Abstract:	<p>This study investigates possible effects of in utero exposure of rats to a low dose (125 mg/kg bw/day) and a high dose (750 mg/kg bw/day) of Diisononyl phthalate (DINP) during the masculinisation programming window (MPW) which is embryonic day 15.5 to 18.5 (e15.5 - e18.5). Dibutyl phthalate (DBP) was used at a high dose level (750 mg/kg bw/day) as an established positive control substance for anti-androgenic effects on the developing male reproductive tract. We focussed on the MPW and measured a multitude of biological endpoints at various life stages and applied state of the art histopathology staining techniques to refine the characterization of potential changes to the testis, beyond what is currently available with DINP. If DINP can mediate TDS disorders, this exposure window would be sufficient to induce androgen impacts and alter male reproductive tract development as shown earlier in this validated experimental model with DBP. Overall, the results of this systematic comparison provide convincing evidence on the differences between the effects occurring with DBP and DINP. In contrast to what was seen with DBP, DINP did not cause cryptorchidism or hypospadias. There was no effect on anogenital distance/anogenital index (AGD/AGi). Leydig cell aggregates on e17.5 and e21.5 did not increase. There was no reduction of intratesticular testosterone, no effects on sperm motility and sperm count and no effect on adult testosterone or luteinizing hormone (LH) levels were seen. Our results demonstrate and confirm that DINP does not cause adverse reproductive effects and is not an endocrine disruptor.</p>

Highlights

- DINP exposure in the MPW (e15.5-18.5) does not result in effects known for DBP
- DINP exposure in the MPW has no effect ADG on e21.5.
- Leydig cell aggregates on e17.5 and e21.5 were not increased.
- DINP exposure in the MPW does not induce focal testicular dysgenesis.

Abstract

This study investigates possible effects of in utero exposure of rats to a low dose (125 mg/kg bw/day) and a high dose (750 mg/kg bw/day) of Diisononyl phthalate (DINP) during the masculinisation programming window (MPW) which is embryonic days 15.5 to 18.5 (e15.5 - e18.5). Dibutyl phthalate (DBP) was used at a high dose level (750 mg/kg bw/day) as an established positive control substance for anti-androgenic effects on the developing male reproductive tract.

1 We focussed on the MPW and measured a multitude of biological endpoints at various
2 life stages and applied state of the art histopathology staining techniques to refine the
3 characterization of potential changes to the testis, beyond what is currently available
4 with DINP. If DINP can mediate testicular dysgenesis (TDS) disorders, this exposure
5 window would be sufficient to induce androgen impacts and alter male reproductive
6 tract development as shown earlier in this validated experimental model with DBP.

9
10
11
12 Overall, the results of this systematic comparison provide convincing evidence on the
13 differences between the effects occurring with DBP and DINP. In contrast to what was
14 seen with DBP, DINP did not cause cryptorchidism or hypospadias, had no effect on
15 anogenital distance/anogenital index (AGD/AGi) and Leydig cell aggregates on e17.5
16 and e21.5 did not increase. With DINP no reduction of intratesticular testosterone, no
17 effects on sperm motility and sperm count and no effect on adult testosