthetic lethal interactions predicted by analysis of high-throughput dSLAM.**

## **Abstract**

Using analysis of microarray data from 707 unique dSLAM query genes, we predict 1690 synthetic lethal interactions between gene pairs in *S. cerevisiae*, including 1410 previously unknown. This analysis makes use of data from double mutants generated in two orientations—*yko1Δ::URA3* (query) *yko2Δ::KanMX* (target) and *yko2Δ::URA3* (query) *yko1Δ::KanMX* (target)—to improve the predictive ability of microarrays. We compare several methods for using bidirectional information with known interactions available from BioGRID to estimate sensitivity and specificity. Currently, we present data from 707 query genes, but all nonessential yeast knockout mutants are planned. The value of this bidirectional approach should increase as more data become available.

## **Introduction**

Synthetic lethality provides insight into the mechanisms of robustness found in living systems (Hartman et al. 2001; Tucker and Fields 2003; Wagner 2005). Synthetic lethal pairs are two alleles that are individually nonlethal but cause lethality when combined. Also considered are interactions where a growth defect more severe than expected is caused by interaction of two alleles. This has been called “synthetic fitness defect” or “synthetic sick,” though in some cases “synthetic semi-lethality” may be apropos after Dobzhansky (1946). Interaction between two point mutant alleles often coincides with physical interactions between proteins encoded by those genes. In contrast, synthetic interactions found between null alleles rarely coincide with physical interaction between the two genes (Tong et al. 2004; Kelley and Ideker 2005; Ye and

Peysner et al. 2005). These instead represent functions that are required in absence of a compensating pathway.

With introduction of the yeast knockout (YKO) collection (Winzeler and Shoemaker et al. 1999), it became possible to readily probe the near-complete yeast genome for synthetic interactions between null alleles. Several approaches have been applied to the task, including synthetic genetic array (SGA), epistatic miniarray profile (E-MAP), synthetic lethality analyzed by microarray (SLAM), and diploid-based SLAM (dSLAM) (Tong et al. 2001; Schuldiner et al. 2005; Ooi et al. 2003; Pan et al. 2004). In SLAM experiments, the two molecular barcodes (TAGs) incorporated into each deletion (Shoemaker et al. 1996), called UPTAG and DNTAG, are simultaneously interrogated to estimate changes in strain abundance between conditions. All UPTAGs or all DNTAGs can be amplified from a sample using universal flanking primer sites.

In dSLAM, pooled heterozygous diploid YKOs are transformed with a second “query” null mutation. These diploids containing query and target null alleles in heterozygous condition are then sporulated, and haploid *MATa* cells are selected with or without requirement for the query allele (experiment and control, respectively). The cells that survive selection are then processed for genomic DNA and used to prepare labeled TAGs. We present results from high-throughput dSLAM experiments, and predict new interactions based solely on these microarray data.

## **Methods**

Synthetic lethality screens were performed generally as described by Pan et al.

(2007). Briefly, pooled haploid-convertible YKO mutants were transformed *en masse* with a deletion construct consisting of ~1.5 kb up- and downstream sequence for the query ORF surrounding a URA3 cassette. Transformants were selected on –uracil media, scraped and sporulated. *MATa* haploids were selected on “magic” haploid selection media +G418 (control) and –uracil +G418 (experiment).

Genomic DNA purified from each selection was used as template for TAG labeling reactions as described (Yuan et al. 2005). TAGs from control samples were labeled with Cy5, and experiment samples were labeled with Cy3. Labeled TAGs were hybridized to custom microarrays (“Hopkins Tag Array” from Agilent, Gene Expression Omnibus accession number GPL1444) as previously described, and scanned using a GenePix scanner (Axon Instruments).

Microarray results were stored as GenePix Results (“.gpr”) files and organized into subsets by primer batch. Each set of scans from a single primer batch was analyzed using R, an open-source data processing environment (Ihaka and Gentleman 1996). The *limma* package (Smyth 2005) of BioConductor (<http://www.bioconductor.org>) was used for data structures, normalization, and generation of moderated *t*-statistics for replicate data using the empirical Bayes procedure (Smyth and Speed 2003). The array data were obtained from the GenePix median pixel intensity values. Arrays were normalized and background subtracted using the “loess” and “normexp” methods of the “normalizeWithinArrays()” function in *limma*, respectively (Smyth 2004). The background subtraction was performed with an offset of 16 to reduce variance explosion at low intensities. Array average intensities were then normalized using the “Aquantile” method of the

“normalizeAcrossArrays()” function. Data for UPTAG and DNTAG were treated separately in all cases. Deletions of ORFs adjacent to the query can cause artificially high control/experiment ratios because of interference with the targeting of the deletion construct to the chromosome homologue carrying the knockout, and subsequent repulsion during meiosis due to linkage. Therefore, ORFs within 2 of either side of the query were assigned a *Z*-score of 0. Once *Z*-scores were produced for each array, the results of all primer sets were combined and analysis was continued using R.

## Results

We performed dSLAM experiments on 707 unique query open reading frames (ORFs) using procedures as described in Pan et al. (2007). DNA from double mutant cells was used to label TAGs with Cy3, while Cy5 was used to label TAGs from control single-mutant DNA. Here, large values for control/experiment (C/E) ratio are expected for strains that do not survive deletion of both ORFs. In general, normalization procedures were similar to those previously described (Peyser et al. 2005). See Methods for a complete description of normalization and background correction. As shown in Peyser et al. (2005), two problems associated with TAG arrays are primer-batch-specific artifacts, and poorly hybridizing TAGs. In this work, we apply new techniques for identifying bad TAGs and primer artifacts using many microarray hybridizations. In addition, we make use of information from two knockout orientations—*yko1Δ::URA3* (query) *yko2Δ::KanMX* (target) and *yko2Δ::URA3* (query) *yko1Δ::KanMX* (target)—to increase specificity for each gene pair.

### Broken TAGs

*A priori*, signal from TAGs that provide no information should never change, and variation seen for these TAGs should be solely due to noise. We examined a large number of TAG hybridizations to define the variability of each TAG and remove those with extremely small standard deviation (SD). Data from 1121 scans were quantile normalized (Bolstad et al. 2003) across all scans and both colors (Cy5 and Cy3) for UPTAG and DNTAG separately, without regard to primer batch. Following normalization, the average  $\log_2$  signal intensity was plotted with a robust estimate of the SD (median absolute deviation, MAD) of the  $\log_2$  intensities (Figure 1). As expected, extremely small values for MAD are associated with low signal intensity. We applied a cutoff to the MAD values, at approximately the midpoint between two modes in the distributions (0.40 for UPTAG and 0.35 for DNTAG), and annotated all TAGs below these cutoffs as “failed” (see Supplementary Table 1). If these bad TAGs provide no information about the target molecules, their data will consist of only noise. The identification of failed TAGs permits removal of these data to reduce this noise. Additionally, some YKO (192 strains) were created with no DNTAG. For convenience, these strains were also annotated to have bad DNTAGs.

Figure 2 displays density histograms of TAG behavior by type across multiple microarrays. The distribution of bad TAGs coincides with negative control features included on the arrays (see Yuan et al. 2005). Additionally, while essential mutants should not grow on haploid selective media, the TAG signals for those mutants are detectable on microarrays, presumably due to presence of dead or dying cells. This distribution is bimodal before removal of bad TAGs, which do not provide information

about the low levels of essential mutants. Note that bad TAGs as defined in Figure 1 simply reproduce the negative control distribution.

### **Removing artifacts**

Most importantly, primer-batch-specific artifacts cause spurious results for some TAGs. These artifacts are generally consistent within a single batch of labeled primer, but vary between batches (Peyser et al. 2005). One remedy is to remove the TAGs with artifactual signal from analysis. In contrast, here we apply a transformation to the data that expresses changes in TAG levels between experimental conditions as change from typical TAG  $\log_2$  ratios within each primer batch. This assumes that YKO usually do not change abundance between experimental conditions, and that  $\log_2$  ratios that are not 0 on average are influenced by artifacts. We know this is false for some strains that respond to the uracil selection without regard to the query deletion (see Table 1). However, since this uracil effect is not the desired biological phenotype, its removal is also beneficial. We define typical TAG behavior by using the mean and SD of the  $\log_2$  C/E ratio for each TAG among a set of many hybridizations performed with the same primer batch. Again, we use the MAD as a robust estimate for SD. The data are transformed to a  $Z$ -score, which is the number of SDs from the mean. Figure 3 shows the procedure for two TAGs, one of which is typical, and one of which displays a primer-batch-specific artifact. The  $Z$ -score procedure re-centers the distributions and equalizes the variance. This method is successful at equalizing variance across intensities, as well (see Durbin and Rocke 2002; Huber et al. 2002).

The  $Z$ -score procedure improves on the filtering method presented in Peyser et al.

(2005) by retaining data that would otherwise be removed. For example, the TAG represented by the red line in Figure 3 displays  $\log_2$  ratio higher than its typical behavior on 1 microarray, corresponding to a Z-score of about 7 (arrow). This TAG would have been removed from analysis with the previously described filtering procedure since the average  $\log_2$  ratio is much greater than 0. With this Z-score method, the potentially useful information is retained.

### **Combining UP- and DNTAG information**

Each knockout strain (except for 192 strains lacking DNTAGs) has information from two TAGs. However, when a TAG feature provides no information about the abundance of target molecules, including the corresponding data will provide only noise. Therefore, when combining UP- and DNTAG information, only functional TAGs should be retained.

When combining independent normal distributions with mean and SD of 0 and 1, adding the values then dividing by the square root of 2 results in a distribution that is also mean 0 and SD of 1. In Figure 4, this can be understood as a measure of the distance along the red line from the origin to a perpendicular line that intersects the point. When TAGs are combined in this manner, a standard normal distribution can be maintained by substituting the UP- or DNTAG value for the combined value when any corresponding DN- or UPTAG is annotated “failed.” This method weights strains with agreement for UPTAG and DNTAG higher than strains with only one functional TAG, but less than the double weight provided by adding Z-scores.

## Combining information from two arrays

Significant noise is detectable in microarray experiments when comparing biological replicates. Figure 5 shows  $Z$ -scores from two of three independent dSLAM screens performed with the same query. While the same experiment was performed, the results are not highly correlated ( $r = 0.15$ ). However, low  $p$ -values (warm colors) produced using the empirical Bayes moderated  $t$ -statistic (Smyth 2004) are associated with results where two arrays agree and are enriched for true positive interactions (Tong et al. 2004), indicated by black filled circles. This level of variation in microarray experiment results is not unique to TAG microarrays, and poses a problem for the high-throughput project since only one experiment is planned for each query ORF.

One feature of  $yko1\Delta yko2\Delta$  interactions is that interesting results should occur both where  $yko1\Delta$  serves as query and when  $yko2\Delta$  does. Here we investigate the utility of information for deletions made in both orientations. While we were unable to produce  $p$ -values as indicated in Figure 5 with only two experiments, we could use the additional information for each interaction from the corresponding gene pair.

One method to combine the data from two orientations would be to average the values in the same manner as UP- and DNTAG were combined. Another possibility is to keep UP- and DNTAG values separate and choose the median of up to four values. This would reduce the impact of a single spuriously extreme value. Notice that both of these methods both make it possible to predict interactions for gene pairs where one mutant strain has no working TAGs.

We present a method that views agreement in the  $Z$ -scores from the two orientations

as confirmatory, and disagreement as evidence of noise. This is shown in Figure 6, which displays the combined UP- and DNTAG Z-score for each orientation of a given gene pair. As expected, points are more dense in the upper right quadrant, consistent with a real synthetic lethal effect detected in two microarrays. If points in the lower right quadrant are a good representation of noise, the two quadrants can be compared to estimate the false discovery rate (FDR). We perform this estimation by creating hyperbolic cutoffs as shown in Figure 7, and counting the number of points present above corresponding cutoffs in each quadrant. Thus, when a cutoff generates 100 predicted SL pairs in the upper right quadrant, and the corresponding cutoff generates 25 expected false interactions in the lower right quadrant, the estimated FDR is 0.25 at that cutoff. If we knew the true phenotypes of all 100 pairs above that cutoff, we would expect that 75 are true, and 25 are above the cutoff simply due to noise. This estimated FDR should be conservative, since not all points in the lower right quadrant will be truly false.

We can similarly perform this procedure for gene pairs in the lower left quadrant. Here, two gene deletions together appear to improve growth compared to the individual deletions. This phenotype is termed Synthetic Rescue, though it historically applied to a lethal allele becoming nonlethal in presence of another allele. We apply it to nonessential gene deletions that display improved fitness in response to deletion of a second gene.

One weakness of this method is that YKO strains with no functional TAGs cannot yield predicted interactions involving that strain. This is the case even when the ORF is used as the query. Thankfully only 78 nonessential heterozygous diploid strains, 7 of which are included in this analysis, have both TAGs flagged as bad. For these strains, the

Z-scores can be used directly to generate candidate lists, and additional experiments can be performed to improve predictions.

### **FDR method outperforms alternatives**

For comparison of the sensitivity and specificity of the averaging, median, and hyperbolic FDR methods, we annotated gene pairs as previously known synthetic genetic interactors or as not known, based on BioGRID release 2.0.20 (Stark et al. 2006). We then generated receiver operating characteristic (ROC) curves for each method considering all unknown interactions false (Figure 8). In the stringent regime, the hyperbolic FDR method outperforms the average or median, with improved sensitivity (true positive fraction) at high specificity (low false positive fraction). The ROC treats all unknown pairs as false; this underestimates sensitivity since some unknown pairs will actually be true. However, if we assume the impact of false negatives is similar across the methods, our conclusion about the relative ability of each method should hold.

Since the database is not complete, we tested unknown interactions within the 100 top predictions from each method. Some predicted interactions were not tested due to technical problems, such as failure of the PCR for production of the targeting construct. We performed random spore analysis using procedures as described in Pan et al. (2007). As with the ROC based on BioGRID interactions, the hyperbolic FDR provides the best performance, with 72 of 88 tested predictions confirmed or previously known (82%), versus 44 of 82 (54%) for the average and 18 of 86 (21%) for the median.

Using the estimated FDR, we predict 1690 synthetic lethal interactions with FDR cutoff of 0.5, 280 of which are listed in BioGRID (we also predict 22 synthetic rescue

interactions). Predicted synthetic lethal and rescue interactions are listed in Tables 2 and 3, respectively. If the FDR is an accurate estimation of false positives, we expect 845 of these predicted synthetic lethal interactions to be true.

## **Discussion**

With 707 out of ~5000 queries yielding at least 845 estimated true interactions from bidirectional data, the number of true synthetic lethal interactions expected per gene is approximately 8. This number is significantly lower than the 34 interactions per query found by Tong et al. (2004). However, the Tong et al. data set contained queries chosen for biological interest, and there were ~30 queries that were abandoned when few potential interactions were detected in the first screen. For both of these reasons the reported data are likely biased toward more interactions per query. Regardless, the true number of synthetic interactions per gene in *S. cerevisiae* is probably more than 8.

When researchers have a particular interest in one of the genes used as a query, additional interactions may be discovered by examining the entire data set, rather than the subset for which bidirectional data are available. The candidates from such a method will contain a higher fraction of false positives, but with verification by random spore or tetrad analysis (Tong et al. 2001; Pan et al. 2007) many additional true positives could be revealed. We present a conservative method for generating synthetic interaction predictions without subsequent verification. Without applying this conservative bidirectional approach, we would predict 11 801 candidate interactions at combined  $Z$ -score  $\geq 5$ , or 24 996 at combined  $Z$ -score  $\geq 4$ . While candidate interactions may be interesting for selected genes, we focus on expanding the number of dSLAM screens

available for bidirectional analysis, rather than manual verification of these candidates.

## **Acknowledgments**

Direction was provided by Dr Forrest A. Spencer, and statistical guidance was provided by Dr Rafael A. Irizarry. High-throughput experiments and protocol development were performed by Dr Pamela B. Meluh, Carol W. Tiffany, Ou Chen, Sharon Sookhai-Mahadeo, Emily Kleinhans, Abid Khan, Courtney Hollender, and Dr Xuewen Pan. Dr Daniel S. Yuan developed the microarray and the hybridization procedure. Dr Jef D. Boeke coordinated the project and provided discussion.

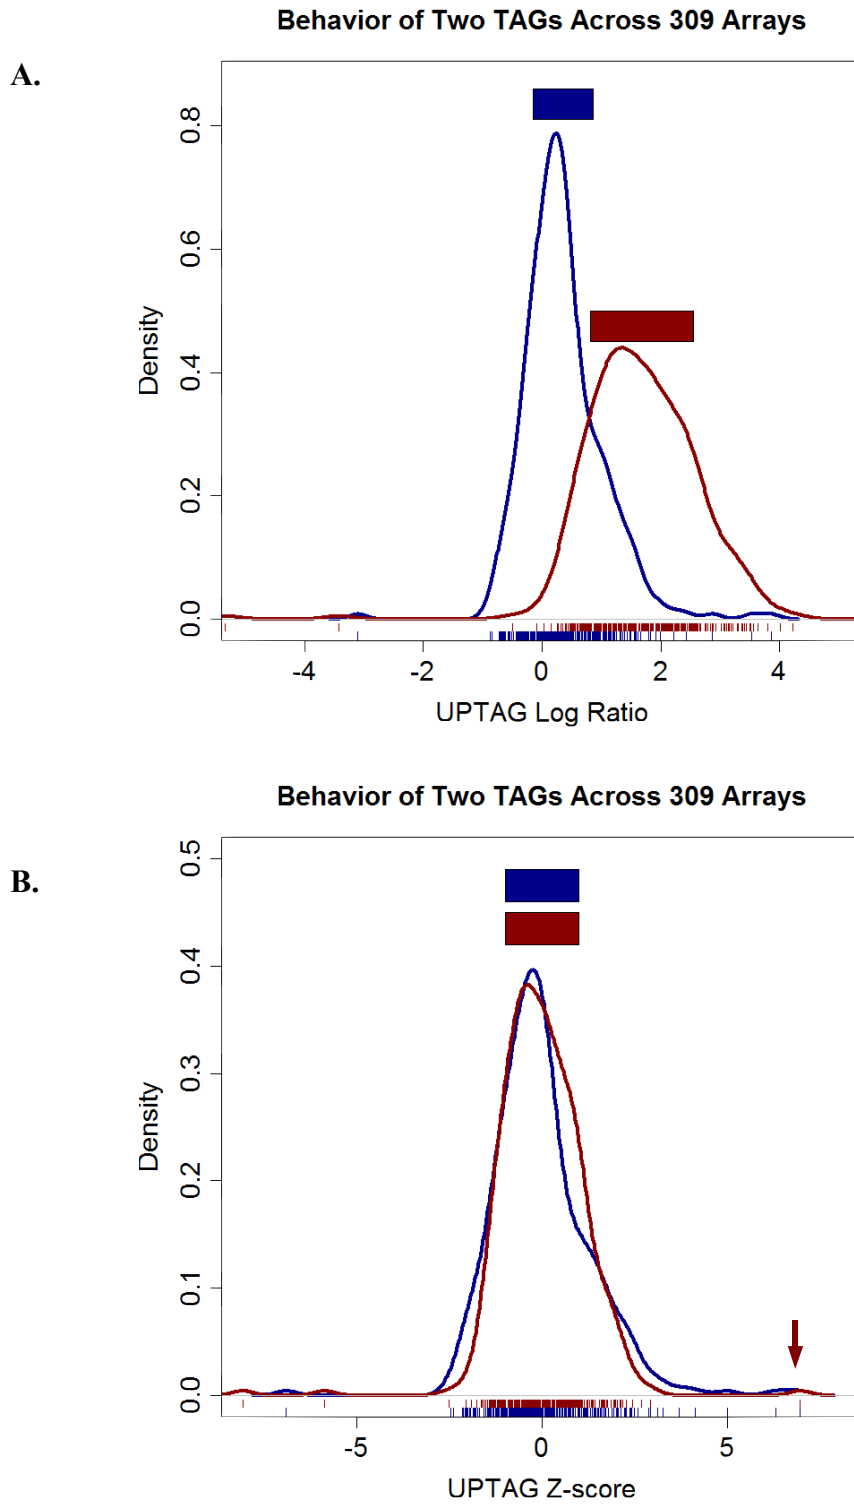

**Figure 1.** Density scatter plots for UPTAG and DNTAG signal deviation versus intensity. For each UPTAG and DNTAG, the SD of  $\log_2$  intensity was estimated using the MAD, and plotted versus the average  $\log_2$  intensity for that TAG. Dark blue indicates high density of points. Red lines at 0.40 for UPTAG and 0.35 for DNTAG indicate MAD cutoffs for annotating failed TAGs.

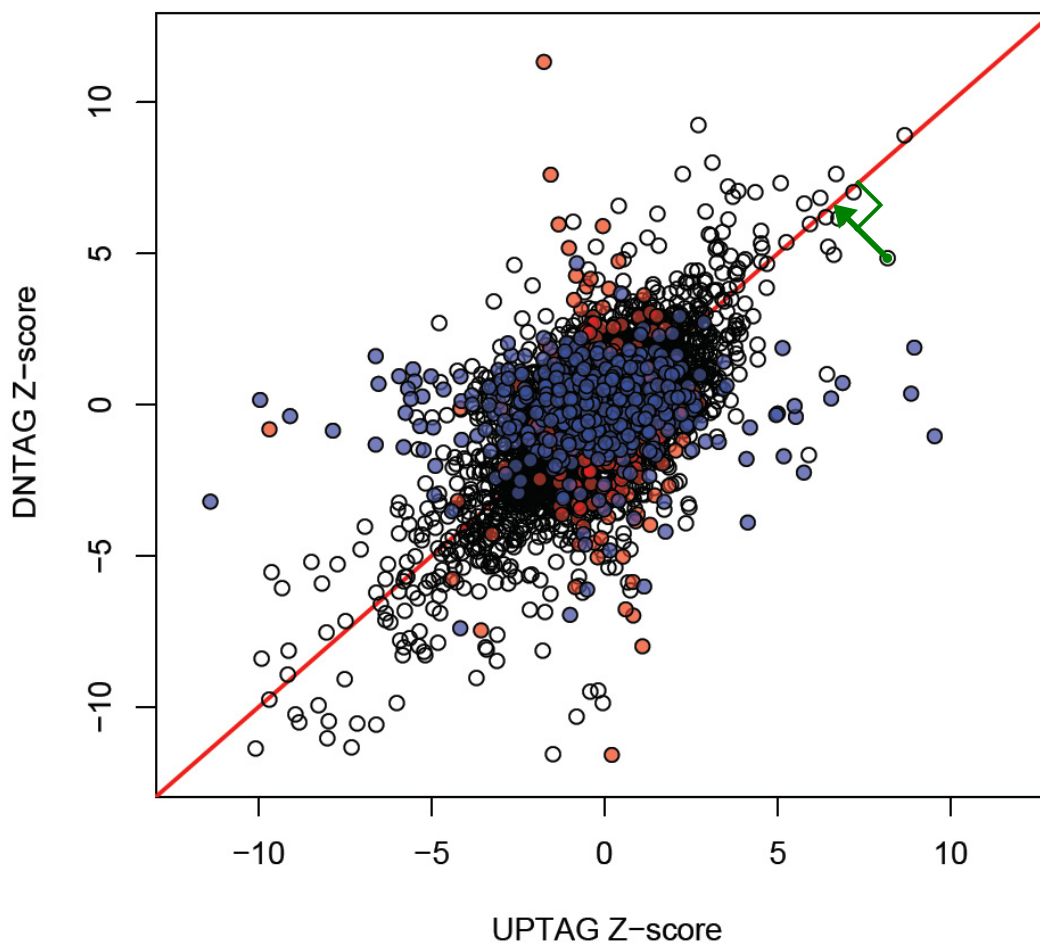

**Figure 2.** TAG intensity by type. Density histograms showing probability densities (y-axis) for average  $\log_2$  intensities (x-axis) of various categories of TAGs across 309 microarrays. Both UPTAG and DNTAG values are included in each category.

**Figure 3.** Behavior across 309 arrays for 2 UPTAGs. (A) Density histograms showing probability densities ( $y$ -axis) for  $\log_2$  ratios ( $x$ -axis) of 2 UPTAGs across 309 normalized microarrays. All arrays were prepared from a single batch of labeled primer. Blue line is the distribution of values for a typical TAG, and red line is from a TAG that displays primer-batch-specific artifacts. Ticks along the  $x$ -axis show location for each value. Rectangles span the mean  $\pm 1$  SD. (B) Density histograms showing probability densities for the  $\log_2$  ratio  $Z$ -scores of the 2 UPTAGs shown in (A). Rectangles span the mean (0)  $\pm 1$  SD. Arrow indicates elevated  $Z$ -score in one microarray for the TAG shown in red.

**Figure 3.**

### UP- and DNTAGs from one array

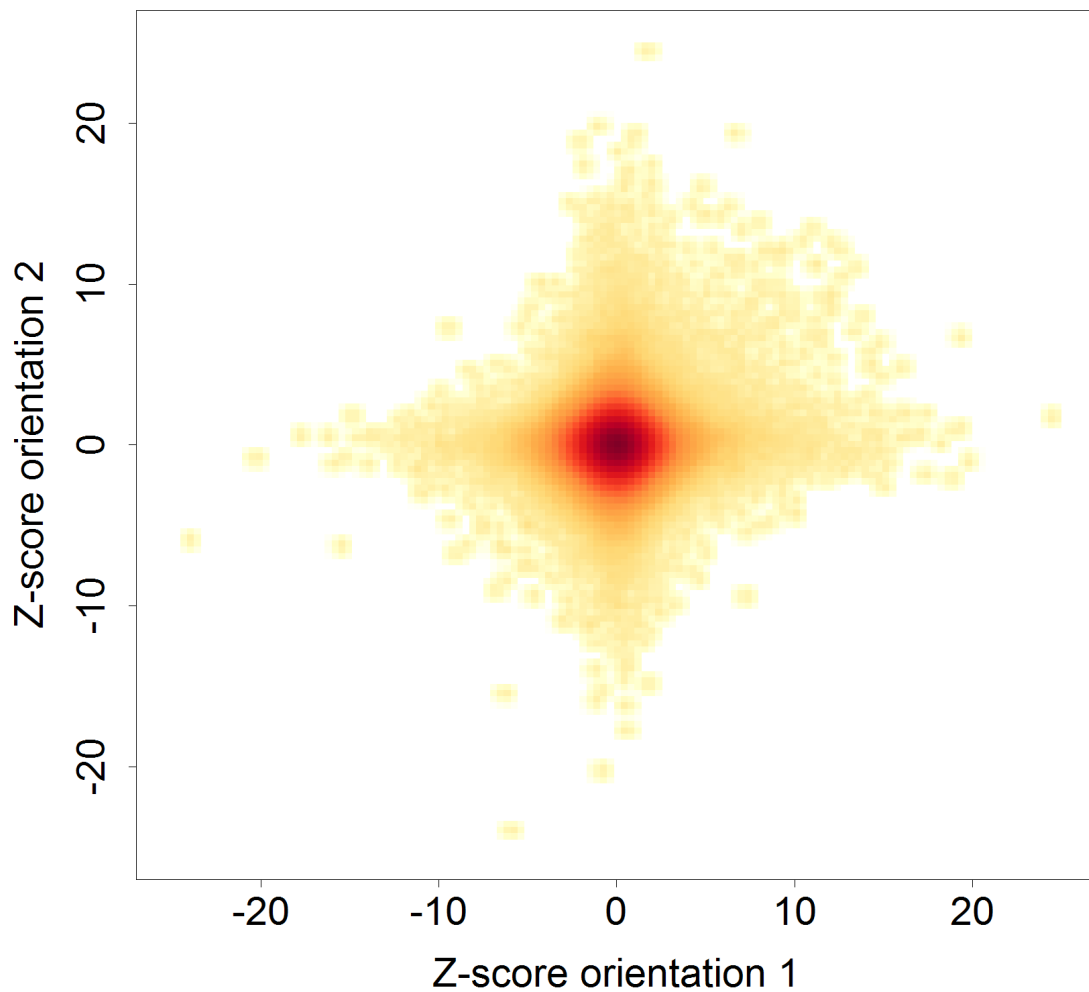

**Figure 4.** UP- and DNTAGs from a single hybridization. The DNTAG Z-score is plotted versus the UPTAG Z-score for all YKO strains in a single experiment. Red points represent strains with the UPTAG annotated bad and a working DNTAG, blue points are bad DNTAG and good UPTAG, and open circles are YKOs with two good TAGs. Green arrow represents the weighted average transformation for a point with two good TAGs.

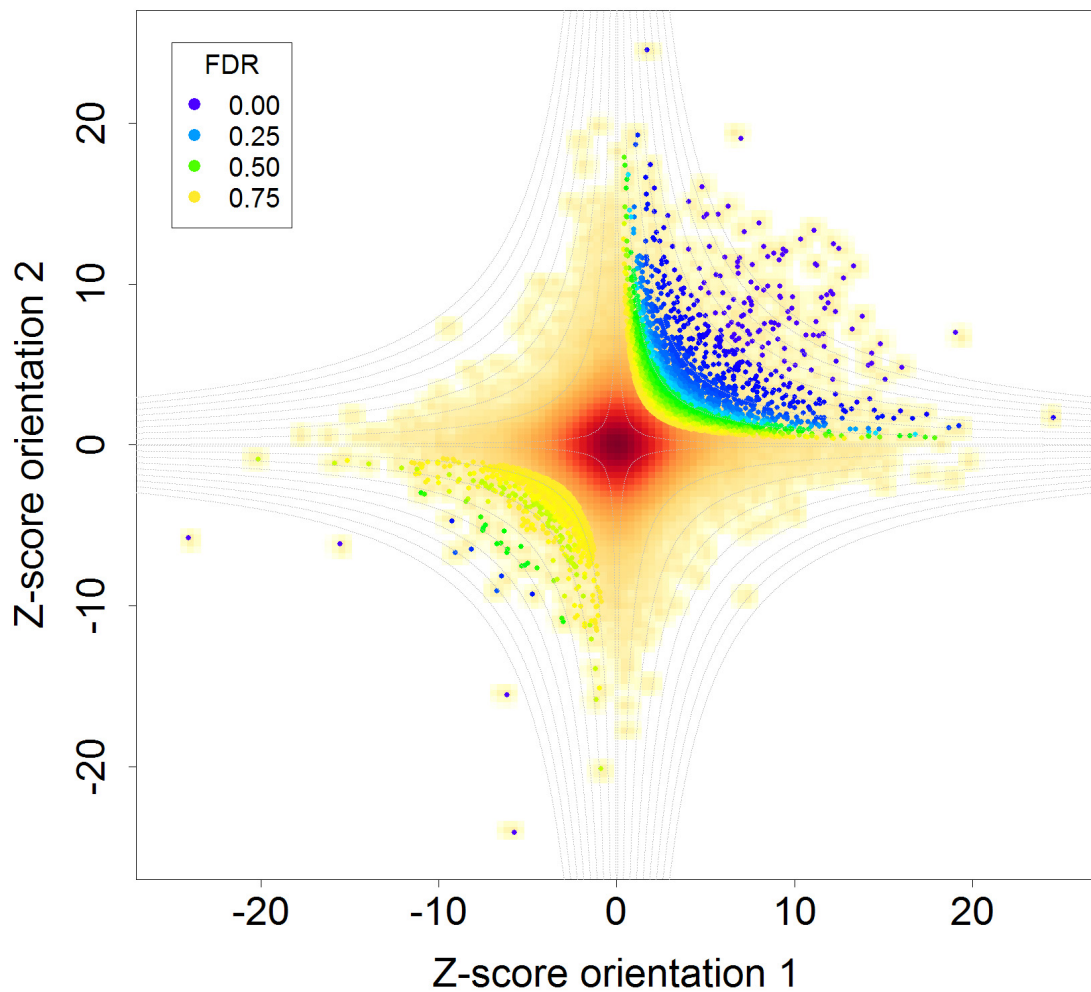

## Biological replicate experiments

**Figure 5.** Replicate experiments reveal variability. Three biological replicate experiments were performed with *YCL016C (DCC1)*, and  $p$ -values were generated using an empirical Bayes procedure. Combined  $Z$ -scores from two of the arrays for each YKO are shown, with circle color representing  $p$ -value on a logarithmic curve from  $p = 0$  (warm colors: orange) to  $p = 1$  (cool colors: blue). Filled black circles are known synthetic lethal (large circles) or fitness defect (small circles) from Tong et al. (2004).

**Figure 6.** Z-score agreement suggests true interactions. Density scatter plot of combined Z-scores of two marker orientations for each gene pair. Darker orange regions represent higher density of points. More points are found in the upper right quadrant and lower left quadrant, where Z-scores agree between two marker orientations, than in the lower right and upper left quadrants.

**Figure 7.** Estimation of noise using distribution of Z-scores. Density scatter plot of combined Z-scores for two marker orientations from Figure 6 overlain with estimated FDR. Selected hyperbolic cutoffs are shown in gray. Points are shown and colored by estimated FDR for all gene pairs up to FDR = 0.75. Both synthetic lethal (upper right) and synthetic rescue (lower left) are shown.

**Figure 8.** ROC curves. Three methods for combining information from two marker orientations were compared for specificity and sensitivity using synthetic genetic interactions found in BioGRID release 2.0.20 as true. All other interactions were considered false. The true positive fraction was plotted versus the false positive fraction for decreasing average or median Z-score values, and increasing FDR values. (A) The segment of the ROC curve showing up to ~1000 false positive interactions and ~200 true positive interactions. (B) and (C) Expanded segments of the ROC curves.

Figure 8.

## Chapter 5.

### Gene function prediction from congruent synthetic lethal interactions in yeast

## **Abstract**

We predicted gene function using synthetic lethal genetic interactions between null alleles in *Saccharomyces cerevisiae*. Phenotypic and protein interaction data indicate that synthetic lethal gene pairs function in parallel or compensating pathways. Congruent gene pairs, defined as sharing synthetic lethal partners, are in single pathway branches. We predicted benomyl sensitivity and nuclear migration defects using congruence; these phenotypes were uncorrelated with direct synthetic lethality. We also predicted *YLL049W* as a new member of the dynein-dynactin pathway and provided new supporting experimental evidence. We performed synthetic lethal screens of the parallel mitotic exit network (MEN) and Cdc14 early anaphase release pathways required for late cell cycle. Synthetic lethal interactions bridged genes in these pathways, and high congruence linked genes within each pathway. Synthetic lethal interactions between MEN and all components of the Sin3/Rpd3 histone deacetylase revealed a novel function for Sin3/Rpd3 in promoting mitotic exit in parallel to MEN. These *in silico* methods can predict phenotypes and gene functions and are applicable to genomic synthetic lethality screens in yeast and analogous RNA interference screens in metazoans.

## **Introduction**

The robustness of a biological network to defects can be probed by synthetic lethality, which reveals that a cell survives individual gene deletions, but cannot survive deletion of specific gene pairs. Synthetic lethal interactions have been rationalized with two hypotheses: (i) two genes in a single linear pathway can show synthetic lethality; (ii)

synthetic lethal genes act in parallel or compensating pathways (Tucker and Fields 2003). These two hypotheses predict distinctly different patterns of synthetic lethality: enrichment of interactions within single pathways versus depletion of interactions within pathways and enrichment between pathways. These two hypotheses also make different predictions for the nonlethal phenotypes of the underlying single gene deletions: a shared phenotype for genes in a single pathway, or possibly differing phenotypes for genes in parallel pathways.

Hypothesis (i) is possible only when alleles are hypomorphic but not complete loss-of-function mutants: each mutation reduces flux partially, but the combined reduction from two mutations leads to lethality. Hypothesis (i) does not apply to synthetic lethality between null alleles, with complete loss of function. Hypothesis (ii) is expected in this case, with each null mutation knocking out one of the two parallel pathways that sustain normal growth. In this view, an essential protein complex that retains function when single nonessential subunits are deleted (but not multiple subunits simultaneously) is formally represented by multiple pathways, one for each functional stoichiometry, connected in parallel.

Data sets to test these rationales are arising from high-throughput synthetic lethality screens accomplished in *Saccharomyces cerevisiae* using synthetic genetic array (SGA) and synthetic lethality analysis on microarrays (SLAM). These screens test a deletion of interest (query gene) against all possible viable yeast single-deletion strains (target genes) (Tong et al. 2001; Ooi et al. 2003; Pan et al. 2004). As human disease susceptibility may encompass gene mutations in multiple pathways, synthetic lethality is relevant to human

disease processes (Tucker and Fields, 2003).

We focus on the subset of genetic interactions restricted to synthetic lethal interactions and synthetic fitness (slow growth) defects between *null alleles*. These interactions are easier to interpret than more general genetic interactions (enhancer, suppressor screens) or other types of mutant alleles (e.g., hypomorphs of essential genes). Null mutants constructed by the International Yeast Gene Deletion Consortium represent the vast majority currently under study by the yeast community (Giaever et al. 2002). For brevity, we use the term synthetic lethal to include both the lethal and reduced fitness phenotypes.

Synthetic lethal interactions have been used to predict that interaction partners share function in the same pathway (Tong et al. 2001, 2004; Wong et al. 2004). Here, we emphasize the alternative hypothesis suggested above, that synthetic lethal interactions bridge parallel pathways, which are in a sense orthogonal to direct synthetic lethal interactions (Figure 1A). This concept is formalized computationally as follows. Pathway membership is inferred using the hypergeometric *P*-value for a shared pattern of interaction partners, which we abbreviate as the congruence score (Figure 1B). We present evidence that functional associations inferred from the congruence score are stronger than associations between the synthetic lethal interaction partners themselves. Two types of functional associations are explored: biochemical participation in protein complexes, through joint analysis of synthetic lethal interactions (Tong et al. 2004) with protein complex data (Gavin et al. 2002; Ho et al. 2002; Mewes et al. 2004) (see Supplementary information, Supplementary Figures S1 and S2); and phenotypes of the

underlying single gene deletion mutants, including nuclear migration and drug sensitivity. The nuclear migration assay and the physical interaction detected between Jnm1p and Yll049wp confirm our prediction that the previously uncharacterized yeast gene *YLL049W* is a new member of the dynein–dynactin pathway.

## **Results**

### **Congruent genes function in the same pathway**

As has been noted previously, only ~1% of synthetic lethal interactions occur between genes whose products reside in a single protein complex (Tong et al. 2001). While, as pointed out by the authors of that paper, this is a greater fraction than would be expected by chance, it is clear that the vast majority of synthetic lethal interactions are not explained by common protein complex membership and we would argue that this 1% represents the exception and not the rule. The parallel pathway model suggests that genes sharing synthetic lethal interaction partners may function in a single pathway, and their gene products should have an increased probability to reside in a single protein complex.

The raw number of shared genetic interaction partners has been used previously to rank the probability of a physical interaction between the corresponding gene products (Tong et al. 2004). Here, we instead use the hypergeometric *P*-value for the number of shared neighbors, which accounts for the number of interaction partners of each gene (Figure 1B). To convert this value to a convenient scale, we define the congruence score as the negative  $\log_{10}$  of the *P*-value; related measures have been used to analyze protein interaction networks (Goldberg and Roth 2003; Schlitt et al. 2003) and multiple

characters from single RNA interference (RNAi) screens (Gunsalus et al. 2004). The congruence score has the benefit of providing a natural significance threshold incorporating the size of the network. The performance of a predictive method can be visualized by plotting the number of true positives versus the number of false positives as a function of the number of predictions made, known as a receiver operating characteristic (ROC) curve. Based on the area under the ROC curve, the performance of congruence score method is superior to counting the number of shared partners in predicting protein complex membership in the stringent regime (Supplementary Figure S3 and Supplementary Table S1).

We separated the synthetic lethal interaction data into ‘query’ and ‘target’ sets, based on whether each gene node represents a non-essential query gene (126 are included in the published data) or a target gene (982 of which are synthetic lethal partners of at least one query). We calculate congruence scores for each pair of target genes (Supplementary Figure S4).

The fraction of target gene pairs in the same protein complex (Gavin et al. 2002; Ho et al. 2002) increases with congruence score, rising to 100% at the highest values (Figure 2A). Analysis using the MIPS database of curated complexes (Mewes et al. 2004) yields similar results (Supplementary Figure S5). Even for the smallest non-zero congruence scores, the observed fractions of pairs within the same complex are greater than expected by chance ( $P < 0.005$ ). Gene products of pairs with congruence score  $\geq 5$  have a higher probability of protein complex co-residence than products of synthetic lethal interaction partners. Moreover, using synthetic lethal interactions to predict

complex co-residence shows higher false positive rate ( $\frac{[\text{false positives}]}{[\text{false positives} + \text{true negatives}]}$ ) and higher false discovery rate ( $\frac{[\text{false positives}]}{[\text{false positives} + \text{true positives}]}$ ) than using congruence score (Supplementary Figure S3).

Functional associations, determined by extracting Gene Ontology (GO) (Ashburner et al., 2000) annotations and calculating correlations based on the depth of the deepest parent term (see Materials and methods), are greater for congruent genes than for synthetic lethal pairs. Biological Process and Cellular Component correlations increase with congruence score and are greater than the similarity between direct genetic interaction partners (Figure 2B). As is typically the case, the GO Molecular Function annotations have smaller correlation as they refer to molecular, rather than biological, roles. For congruence scores  $\geq 7$ ,  $\geq 10$ , and  $\geq 6$ , respectively, the GO process, function, and component correlations for congruent gene pairs are significantly higher than the corresponding correlations for the raw synthetic lethal pairs (0.25, 0.05, and 0.31), respectively ( $P < 0.05$ ). Calculations based on semantic similarity of GO terms (Lord et al. 2003) show even stronger performance of the congruence score relative to synthetic lethality (Supplementary Figure S12).

In summary, a congruence interaction with score  $\geq 10$  provides a tighter functional relationship than synthetic lethality, consistent with our interpretation of single versus parallel pathways. Although individual synthetic lethal gene pairs may share synthetic lethal partners (as observed by Tong et al. 2004), high congruence score typically excludes direct synthetic lethal interaction, in agreement with our model (Figure 2C). When congruence score is greater than or equal to 14, the binomial  $P$ -value for observed

number of synthetic lethal interactions becomes insignificant given the overall frequency of synthetic lethal interactions observed in the entire congruence data set ( $P > 0.05$ ).

A network generated by setting a threshold congruence value  $\geq 10$  recapitulates known functional associations and suggests novel associations (Figure 2D). Sets of genes known to function within the same pathway tend to cluster together. As expected, the congruence links overlap known protein interactions, whereas synthetic lethal links do not. For example, a prefoldin complex gene cluster inferred from congruence links (*PAC10*, *GIM3*, *GIM4*, *GIM5*, and *YKE2*) corresponds to the *PAC10* complex shown in Supplementary Figure S1B.

In some cases where proteins encoded by genes with congruence links were not detected within the same protein complex by high-throughput studies (Gavin et al. 2002; Ho et al. 2002), other experiments have indicated physical interactions. *SWR1*, *SWC1*, *VPS71*, *VPS72*, *SIF2*, and *ARP6* encode subunits of *SWR1* chromatin remodeling complex catalyzing exchange of histone H2A with histone variant Htz1p (Mizuguchi et al. 2004). Genes in a highly connected congruence cluster may function in the same pathway through transient physical interactions, or they may participate in a pathway as separate physical entities. For example, Cin1p, Cin2p, and Pac2p are all tubulin folding factors that function in a pathway leading to microtubule stability (Hoyt et al. 1997). Physical interaction between Pac2p and Cin1p has been reported (Fleming et al. 2000). Cin8p is a kinesin motor protein involved in mitotic spindle assembly and chromosome segregation, and interacts with microtubules (Gheber et al. 1999). Possibilities include that Cin1p, Cin2p, Pac2p, and Cin8p interact transiently during mitosis, or that they

influence the same molecular environment independently. For example, activities of Cin1p, Cin2p, and Pac2p might generate an optimal microtubule substrate for Cin8p.

The largest connected component in Figure 2D includes known members of the dynein–dynactin spindle orientation pathway (*ARPI*, *NUM1*, *DYNI*, *PAC11*, *PAC1*, *DYN2*, *JNMI*, *YMR299C*, and *NIP100*) and corresponds to a group observed previously using clustering (Tong et al. 2004). The dynactin protein complex (Arp1p, Jnm1p, and Nip100p) defined by biochemical studies is required for proper spindle orientation and chromosome partitioning to daughter cells during anaphase (Kahana et al. 1998). Additional reported protein–protein interactions in this congruence cluster include Jnm1p–Yll049wp, Nip100p–Pac11p, Pac11p–Dyn2p, and Pac11p–Num1p (Uetz et al. 2000; Farkasovsky and Kuntzel 2001; Ito et al. 2001). We predict *YLL049W* as a new component of the dynein–dynactin spindle orientation pathway, which is consistent with previous observation (Tong et al. 2004). We have experimentally validated the functional prediction of *YLL049W* by showing that its null mutant allele exhibits a nuclear migration defect similar to dynactin component *JNMI*. Furthermore, we have successfully detected a physical interaction between Jnm1p and Yll049wp using a directed two-hybrid test. Both experiments will be described in detail in the next section. The second uncharacterized open reading frame (ORF), *YDR149C*, is also congruent to dynein–dynactin components. Its ORF overlaps the beginning of its neighbor *NUM1*, and we suggest that the *ydr149c*Δ phenotype is in fact due to concomitant mutation of *NUM1*.

### **Congruence scores predict pathway components and quantitative phenotypes**

Distinct lesions to a single pathway branch should result in similar systems-level

perturbations. We reasoned that similarity of a numeric phenotype of a deletion mutant should be better predicted by congruence score than by a direct synthetic lethal interaction.

We investigated the ability of the congruence score to predict the penetrance of nuclear migration defects in a population of mutant cells. Mutations in the dynein–dynactin spindle orientation pathway are known to increase the nuclear migration defect rate. We selected six genes in the pathway as landmarks (*DYNI*, *ARPI*, *DYN2*, *JNMI*, *NUMI*, and *NIP100*) and then measured the defect rate at 13 °C for 59 mutants of genes with congruence score  $\geq 4$  to at least one of the landmarks (Supplementary Figure S6 and Supplementary Table S2). To summarize the relationship between phenotype and congruence score, each mutant’s migration defect (% abnormal) was plotted as a function of congruence scores to landmark genes (Figure 3A). The average congruence score is highly correlated with the defect rate (Spearman correlation coefficient = 0.51, two-sided  $P = 3.9 \times 10^{-5}$ ). Additionally, at or above congruence score of 10, all mutants exhibit moderate to severe nuclear migration defects (14–80% abnormal cells).

Among the mutants found to exhibit a nuclear migration defect was one representing the unstudied gene *YLL049W* (Supplementary Table S2). Further analysis of the *yll049w* mutant showed that the observed defects are temperature-dependent, similar to *jnm1* mutants, whereas a mutant for the Kinesin-related *KIP2* gene displayed temperature-independent defects (Supplementary Table S3). Notably, the *JNMI–YLL049W* congruence score (15.2) is higher than the *JNMI–KIP2* congruence score (10.8), consistent with more similar phenotypes.

It is evident from this analysis that uncharacterized ORF *YLL049W* is required for robust nuclear migration. High-throughput yeast two-hybrid results suggested a protein–protein interaction between Yll049wp and dynactin subunit Jnm1p (Ito et al. 2001). We have experimentally confirmed this physical interaction between Yll049wp and Jnm1p using a different two-hybrid system (Supplementary Figure S7). These results provide supporting evidence for interaction between the two proteins, but do not address whether the association is stable, transient, or bridged by other proteins. The dynein–dynactin pathway for nuclear positioning includes many protein components that are not dynein or dynactin complex members, whose contributions influence microtubule dynamics, the formation of a capture site on the cell cortex, and proteins that regulate spatial and temporal steps in the determination of nuclear orientation and migration during the cell cycle (Sheeman et al. 2003; Knaus et al. 2005; Li et al. 2005). Kip2p acts to ensure nuclear positioning within the dynein–dynactin pathway (Miller et al. 1998) by transporting dynein to the microtubule plus ends (Lee et al. 2003; Carvalho et al. 2004).

Our data indicate that *YLL049W* is a previously unknown component of the dynein–dynactin spindle orientation pathway and suggest that it might be a subunit of yeast dynactin. Elucidation of the specific molecular function of *YLL049W* will require further study.

To test the general application of using congruence score as phenotype predictor, we chose sensitivity to benomyl, a microtubule-depolymerizing agent, as our second phenotype assay for deletion mutants. The microtubule biogenesis gene *CINI* (Hoyt et al. 1990) was selected as the benomyl-sensitive landmark. Null mutants of 31 genes with

congruence scores  $\geq 4$  for *CINI* were tested for growth defects on medium containing 5 mg/ml of benomyl at 25 °C (Supplementary Table S4). With increasing congruence score cutoff, the fraction of benomyl-sensitive null mutants rises to 1 (Figure 3B). We again observed significant correlation between the congruence score and the fraction of benomyl-sensitive mutants (Spearman correlation coefficient = 0.49, two-sided  $P = 0.006$ ).

To validate the hypothesis that congruence interaction inferred from synthetic lethality indicates a closer functional association between genes than direct synthetic lethality, we selected landmarks of seven benomyl-sensitive mutant strains (*cin1* $\Delta$ , *yml094c-a* $\Delta$ , *pac10* $\Delta$ , *pdf1* $\Delta$ , *gim3* $\Delta$ , *tub3* $\Delta$ , and *gim5* $\Delta$ ) from the top list of 451 candidate benomyl-sensitive mutant strains from a recent high-throughput genetic screen (Pan et al. 2004). We then ranked genes based on their average congruence score with seven landmarks (Supplementary Table S5). As a test of the competing hypothesis that synthetic lethal interactions themselves indicate direct functional associations, we also ranked genes by the raw number of synthetic lethal interactions with seven landmarks (Supplementary Table S6). The congruence score and the raw number of interactions were then tested for correlation with benomyl LD<sub>50</sub>, the dose that is lethal to at least 50% of the cells, equivalent to control/experimental hybridization signal ratio  $\geq 2$  used as threshold by Pan et al. (2004). The congruence score is significantly correlated with LD<sub>50</sub> (Spearman correlation coefficient = -0.17, two-side  $P = 0.04$ ), but the number of synthetic lethal links is not (Spearman correlation coefficient = 0.06, two-side  $P = 0.22$ ) (Figure 3C and D). These results support the idea that genetic congruence correlates

better with a given phenotype than direct synthetic lethal interaction and indicate that congruence is a superior measure for predicting certain phenotypes.

All genes having high congruence scores with landmarks are involved in direct microtubule biogenesis. For example, *PAC10*, *YKE2*, *GIM3*, *GIM4*, and *GIM5* all belong to the prefoldin complex that acts to deliver unfolded proteins to cytosolic chaperonin (Geissler et al. 1998; Vainberg et al. 1998). On the other hand, we noticed that some genes with multiple synthetic lethal interaction links with landmarks tend to function in a distinct pathway from microtubule biogenesis. For example, *SWC1* and *ARP6* are subunits of *SWR1* chromatin remodeling complex catalyzing exchange of histone H2A with histone *HTZI* (Mizuguchi et al. 2004).

### **Physical co-residence predicts genetic congruence**

Because increasing congruence score is related to protein complex co-residence, we predicted that genes encoding proteins known to co-reside in a complex would have similar synthetic lethal interaction profiles. We verified this hypothesis using *PFD1* as a dSLAM (diploid-based synthetic lethality analysis on microarrays) query; the remaining prefoldin complex members have been characterized as queries in the SGA study. We identified 33 *PFD1* synthetic lethal partners (Supplementary Table S7). High congruence values between *PFD1* and other prefoldin components, *GIM3*, *GIM4*, *GIM5*, *PAC10*, and *YKE2*, equal to 14, 14, 9, 15, and 16, demonstrate the overlap between congruence links and protein complex membership (Supplementary Table S8). The five prefoldin members used as query genes in SGA exhibit much more significant overlap among themselves (congruence scores in the range of 23–67) than to *PFD1*. However, this may arise from

systematic biases between the SGA and dSLAM methods rather than a biological distinction for *PFD1*. Additionally, 13 of 33 *PFD1* synthetic lethal partners map to reported protein complexes (Supplementary Table S7). Notably, none of the 33 *PFD1* synthetic lethal partners is a prefoldin component. This supports the hypothesis that physical and synthetic lethal interactions are generally orthogonal.

### **Synthetic lethal interactions predict parallel pathways**

We further tested the hypothesis that synthetic lethal interactions between null alleles define parallel pathways, by performing dSLAM screens of genes required for mitotic exit. Two parallel pathways, the Cdc14 early anaphase release (FEAR) and the mitotic exit network (MEN), are required for release of the essential protein phosphatase Cdc14p from nucleolus during yeast cell cycle (Stegmeier et al. 2002). Components of the FEAR network include *SLK19* and *SPO12*, whereas those of MEN include *LTE1* and *CLA4*. Double mutant cells of these two pathways fail in Cdc14p release from the nucleolus and arrest in telophase with a large-budded morphology.

To test the parallel pathway model, we performed dSLAM experiments using *SLK19*, *SPO12*, and *LTE1* as queries; *CLA4* was previously used as a query in the SGA study (Tong et al. 2004) (Supplementary Table S9). We re-identified known synthetic lethality interactions between the FEAR and MEN pathways (Stegmeier et al. 2002; Goehring et al. 2003). High congruence was observed between *SLK19* and *SPO12*, and between *LTE1* and *CLA4*, but not across FEAR/MEN pathways (Supplementary Table S10). In addition, our genome-wide screens discovered synthetic lethal interactions between *LTE1* and *SIN3*, *RPD3*, *PHO23*, and *SAP30*, the components of the Sin3/Rpd3

histone deacetylase complex (Loewith et al. 2001) (Figure 4A and Supplementary Table S9). Although most were initially not identified in the previous study (Tong et al. 2004), we also observed synthetic lethal interactions between *CLA4* and all four components of the Sin3/Rpd3 complex (data not shown). These interactions were specific to MEN because synthetic lethality was not observed between the Sin3/Rpd3 histone deacetylase components and FEAR network components in either dSLAM or individual assays. These results led us to predict that the Sin3/Rpd3 histone deacetylase might play an important role during mitotic exit when the MEN pathway is mutated. In support of this, cells of the double mutants, *lte1Δ rpd3Δ*, *lte1Δ sin3Δ*, *lte1Δ sap30Δ*, *lte1Δ pho23Δ*, were unable to exit mitosis, and arrested with a dumbbell-shaped morphology typical of a mitotic exit defect. Furthermore, the viability of these double mutants was restored when *TAB1-6*, a dominant allele of *CDC14* that binds weakly to the negative regulator Cfi1p/Net1p (Shou et al. 2001), but not the wild-type *CDC14* was expressed (Figure 4B). Interestingly, this *TAB1-6* allele also suppressed the lethality of an *lte1Δ slk19Δ* double mutant (Figure 4B). Thus the Sin3/Rpd3 histone deacetylase likely acts in parallel with MEN in promoting exit from mitosis.

## Discussion

Synthetic lethal interaction provides evidence for compensating gene function. This compensation has been rationalized as buffering within a single pathway, or buffering between two parallel or compensating pathways (Tong et al. 2001, 2004; Wong et al. 2004). We find that the parallel pathway model permits successful inference of protein complex membership from synthetic lethal data. The parallel pathway model, but not the

single pathway model, yields successful predictions for phenotypes including nuclear migration defect rates and drug sensitivity. The parallel pathway model is also consistent with known pathways comprising genes identified in synthetic lethal screens. The model motivated our confirmation of *YLL049W* as participating in the dynein–dynactin nuclear migration pathway by phenotypic analysis, permitted identification of benomyl-sensitive strains based on congruence to landmark genes, and yielded a novel prediction of Sin3/Rpd3 histone deacetylase as a new module for mitotic exit that acts in parallel with MEN.

Using a different analysis strategy, Kelley and Ideker (2005) recently reported that synthetic lethal interactions are typically ‘between pathway’, whereas ‘within-pathway’ interactions occur infrequently. For their purposes, all subsets of proteins that are densely connected by physical interactions in non-mutant cells were considered ‘within pathway’. If a pathway is defined strictly by its components, however, the view that null allele synthetic lethality must always occur between parallel pathways can be enforced, precluding ‘within-pathway’ explanations. In such a view, members of a protein complex that functions in the absence of either of two subunits, but not both, would participate in three parallel pathways: one that includes all possible components, and one for each ‘incomplete’ complex (all of which might function in non-mutant cells). More generally, methods that summarize synthetic lethal relationships are often more useful than raw synthetic lethal pairs.

This recent analysis also predicted that *Yll049wp* associates with dynactin during spindle orientation (Kelley and Ideker 2005), consistent with our observation from

congruence analysis that *YLL049W* is functionally related to dynein–dynactin pathway. Our characterization includes experimental validations that support the prediction, and provides evidence from congruence score and detailed phenotype that the function of *YLL049W* is more similar to *JNMI* than *KIP2*. Confirmation of a physical interaction between *YLL049W* and *JNMI* further suggests that the prediction will be useful in future detailed analysis of the molecular role of *YLL049W*.

The congruence score metric compares favorably with other methods for inferring functional associations from synthetic lethal data. First, it produces stronger inference of gene function than the underlying direct genetic interactions. For example, direct interactions are unable to predict benomyl sensitivity, whereas congruence is a strong predictor of similar sensitivity. Second, the congruence metric naturally provides a *P*-value and can give improved performance relative to the raw count of the number of shared interaction partners. Finally, the *P*-values provided by the congruence score can provide an advantage over methods such as hierarchical clustering, which continue to depend on visual inspection of clusters and definition of cluster boundaries.

The quantitative characteristic of each congruent pair interaction can be used to consider interactions above a given threshold, allowing experimentalists to consider which network features reflect the most significant evidence in the data set, and to include less significant observations to be evaluated when desired. Importantly, a congruence summary at any significance level quantitatively relates genes according to their functional similarity by interaction profiles, not individual synthetic lethal pairings. To identify congruent gene pairs with greater or lesser significance, the interaction

linkages can be annotated, or the map can be redrawn at differing congruence cutoff scores. For example, Supplementary Figure S8, Figure 2D, and Supplementary Figure S9 are all target gene congruence network by setting congruence score  $\geq 8$ ,  $\geq 10$ , and  $\geq 15$ , respectively. This aspect of network analysis will become increasingly important as the information summarized within it grows. Some biologically important relationships may inherently be present in the genetic congruence network only at relatively low significance overall. These can be viewed by extracting a local network containing first-degree congruence relationships in much the same way as the current large-scale interaction network is commonly viewed in subsections (Tong et al. 2001, 2004; Ooi et al. 2003).

A possible limitation of our analysis is the low coverage of the synthetic lethal network, with only ~2% screened by high-throughput methods using query genes selected on the basis of specific biological themes (Tong et al. 2004). To assess the sensitivity of our analysis to missing data, and also to possible false positives, we repeated our analysis with data sets modified to contain up to 30% false positives (random interactions added to the data) and 30% false negatives (observed interactions removed from the data) (Supplementary Figure S10). Note that the false-positive rate is quite low for the SGA data owing to confirmation by tetrad or random spore analysis; false negatives are estimated in the range of 17–41% (Tong et al. 2004). Although the congruence scores shift to lower values, the overall performance is similar to using the original data set (compare Figure 2 and Supplementary Figure S10). These observations suggest that the congruence score method is robust to noisy and incomplete data.

Continuing genetic interaction screens will generate increasing volumes of data. A critical challenge is to develop computational approach to integrating these data and eventually understanding gene function. Several hurdles will need to be surmounted. Essential genes are missing from the synthetic lethal network, although they may be probed eventually using non-null mutant alleles. Certain higher-order redundancy processes may also require more than two-gene deletion to be observed. The most promising approach to ease the limitations may be to combine different types of networks for improved inference. We have performed joint analysis on genetic network and physical network to argue that the correct functional links between genes should be orthogonal to the synthetic lethal interaction (see Supplementary information). Future studies by combining other types of heterogeneous network data, such as gene expression and phylogenetic information, will certainly improve our inference of biological systems.

This work in budding yeast, made possible by the development of the comprehensive deletion collection, massively parallel phenotyping techniques, and quantitative analysis of synthetic lethal interaction data within a statistical framework, will create a template for testing and improving our understanding of biological buffering and genetic robustness in many systems as researchers gather similar information data sets from other organisms. Genome-wide synthetic lethality screens using RNAi are becoming available in other organisms (van Haaften et al. 2004) and may eventually allow analysis similar to the one we have performed in yeast. Full-genome RNAi screens have been conducted for *Caenorhabditis elegans* and *Drosophila melanogaster* (Kamath et al. 2003; Boutros et al. 2004), and genome-wide screens in other metazoans are in

progress. In instances where RNAi knockdown is complete, the congruence score method should provide a quantitative metric for shared gene function through calculating the probability of a gene pair sharing phenotypic defects in the RNAi screens. Therefore, the methodology we have applied to predict gene functions from yeast genomic synthetic lethality can be certainly extended to analogous RNAi screens for the discovery of novel gene tasks in higher organisms.

## **Materials and methods**

### **Data sources**

Synthetic lethal interactions, including lethal and sick phenotypes, were derived from SGA analysis in budding yeast, *S. cerevisiae* (Tong et al. 2004). We removed six essential query genes from the original 132-query gene network, including *MYO2*, *SCC1*, *CDC2*, *CDC7*, *CDC42*, and *CDC45*. The intermediate (viable) phenotypes exhibited by conditional alleles of essential genes may include loss-of-function, unregulated function, and gain-of-function aspects. In contrast, null alleles of non-essential genes are by definition solely loss-of-function mutations. We ascertained that our results and conclusions do not change when these six essential genes are included in the analysis. Yeast protein complex data were collected from two high-throughput studies, TAP and HMS-PCI, both using approaches of affinity purification of tagged bait protein to pull down complexes followed by mass spectrometry analysis (Gavin et al. 2002; Ho et al. 2002). Protein complexes that contain two or more non-essential gene encoded proteins were used (353 complexes from TAP and 427 complexes from HMS-PCI). We defined a protein complex to include the bait protein and all prey proteins detected by the bait.

Similar analysis was also performed using curated MIPS protein complex data set ('complexcat.scheme', June 12, 2003, 145 complexes with two or more non-essential gene encoded proteins) (Mewes et al. 2004) and results are provided in the Supplement. Pairwise protein interactions in *S. cerevisiae* derived from high-throughput yeast two-hybrid assays (Uetz et al. 2000; Ito et al. 2001) were also analyzed and found to support our conclusions (results not shown).

### **Randomization of synthetic lethal interactions**

Synthetic lethal interactions from SGA were reported as a pair of genes directed from the query gene to the target gene. A randomized network was generated by keeping the query gene list unchanged, randomly picking one of the 982 target genes identified in the SGA screen according to the probability of each target gene shown in the interaction list with replacement, and matching it to the query gene. Duplicate query–target pairs and self-interaction pairs are rejected during randomization. Results depict the average over 10 randomizations.

### **Probability of congruence and congruence score**

We separated the SGA interaction data into query and target sets, based on whether each gene node represents a non-essential query gene (126 are included in the published data) or a target gene (982 of which are synthetic lethal partners by at least one query). We depict results for the target genes, as the number of primary nodes is much larger and should, in principle, include the query genes.

The probability of a gene pair sharing at least  $k$  synthetic lethal interaction partners

was derived from the hypergeometric distribution:

$$p(x \geq k) = \sum_{x=k}^{\min(m, n)} \frac{C(m, x) \cdot C(t-m, n-x)}{C(t, n)},$$

in which  $C(j, k)$  is the combinatorial factor  $j!/k!(j-k)!$ ,  $m$  is the number of synthetic lethal interaction partners for gene 1,  $n$  is the number of synthetic lethal interaction partners for gene 2, and  $t$  is the total number of query genes (126 genes) if calculation is for a target pair or the total number of target genes (4700 genes) if calculation is for a query pair. The congruence score is  $-\log_{10}[p(x \geq k_{obs})]$ . High-scoring pairs from query genes reveal similar patterns as target genes (Supplementary Figure S11) from the data set of Tong et al. (2004).

To correct for multiple testing of target pairs, we estimate that a final  $P$ -value of 0.01 requires a per-link  $P$ -value of  $\sim 0.01/982^2$ , or  $10^{-8}$ , corresponding to a congruence score of 8 or more. For illustrative purposes, we selected a more stringent threshold of 10 (Figure 2D). At this significance, the congruence network contains only 68 nodes with 138 first-degree interactions, summarizing relationships among 1184 synthetic lethal pairs overall.

### **Network visualization**

Network figures were created using *Cytoscape 1.1* (Shannon et al. 2003).

### **GO annotation correlation**

GO is held as a directed acyclic graph (DAG) to describe attributes of gene products in three ontologies—biological process, molecular function, and cellular component

(Ashburner et al. 2000). To calculate the GO term similarity between a pair of genes, depths of different subbranches of the GO DAG have been recorded for each gene. Here, we assume that all of the links in the GO DAG are of equal weight. Then, the deepest depth in the GO DAG at which the pair of genes share an annotation was found and defined as depth  $d$ . Gene pairs with genes without annotation were discarded. The maximal depth  $\text{Max}(\text{depths})$  and minimal depth  $\text{Min}(\text{depths})$  for all genes in the synthetic lethal data set were calculated for each of three ontologies. The GO annotation correlation for a pair of congruent genes with depth  $d$  was defined by  $(d - \text{Min}(\text{depths})) / (\text{Max}(\text{depths}) - \text{Min}(\text{depths}))$ . For example, the maximal depth is equal to 17 and the minimal depth is equal to 1 for biological process ontology. The deepest depth for shared annotation of gene pair *JNMI* and *KIP2* is 11. Thus, the GO annotation correlation for *JNMI* and *KIP2* for biological process is calculated as  $(11 - 1) / (17 - 1) = 0.63$ . This is similar to the GO depth correlation in a previous study of *Drosophila* physical interactions (Giot et al. 2003), except that the previous study normalized the depth correlation to fall in the range 0–1. This method differs from the semantic similarity method (Lord et al. 2003) in two ways: (1) it weights GO terms by depth, whereas semantic similarity weights terms by frequency; (2) it uses the depth of the deepest annotated term, whereas semantic similarity averages over annotations. Results from the two methods are consistent (Supplementary Figure S12).

### **Noise robustness analysis**

To account for 17–41% false negatives in the SGA data set, we randomly removed 30% of interactions from the original data assuming reported interactions are all correct.

To account for potential false positives (although SGA data set contains very few false positives as every interaction has been individually confirmed), we randomly replaced 30% of original interactions with random interactions. These two data sets containing false negatives and false positives, respectively, were used to repeat the congruence analysis, and this process was repeated 10 times (Supplementary Figure S10).

### **Experimental validation and discovery of gene function required for nuclear migration by highly significant congruence score**

Null mutants of 59 genes with congruence scores greater than or equal to 4 for six landmark genes (*NUM1*, *DYN1*, *DYN2*, *ARPI*, *JNMI*, or *NIP100*) were tested for nuclear migration defects at 13 °C. Deletion mutants were grown in YPD at 30 °C until low-log phase and then cultures were shifted to 13 °C for 24 h. Formaldehyde was added to 3.7% and cells were incubated at room temperature overnight. Cells were washed in 1 M sorbitol/50 mM potassium phosphate pH 7.5 (SK), permeabilized in SK + 3.7% formaldehyde + 0.5% Triton X-100 for 7 min, washed in SK, and then stained in SK + DAPI (100 ng/ml). Cells were examined under a fluorescence microscope, and 50 or 100 single large budded cells were scored for nuclear morphology. Normal cells had one DAPI mass at or through the bud neck or two DAPI masses, one in each cell body.

### **Experimental validation of gene function required for benomyl resistance by highly significant congruence score**

Null mutants of 31 genes with congruence scores greater than or equal to 4 for *CIN1* were tested for growth defects on media containing low concentrations of benomyl at 25 °C. Deletion mutants were grown on YPD agar, equal amounts of yeast (by OD<sub>600</sub>)

were suspended in water in a 96-well plate and five-fold dilutions were performed. A 96-pin device was used to transfer yeast from each well to a YPD agar plate containing benomyl (5 µg/ml in DMSO) and to YPD agar with DMSO only. Plates were incubated at 25 °C for 3 days and scored for growth defects on benomyl versus DMSO alone.

### **Experimental validation of genetic congruence from physical co-residence**

dSLAM was performed using *PFDI* as query gene and a pool of ~6000 heterozygous diploid knockout strains. The detailed method is described elsewhere (Pan et al. 2004). Briefly, the heterozygous deletion collection was transformed with a *PFDI* knockout construct as a pool, sporulated, and haploid double mutants were selected. Knockout-specific barcode tags were amplified with Cy3-labeled primers and hybridized to a microarray with Cy5-labeled control tags from haploid single mutants. Mutants were scored as positive only if both UPTAG and DNTAG had ratios greater than 2.0.

### **Experimental validation of parallel pathways predicted by synthetic lethal interactions**

dSLAM was performed using *LTE1*, *SPO12*, and *SLK19* as query genes. The procedure is same as *PFDI* experiment described above. The data presented are the results of individual confirmation by random spore analysis or tetrad analysis.

### **Experimental validation of physical interaction predicted by congruence scores with dynein–dynactin landmark genes**

Yeast two-hybrid experiments were performed using activation and binding domain vectors pOAD (*LEU2*-marked) and pOBD-2 (*TRP1*-marked), respectively, and yeast

strains PJ69-4a and PJ69-4alpha (James et al. 1996). Materials were kindly provided by Stanley Fields, Yeast Resource Center. GAL4-binding domain fusions were transformed into PJ69-4alpha and GAL4-activation domain fusions were transformed into PJ69-4a. The two strains were mated and diploids were selected on SC –Leu –Trp. The resulting diploids were plated on SC –Ade –His media in two dilutions (2 µl of 0.1 OD<sub>600</sub>/ml and 0.02 OD<sub>600</sub>/ml) at 30 °C. Growth at 4 days demonstrated a strong physical interaction between Jnm1p and Yll049wp (Supplementary Figure S7).

The constructs used were JNM1-BD, JNM1 fusion with GAL4-binding domain; YLL049W-AD, YLL049W fusion with GAL4-activation domain; BD, binding domain alone; AD, activation domain alone.

Two independent JNM1-BD and two independent YLL049W-AD transformants supported growth when appropriately combined. YLL049W-BD + AD alone resulted in growth owing to self-activation and was therefore not informative (data not shown).

The plasmids and strains used for this study are distinct from those used by Ito et al. (2001), who reported high-throughput yeast two-hybrid interaction between *JNMI* and *YLL049W*.

### **Genotypes**

PJ69-4a: *MATa trp1-901 leu2-3,112 ura3-52 his3-200 gal4Δ gal80Δ LYS2::GAL1-HIS3 GAL2-ADE2 met2::GAL7-lacZ*

PJ69-4α: *MATα trp1-901 leu2-3,112 ura3-52 his3-200 gal4Δ gal80Δ LYS2::GAL1-HIS3 GAL2-ADE2 met2::GAL7-lacZ*

We attempted further confirmation of the physical interaction between Yll049wp and Jnm1p with both co-immunoprecipitation (co-IP) and GST pull-down experiments. We first attempted to make yeast strains expressing fusion proteins (Yll029w-3HA, Yll049w-13Myc, Jnm1-3HA, and Jnm1-13Myc) by genomic integration using the Pringle cassettes that confer G418 resistance (Longtine et al. 1998). For all four cases, multiple G418-resistant integrants were selected and confirmed by PCR diagnosis. In each case, yeast extracts were prepared from two representative candidate clones and analyzed by Western blot for expression of fusion protein. While the Jnm1-3HA and Jnm1-13Myc fusion proteins were easily detected, we were unable to detect either Yll049w-3HA or Yll049w-13Myc. One possible explanation is that the expression level from the endogenous *YLL049W* promoter is so low that the fusion proteins cannot be detected. We thus obtained from Dr Heng Zhu a plasmid (with URA3 as the selectable marker) that has been reported to overexpress GST-Yll049w under control of the robust galactose-inducible *GALI* promoter (Zhu et al. 2001). We transformed this plasmid into yeast strains expressing both Jnm1-3HA and Jnm1-13Myc and grew the transformants in synthetic medium lacking uracil (for selecting the plasmid). Standard galactose induction protocol was followed to induce expression of GST-Yll049w (Zhu et al. 2001). Again, we were unable to detect the GST-Yll049w fusion protein in these strains. In contrast, GST-Ctf4 and GST-Jnm1 fusion proteins were expressed at high levels from strains harboring the corresponding GAL1-GST fusion plasmids under the same conditions. This result suggests that the Yll039w protein might become extremely unstable when tagged with epitope tags. Given that the Yll049w fusion proteins were not expressed at

detectable level, we were unable to perform co-IP or GST pull-down experiments to confirm a physical interaction between Yll049w and Jnm1. We also note that a yeast strain expressing Yll049w-TAP was not available from the collection of TAP-tagged yeast strains made by O'Shea and Weissman's group (Ghaemmaghami et al. 2003), possibly because such a strain did not express detectable fusion protein.

### **Acknowledgments**

JSB acknowledges support from the Whitaker Foundation, NIH/NIGMS, and NIH/NCRR. FAS, JDB, XP, and BDP were supported in part by NHGRI grant HG02432 and by the Technology Center for Networks and Pathways (RR020839). BP acknowledges support from an NIH/NIGMS training grant. XP was partly supported by a postdoctoral fellowship from the Leukemia & Lymphoma Society. We also thank Dr David Cutler and Dr Angelika Amon for invaluable discussions, Dr Raymond Deshaies for providing the TAB1-6 allele, and Dr Stanley Fields for providing vectors pOAD and pOBD-2 and strains PJ69-4a and PJ69-4 $\alpha$ .

### **Statement of contributions**

PY developed statistical and computational methods and generated information-based predictions.

BDP developed the congruence calculation, conducted the nuclear migration and benomyl screens, and two-hybrid test for interaction between Yll049wp and Jnm1p.

XP conducted the *PFD1*, *LTE1*, *SPO12*, and *SLK19* dSLAM screens and the suppression of synthetic lethality between *LTE1* and the Sin3/Rpd3 components by

*TABI-6.*

JDB and FAS helped initiate and supervised the experimental work.

FAS and JSB helped initiate the theoretical work, and JSB supervised the theoretical and computational work.

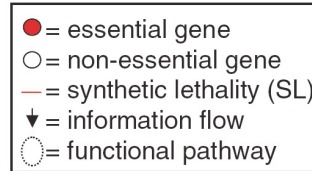

**Figure 1.** Congruent synthetic lethal (SL) interactions are consistent with functional pathway membership. (A) A simplified synthetic lethality pathway model. Black arrows indicate the schematic flow of a process, with essential genes (red circles) connected by non-essential genes (black circles) organized into two parallel pathway branches (black dashed lines). If at least one of the pathway branches is required for viability, SL interactions (red lines) will be observed between the pathway branches but not within a pathway branch. In this picture, deleting any component of a pathway branch destroys its activity. (B) Directly observed SL genetic interactions bridge pathway branches. The table indicates that SL interactions will be observed between components of the two pathway branches, whereas no interactions will be observed within a branch. (C) Functional associations inferred from the congruence score (blue lines) join the components of a pathway branch. The table indicates raw number of SL interaction partners shared by a pair of genes and its conversion to the congruence score, calculated as the  $-\log_{10} P$ -value for partner sharing. The congruence connections are orthogonal to the direct SL interactions and align with pathway membership.

**Figure 1.**

**Figure 2.** Genetic congruence predicts physical colocalization and shared gene function. Cumulative bins were constructed for all target gene pairs using a threshold congruence score. (A) High congruence score predicts protein complex membership. The red dot at congruence score 5 indicates the threshold at which congruent gene products are more likely than synthetic lethal partners to reside in the same protein complex ( $P < 10^{-6}$  for co-residence of the congruent pairs). (B) A high congruence score predicts GO annotation correlations (biological process, molecular function, and cellular component). Red symbols label the thresholds above which annotations of congruent gene pairs are more highly correlated than annotations for synthetic lethal pairs. (C) High congruence excludes synthetic lethal interaction. The black dashed line labels the threshold value of congruence score 14, above which the binomial  $P$ -value for observed number of synthetic lethal interactions is insignificant ( $P > 0.05$ ). (D) Synthetic lethal interactions have been used to calculate congruence scores (blue lines, threshold congruence score  $\geq 10$ ) that connect genes in the same pathway branch. Congruence edges are generally orthogonal to the underlying synthetic lethal interactions and parallel to protein complex membership (green lines, membership in a single complex; black lines, overlap of congruence and protein complex edge). The shaded inset shows the synthetic lethal interactions (red lines) underlying the congruence edge between *UBA4* and *ELP6*. Congruence networks at thresholds 8 and 15 are shown as Supplementary Figures S7 and S8.

**Figure 2.**

**Figure 3.** The congruence score but not the number of synthetic lethal interactions predicts numeric phenotypes for deletion mutants. (A) Null mutants of 59 genes with congruence score  $\geq 4$  for six landmark genes (*DYNI*, *ARPI*, *DYN2*, *JNMI*, *NUM1*, and *NIP100*) known to be required for robust nuclear migration were measured for percent abnormal nuclear migration at 13 °C. Each mutant's nuclear migration defect is plotted by congruence score to each landmark gene (congruence score range is labeled) and by average congruence score (dots). (B) Null mutants of 31 genes with congruence score  $\geq 4$  for landmark gene *CINI* known to be required for benomyl resistance were tested for benomyl sensitivity at concentration 5  $\mu\text{g/ml}$ . The fraction of benomyl-sensitive null mutants is plotted with each congruence score cutoff. (C, D) Null mutants of 451 candidate benomyl-resistant genes are ranked based on their average congruence score or number of synthetic lethal interactions with seven landmark genes (*CINI*, *YML094C-A*, *PAC10*, *PFD1*, *GIM3*, *TUB3*, and *GIM5*) known to be required for benomyl resistance (Pan et al., 2004). The LD<sub>50</sub> benomyl concentration is defined by the lowest benomyl concentration when the control/experimental hybridization signal concentration  $\geq 2$ . The red mark represents the median LD<sub>50</sub> benomyl concentration.

**Figure 3.**

**Figure 4.** Parallel pathways required for mitotic exit. (A) Synthetic lethal interactions define parallel pathways: FEAR, MEN, and Sin3/Rpd3 complex. The Sin3/Rpd3 complex could function in the FEAR pathway; here, we depict a separate pathway because we demonstrate that it is parallel to MEN. (B) Suppression of *rpd3Δ lte1Δ* synthetic lethality by *TAB1-6* (*CDC14* allele). A haploid convertible heterozygous diploid double mutant (*LTE1/lte1Δ::natMX XXX/xxxΔ::kanMX*, *XXX* stands for *RPD3* or *SLK19*) was transformed with a vector (YCplac33), or a plasmid expressing the wild-type *CDC14* or *TAB1-6*. The resultant transformants were sporulated and the meiotic progenies were spotted with 10× serial dilutions onto haploid selection media specific for haploid *MATa* cells of indicated genotypes. Cells were incubated at 30 °C for 3 days and photographed. The synthetic lethality between *LTE1* and other components of the Sin3/Rpd3 complex was also similarly confirmed. The results of this experiment were recapitulated by tetrad analysis on YPD (data not shown).

**Figure 4.**

## **Supplementary information:**

### **Synthetic lethal genes bridge parallel pathways**

Protein complexes are often the functional units that implement biological processes. Knowledge of protein complex organization can help explain the functions of genes within the context of biological pathways. We hypothesized that protein complex data can reveal quantitative, hierarchical organization of synthetic lethal interactions. Specifically, members of different protein complexes in parallel pathways should cluster in groups of direct synthetic lethal partners. Synthetic lethal interactions between these groups should ‘bridge’ the parallel pathway branches they reveal.

To explore this hypothesis, we first calculated the total number of synthetic lethal interactions between protein complexes using synthetic lethal dataset generated from the SGA approach (Tong et al. 2004) and high-throughput protein complex datasets (Gavin et al. 2002; Ho et al. 2002). Of 3799 synthetic lethal pairs of knock-out mutants, 1083 (~30%) bridge distinct protein complexes, with one member of a synthetic lethal pair in a different complex than its partner. Since only ~1% of synthetic lethal pairs reside within the same protein complex (Tong et al., 2004), a synthetic lethal interaction is 30× more likely to bridge two distinct complexes than reside within a single complex. Analysis using interactions from curated protein complex data (Mewes et al. 2004) and from high-throughput yeast two-hybrid screens (Ito et al. 2001; Uetz et al. 2000) also support our hypothesis that synthetic lethal pairs are more likely to encode proteins without direct physical interactions. A recent computational study reports similar results (Wong et al. 2004).

For each pair of protein complexes reported in large-scale screens (Gavin et al. 2002; Ho et al. 2002), enrichment of synthetic lethal interaction was quantified as the parallel complex score calculated as the negative  $\log_{10}$  of the binomial  $p$ -value for number of synthetic lethal interactions observed between members of the two complexes given the overall frequency of synthetic lethal interactions observed in the whole data set (see the next section for detail). Significant numbers of protein complex pairs are observed being bridged by synthetic lethal interactions using the actual synthetic lethal interactions compared to a randomized set when parallel complex scores  $\geq 3$  ( $p$ -value  $< 10^{-5}$ , Fig. S1A). The hierarchical view of synthetic lethal interaction by clustering gene products into protein complexes shows protein complex nodes connected by highly significant parallel complex linkages (Fig. S1B). Analysis using the curated MIPS protein complex dataset (Mewes et al. 2004) generates similar results (Fig. S2).

The PAC10 complex is the hub of the parallel complex network, with links to 34 other protein complexes (Fig. S1B). Its hub character is due in part to the bias that all four complex components, *PAC10*, *GIM3*, *GIM5*, and *YKE2* (Gavin et al., 2002), are SGA query genes (Tong et al. 2004). The PAC10 complex proteins detected by mass spectrometry belong to the biochemically characterized Prefoldin complex (*PAC10*, *GIM3*, *GIM4*, *GIM5*, *YKE2*, *PFD1*), involved in tubulin folding and delivering unfolded proteins to cytosolic chaperonin (Geissler et al. 1998; Vainberg et al. 1998). Deletion mutants of Prefoldin complex components are viable, and sensitive to the microtubule depolymerizing drug benomyl (Geissler et al. 1998). The 34 protein complexes linked with the PAC10 complex carry out diverse biological processes including cytoskeleton

organization and biogenesis, budding, transcription regulation, translational membrane targeting, rRNA processing, and DNA damage response (Ashburner et al. 2000). The synthetic lethal interaction linkages indicate that these pairs of protein complexes provide related, but distinct, cellular functions. For some linkages, the relationship is readily understood given current knowledge. For example, the PAC10 complex exhibits enhanced synthetic lethal interactions with the IML3 complex (*IML3*, *MCM21*, *MCM22*, *CTF3*, *CTF19*, *CHL4*, *AME1*, *NKPI*) (Fig. S1B), which is a kinetochore component. It is reasonable to propose that activities of these two protein complexes may be complementary during kinetochore capture or during chromosome movement, when microtubule dynamics and kinetochore activity are coupled. Synthetic lethality may be explained by higher-order effects of combined perturbations of microtubules and kinetochores.

### **Probability of synthetic lethal interaction and parallel complex score**

The probability of at least  $k$  synthetic lethal interactions bridging two protein complexes was calculated from the binomial distribution:

$$p(x \geq k) = \sum_{x=k}^n C(n, x) \cdot P^x \cdot (1 - P)^{n-x} ,$$

in which  $C(n, x)$  is the combinatorial factor  $n!/x!(n-x)!$ ;  $n$  is the total number of possible interactions between two protein complexes; and  $k$  is the number of observed synthetic lethal interactions between two protein complexes. The probability of observing a set of synthetic lethal interactions between two protein complexes  $P$  was approximated to be 0.0064 from  $a/bc$ , where  $b$  equals 126, the number of query genes,  $c$  equals 4700, the

number of target genes, and  $a$  equals 3799, the number of total synthetic lethal interactions observed between query and target genes. The parallel complex score is  $-\log_{10}[p(x \geq k_{obs})]$ .

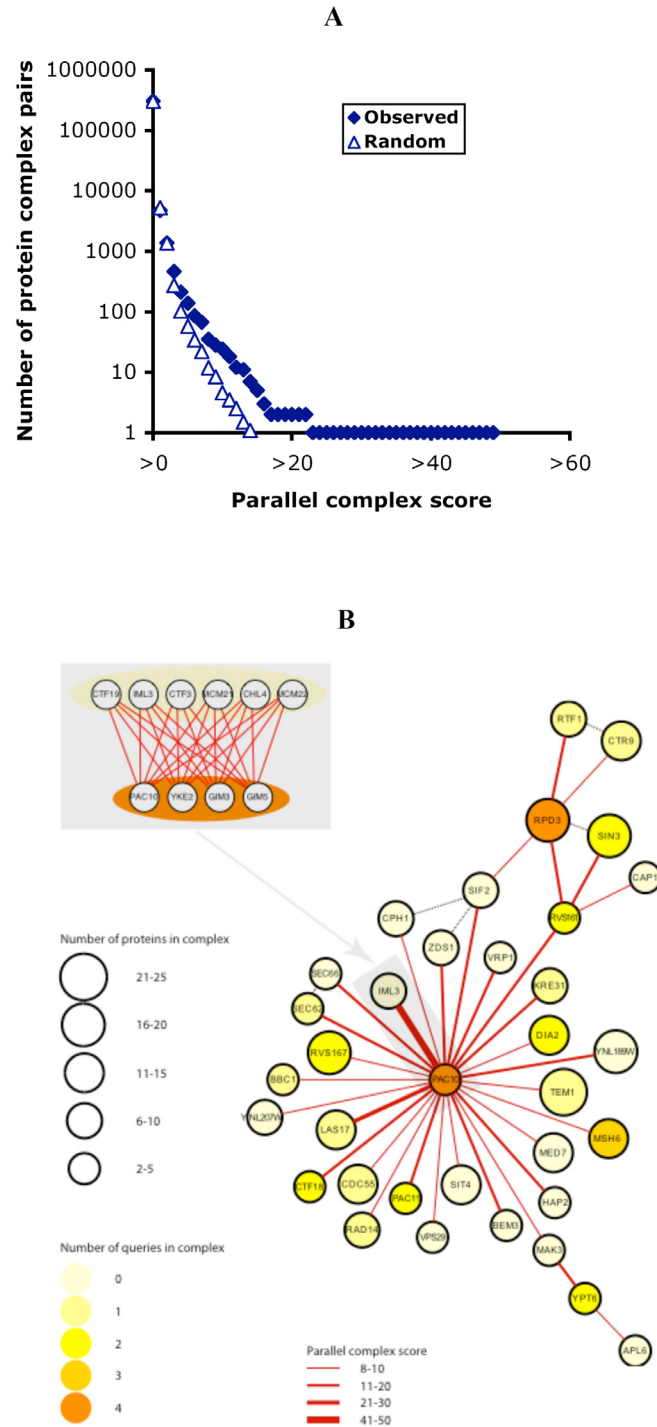

We reasoned that for a final  $p$ -value of 0.01, an appropriate single-test  $p$ -value that incorporates multiple testing all pairs of 780 protein complexes used would be  $\sim 0.01/7802 = 2 \times 10^{-8}$ , corresponding to a parallel complex score of 7 to 8. As the number of complex pairs nearly doubles when the parallel complex score decreases from 8 to 7 (Fig. S1A), we used 8 as the threshold for the visualization (Fig. S1B). Similarly, threshold 7 was used for Fig. S2B.

### **Protein complex pair sharing protein components**

The Jaccard coefficient  $c = (n1 \cap n2) / (n1 \cup n2)$ , where  $n1$  is the number of proteins in complex 1 and  $n2$  is the number of proteins in complex 2, was calculated to define comparable protein complexes. The value of 0.4 was used as the threshold of Jaccard coefficient to define similar complexes in Fig. S1B.

**Figure S1.** Synthetic lethal genes bridge parallel pathways from analysis on high throughput protein complex dataset (Gavin et al. 2002; Ho et al. 2002). (A) Significant numbers of protein complexes are bridged by synthetic lethal interactions than expected by chance ( $p$ -value  $< 10^{-5}$  when parallel complex score  $\geq 3$ ). (B) Pairwise synthetic lethal interactions have been mapped to the level of protein complexes (circles) using the parallel complex score with threshold value  $\geq 8$  (red lines). The size of a circle indicates the number of proteins in the complex, and its color indicates the number of corresponding genes used as SGA queries. Independently reported protein complexes that share multiple components (Jaccard coefficient  $\geq 0.4$ ) are linked (dashed black lines). The shaded inset depicts the pairwise synthetic lethal interactions between components of the PAC10 and IML3 complexes that are summarized by a single parallel complex edge.

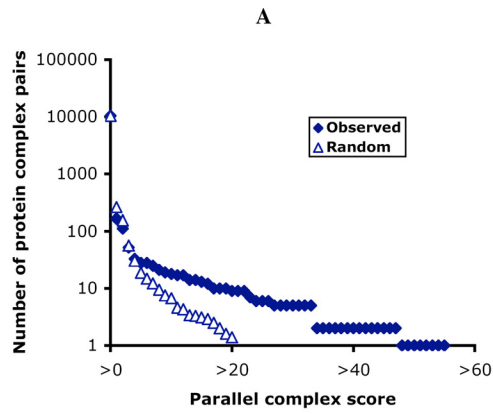

Figure S1.

**Figure S2.** Synthetic lethal genes bridge parallel pathways from analysis on curated MIPS protein complex dataset (Mewes et al. 2004). (A) Significant numbers of protein complexes are bridged by synthetic lethal interactions than expected by chance ( $p$ -value  $< 0.001$  when parallel complex score  $\geq 5$ ). (B) Pairwise synthetic lethal interactions have been mapped to the level of protein complexes (circles) using the parallel complex score with threshold value  $\geq 7$  (red lines).

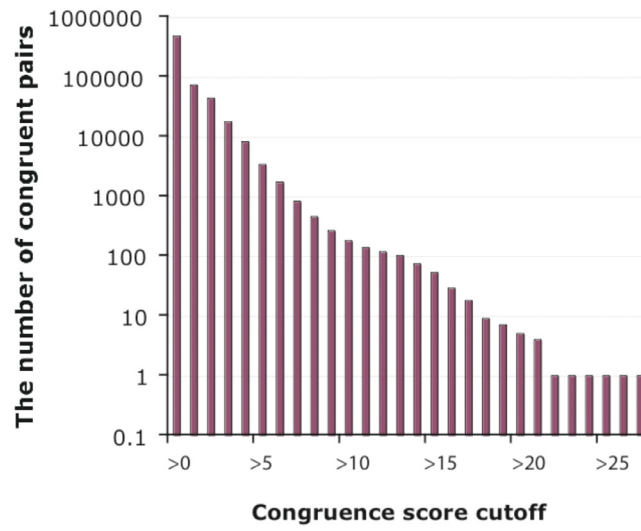

Figure. S2.

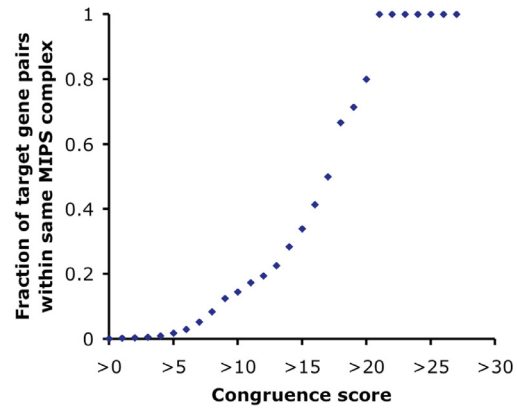

**Figure S3.** The congruence score method is superior to the number of common neighbors in predicting protein complex coresidence of congruent gene encoded proteins. Prediction of coresidence is presented as a receiver operating characteristic (ROC) curve in terms of the false-positive rate (A), equal to (false positives) / (false positives + true negatives), and the false-discovery rate (B), equal to (false positives) / (false positives + true positives). The numbers indicate the cut-off values for congruence score (blue) and common neighbors (purple). Synthetic lethal interaction (red) has higher false positive rate (A) and higher false discovery rate (B) in predicting protein complex coresidence as compared with congruence score method when their true positive rates are comparable. The higher ordinate for the congruence score method implies superior performance based on the area under the curve criterion.

**Figure S4.** The number of target congruent gene pairs at each congruence score cutoff.

**Figure S5.** Congruence score predicts protein complex membership using curated MIPS protein complex dataset.

Abnormal:

**Figure S6.** Examples of nuclear migration phenotypes. Left panel, merged Phase/DAPI images of normal nuclear migration events; right panel, merged Phase/DAPI images of abnormal nuclear migration events.

**Figure S7. Jnm1p binds Yll049wp by yeast-two hybrid assay.**

Yeast-two-hybrid experiments were performed using activation and binding domain vectors pOAD (*LEU2*-marked) and pOBD-2 (*TRP1*-marked), respectively, and yeast strains PJ69-4a and PJ69-4 $\alpha$  (James et al. 1996). Materials were kindly provided by Stanley Fields, Yeast Resource Center. GAL4-binding domain fusions were transformed into PJ69-4 $\alpha$  and GAL4-activation domain fusions were transformed into PJ69-4a. The two strains were mated and diploids were selected on SC –Leu –Trp. The resulting diploids were plated on SC –Ade –His media in two dilutions (2  $\mu$ l of 0.1 OD<sub>600</sub>/ml and 0.02 OD<sub>600</sub>/ml) at 30 °C. Growth at 4 days is shown.

JNM1-BD, *JNM1* fusion with GAL4 binding domain; YLL049W-AD, *YLL049W* fusion with GAL4 activation domain; BD, binding domain alone; AD, activation domain alone.

Two independent JNM1-BD and two independent YLL049W-AD transformants supported growth when appropriately combined. YLL049W-BD + AD alone resulted in growth due to self-activation and was therefore not informative (data not shown).

The plasmids and strains used for this study are distinct from those used by Ito, et al. (Ito et al. 2001), who reported high-throughput yeast-two-hybrid interaction between *JNM1* and *YLL049W*.

Genotypes: PJ69-4a: *MATa trp1-901 leu2-3,112 ura3-52 his3-200 gal4 $\Delta$  gal80 $\Delta$  LYS2::GAL1-HIS3 GAL2-ADE2 met2::GAL7-lacZ* PJ69-4alpha: *MAT $\alpha$  trp1-901 leu2-3,112 ura3-52 his3-200 gal4 $\Delta$  gal80 $\Delta$  LYS2::GAL1-HIS3 GAL2-ADE2 met2::GAL7-lacZ*

**Figure S7.**

**Figure S8.** Target gene pair congruence network with the congruence score cutoff greater than or equal to 8.

**Figure S9.** Target gene pair congruence network with the congruence score cutoff greater than or equal to 15.

**Figure S10.** Noise robustness analysis for the congruence method. (A), (C), and (E) are results derived from the dataset containing 30% of false negative synthetic lethal interactions. (B), (D), and (F) are results derived from the dataset containing 30% of false positive synthetic lethal interactions. The congruence scores generated from datasets containing false negatives and false positives are in the range of 0 to 10 and show similar results as those using the original dataset (compare with Fig. 2a, 2b, 2c). (A) and (B) A high congruence score predicts protein complex membership. Above congruence score of 3, significant numbers of congruence gene products reside in the same complex as compared with synthetic lethal gene products ( $P < 0.05$ ). (C) and (D) A high congruence score predicts Gene Ontology (GO) annotation correlations (biological process, molecular function, and cellular component). Above congruence score of (7, 6, 5) and (8, 7, 5) for (c) and (d), respectively, congruence pairs have significantly higher GO correlation (biological process, molecular function, cellular component) as compared with that of synthetic lethal gene pairs ( $P < 0.05$ ). (E) and (F) High congruence excludes synthetic lethal interaction. Above congruence score of 8 and 7 for (E) and (F), respectively, the binomial p-value for observed number of synthetic lethal interactions is insignificant ( $P > 0.05$ ).

Figure S10.

**Figure S11.** Query gene pair genetic congruence network with the congruence score cutoff greater than or equal to 33. Congruent interactions are labeled with blue lines, physical interactions derived from any two proteins in the same protein complex are labeled with green lines, and black lines represent coexistent congruent and physical interactions.

**Figure S12. Semantic similarity of congruent genes.**

Semantic similarity (Lord et al. 2003) was calculated for congruent gene pairs and synthetic lethal gene pairs using all yeast gene Gene Ontology annotations for training. Open points indicated the congruence scores at which the semantic similarity for congruent genes rises above similarity for synthetic lethal genes (significance  $p < 0.05$ ). These points show that congruence score out-perform direct synthetic lethal interactions at thresholds of 7 (process), 8 (function), and 5 (component). This is superior performance to that indicated in the main text using GO depth correlation, where the crossovers occurred at 7 (process), 10 (function), and 6 (component).

**Table S7.** *PFD1* dSLAM targets. Genes exhibiting synthetic lethality in combination with *PFD1* were detected by microarray analysis after sporulation of a heterozygous deletion mutant pool that had been transformed with a *pfdl* knockout allele. The experimental (*pfdl yko*): control (*yko*) tag signal ratios were determined from Uptag and Downtag hybridizations. In our experience, a signal ratio > 2 for both tags represents a conservative criterion for identification of true synthetic lethal relationships (minimizing false positives). Protein complex residence of *PFD1* dSLAM targets is indicated by the name of the bait protein used to identify complex members.

**Table S8.** Prefoldin Congruence SGA-SGA and dSLAM-SGA:  $i$ , Gene 1 SL interaction set size;  $j$ , Gene 2 interaction set size;  $k$ , interaction set overlap; *Score*,  $-\text{Log}_{10}(P)$ . The total number of target genes is 4700. Because we used conservative dSLAM criteria to identify interactions, only those mutants scored as synthetic lethal (not synthetic sick) from the SGA data were kept for the congruence score comparison.

Comparison	Gene 1	Gene 2	$i$	$j$	$k$	Score
SGA-SGA	GIM3	GIM4	66	50	36	60
	GIM3	GIM5	66	29	19	29
	GIM3	PAC10	66	72	43	67
	GIM3	YKE2	66	47	36	62
	GIM4	GIM5	50	29	16	25
	GIM4	PAC10	50	72	30	44
	GIM4	YKE2	50	47	26	42
	GIM5	PAC10	29	72	19	28
	GIM5	YKE2	29	47	15	23
	PAC10	YKE2	72	47	34	55
dSLAM-SGA	PFD1	GIM3	33	66	12	14
	PFD1	GIM4	33	50	11	14
	PFD1	GIM5	33	29	7	9
	PFD1	PAC10	33	72	13	15
	PFD1	YKE2	33	47	12	16

**Table S9.** The dSLAM screen results for query genes *LTE1*, *SPO12*, and *SLK19*.

Every synthetic lethal interaction has been confirmed by either random spore analysis (RSA) or tetrad analysis.

## **Chapter 6.**

**Predicting pathways in yeast using genome-wide phenotype data.**

## **Introduction**

Deletion of genes operating in the same pathway results in a similar synthetic lethal interaction profile (Ye and Peysner et al. 2005). A measurement termed the “congruence score” describes the similarity of genetic interaction sets for each pair of mutants. High scores are associated with genes exhibiting similar genetic interactions, which function in the same pathway.

The relative growth rates of all yeast knockout (YKO) strains in the presence of a second allele (the “query”) can be thought of as a complex set of phenotypes. It is possible to generalize this to other phenotypes beyond growth in presence versus absence of a query allele. As with genetic congruence (Ye and Peysner et al. 2005), mutants that share similar phenotypes are likely to be components of the same pathway. For example, growth in presence of benomyl (Pan et al. 2004), or in various media (as in Giaever et al. 2002). In Lee and St Onge et al. (2005), mutants were grouped by sensitivity to 12 DNA-damaging agents using hierarchical clustering. Two-dimensional hierarchical clustering is useful for aligning mutants and treatments by similarity, but does not perform well when the source data distributions are varied.

Also included in Giaever et al. (2002) were cell morphology phenotypes.

Phenotypes such as 'round' or 'elongated' are not well-incorporated into hierarchical clustering techniques typically relying on Pearson or Spearman correlation coefficients. However, it is possible to generate a similarity score for each pair of deletion mutants by adapting Resnik's (1995) application of information entropy (Shannon 1948) to shared information content. This shared information content score is based on intersections

within a directed acyclic graph called an ontology. Lord et al. (2003) applied this concept to the Gene Ontology (GO) (Ashburner et al. 2000) to describe the similarity of annotations for human genes. By translating the shared information technique to distributions of phenotype data, I was able to generate a phenotype similarity score. This approach does not require similar data and scores are readily updated. I collected 200 genome-wide yeast phenotype sets from published reports and applied the shared information calculation to all pairs of mutants across all phenotypes.

## **Methods**

Data were collected from published reports of phenotypes for YKO (Table 1). Only screens or selections using an entire collection were obtained. Phenotypes for 5918 open reading frames (ORFs) mutated in each strain were assigned a numeric value, such as 1 or 0 for YKO that are round or not round, respectively. Phenotypes with a severity were assigned appropriately increasing numeric values, and phenotypes with numeric values were rounded to 1 decimal place and used directly. Data were loaded into R (Ihaka and Gentleman 1996), and collected into a set of 5918 numbers corresponding to a list of deleted ORFs. Each list of 5918 values was then written to a single text file with one value per line.

The group of 200 phenotype sets were analyzed using perl. First, the list of ORFs corresponding to each value was read, then for each phenotype the list of values was read. For each pair of ORFs and phenotype, the phenotype similarity score was calculated as the negative logarithm of the fraction of data contained within the inclusive interval between the two values. This is equal to  $-\log_{10}(P)$ , where  $P$  is the chance any randomly

chosen ORF will fall within the range of values defined by the first and second ORFs (see Figure 1). Then for each successive phenotype, the scores for each pair were added, resulting in a final phenotype similarity score of

$$\sum_{i=1}^n -\log_{10}(P_i) = -\log_{10}\left(\prod_{i=1}^n P_i\right),$$

where  $n$  = number of phenotypes and  $P_i$  is the fraction of values found in the inclusive interval between the ORF values, for each phenotype. This measure can be expressed in terms of bits of information if  $\log_2$  is used in place of  $\log_{10}$ . Using  $\log_{10}$  results in a measure of decimal digits rather than binary digits, but a decimal digit is equivalent to 3.322 bits ( $\log 10/\log 2$ ). I express similarity in decimal format here.

Similarity of GO annotations for each gene pair was calculated using a method after Lord, et al. (2003). Briefly, the annotation similarity is expressed as  $-\log_2(P)$ , where  $P$  is the chance of randomly selecting an annotation that is a term shared by both ORFs. The maximum value for similarity is assigned to the pair. There are 3 ontologies within GO: Biological Process, Cellular Component, and Molecular Function. For each of these ontologies, the root term is the name of the ontology, and a gene's annotation consists of the directed acyclic graph from the root to the most specific term. Genes without annotation for biological process, for example, are listed as: “biological\_process” → “biological\_process unknown,” whereas a gene involved in cell-cell adhesion would be annotated “biological\_process” → “biological adhesion” → “cell adhesion” → “cell-cell adhesion.” A gene annotated “biofilm formation” would share “cell adhesion” as the most specific annotation with a gene annotated “cell-cell adhesion” and the gene pair

would be assigned the Biological Process similarity value of  $-\log_2(17/5331) = 8.3$ , where 17 is the number of “cell-cell adhesion” annotations and 5331 is the number of “biological\_process” annotations. GO annotations were obtained from *Saccharomyces* Genome Database (<http://www.yeastgenome.org>) as “gene\_association.sgd” ([ftp://genome-ftp.stanford.edu/pub/yeast/literature\\_curation/gene\\_association.sgd](ftp://genome-ftp.stanford.edu/pub/yeast/literature_curation/gene_association.sgd)) on 2006 December 15, version 1.1308.

Protein-protein interactions were taken from the Krogan et al. (2006) “Core Network” interaction set.

## Results

I tested the phenotype similarity score for its ability to connect functionally related genes by comparing the similarity of GO annotations for increasing similarity of phenotypes. With increasing cutoffs for phenotypic similarity, the decreasing number of gene pairs are enriched for similar GO annotation (Figure 2). Biological Process and Cellular Component display higher similarity than Molecular Function. This is expected, since similar phenotypes should be more closely associated with genes that function in the same pathway, than with genes that carry out similar molecular reactions.

When gene products function in the same pathway, they are more likely to physically interact. Therefore, phenotypically similar genes should encode proteins that are more likely to interact. I calculated the fraction of gene pairs above various phenotype similarity score cutoffs that encode proteins for which physical interaction has been reported in a high-throughput protein-protein interaction study (Krogan et al. 2006). The

fraction of interacting pairs increases with phenotypic similarity, and the number of interacting pairs is higher than expected by chance ( $P \leq 0.05$ ) above phenotypic similarity of 69, with  $P$  calculated using a one-sided Fisher's exact test (Figure 3). At phenotype similarity score of 100 or more,  $P = 7 \times 10^{-30}$ .

With  $\sim 10^3$  gene pairs above phenotype similarity score of 100, that was chosen as a cutoff to display a network connecting similar genes (Figure 4). The entire network at  $\geq 100$  consists of 697 nodes representing genes and 1534 edges representing phenotypic similarity. The largest connected component is 537 nodes and 1418 edges. At phenotype similarity score  $\geq 95$ , there are 5106 interactions among 1289 genes, and at  $\geq 90$ , there are 16 904 interactions among 2282 genes. Many genes known to perform related functions are connected, and novel associations are suggested. Examples of interconnected subsets are: genes related to DNA damage (Figure 5), and genes related to ribosome structure and function (Figure 6). Along with many structural ribosomal genes (*RPS#* and *RPL#*), the ribosome subset includes *ARCI*, which ensures tRNA delivery to the cytoplasm (Galani et al. 2001) and *TSR2*, which is involved in 20S pre-rRNA processing (Peng et al. 2003). Figure 7 shows a small sub-network containing genes related to biosynthesis of tryptophan. All connected genes are members of the superpathway of phenylalanine, tyrosine and tryptophan biosynthesis upstream of or within the tryptophan biosynthesis pathway. The complete list of genes in this segment of the pathway is: *ARO1*, *ARO2*, *ARO3*, *ARO4*, *TRP1*, *TRP2*, *TRP3*, *TRP4*, and *TRP5*. At a more relaxed phenotypic similarity cutoff of 90, all these tryptophan pathway genes are connected with the exception of *ARO4*, which displays no interactions at phenotypic

similarity of 90 or higher.

## **Discussion**

Introduction of the YKO collection has allowed genome-wide examination of phenotypes in deletion mutants. Similar phenotypes are expected for genes that function in a single pathway, and I present a method for quantifying that similarity. This information-content-based approach overcomes some of the problems with current methods, and is able to handle any measure of phenotype. Another pleasing aspect of this method is that when new data become available, they can be readily combined. Each gene pair is given a similarity score for that new phenotype, and those scores are simply added to the previously existing totals.

Results from this calculation are complex and visualization in a graph (Figure 4) presents a large problem. It is likely that, as with high-throughput protein interaction studies, the graph contains interactions that do not represent informative relationships. Simplifying the network by assignment of genes to interconnected modules responsible for some pathway could be accomplished with algorithms such as Markov Clustering (Enright et al. 2002; Brohee and van Helden 2006). Alternatively, subsections of the graph corresponding to genes of interest can be viewed, such as in Figures 5, 6, and 7.

An important use for these relationships is as verification of functionally important physical interactions. Combination of these data with reported protein-protein interaction sets can refine imperfect information. Overlapping indications of interaction by genetic and physical evidence strongly argue for shared pathway membership. Additionally,

phenotypic similarity can group genes into pathways when they do not physically interact. An example is provided in Figure 7, with genes involved in biosynthesis of tryptophan connected. Among the genes in this pathway, only Trp2p-Trp3p and Trp3p-Aro1p have been reported to physically interact (Gavin et al. 2006). The other genes are connected by small molecules that they pass along in the pathway. The ability of phenotypic similarity to find these connections provides additional value over networks based only on physical interactions.

**Figure 1.** Method for calculating  $P_i$ . (A)  $P_i$  for gene pair with phenotype values  $ORF1 = 2$  and  $ORF2 = 3$  is  $(77 + 107)/5918$ .  $ORF1-ORF2$  phenotype similarity score for this phenotype is  $-\log_{10}(184/5918) = 1.5$ . (B)  $P_i$  for gene pair with  $ORF1 = 1.0$  and  $ORF2 = 2.0$  is  $65/5918$ . Phenotype similarity score for this phenotype is  $-\log_{10}(65/5918) = 2.0$ .

## GO Similarity Increases With Phenotypic Similarity

**Figure 2.** GO similarity increases with phenotype similarity score. The average GO similarity is shown along increasing phenotype similarity score cutoffs for Biological Process (magenta line), Cellular Component (cyan line), and Molecular Function (yellow line). Also shown is the number of gene pairs above each cutoff (blue line).

**Figure 3.** Protein interactions are enriched by phenotypic similarity. The fraction of protein pairs reported to physically interact (Krogan et al. 2006) encoded by gene pairs above various phenotype similarity score cutoffs is shown with circles. Filled circles represent sets that are significantly enriched for interacting pairs ( $P \leq 0.05$ ) by one-sided Fisher's exact test. Line shows number of pairs above each cutoff.

**Figure 4.** Network generated by connecting all genes with a phenotype similarity score  $\geq 100$ . Dotted line, interaction score 100–105; thin solid line, interaction score 105–110; medium solid line, interaction score 110–115; thick solid line, interaction score  $> 115$ . (A) Top half of network. (B) Bottom half of network.

# Curriculum Vitæ.

Brian D. Peyser, Ph.D.

---

March 28, 2007

## Personal information:

Born: Muskingum County, Ohio, USA  
May 21, 1975

Home address: 181 West Main Street  
New Market Maryland 21774

Home telephone: 301-865-3910

Email address: [hopkins@bpeyser.fastmail.net](mailto:hopkins@bpeyser.fastmail.net)

## Education and Experience:

B.S. in Plant Pathology; Microbiology and Cell Science: 1993–1997  
College of Agriculture  
University of Florida  
Gainesville, Florida, USA

Research Assistant: 1993–1997  
Ernest Hiebert, Ph.D., principle investigator  
Department of Plant Pathology  
Institute of Food and Agricultural Sciences  
University of Florida  
Gainesville, Florida, USA

Predoctoral Fellow: 1997–1998  
Cell and Molecular Biology  
School of Medicine  
University of Pennsylvania  
Philadelphia, Pennsylvania, USA

Senior Laboratory Technician: 1998–2000

Biological Scientist: 2000–2002  
Maureen M. Goodenow, Ph.D., principle investigator  
Department of Pathology and Laboratory Medicine  
College of Medicine  
University of Florida  
Gainesville, Florida, USA

Ph.D. in Biochemistry, Cellular and Molecular Biology: 2002–2007  
Forrest A. Spencer, Ph.D., advisor  
Department of Molecular Biology and Genetics  
School of Medicine  
The Johns Hopkins University  
Baltimore, Maryland, USA
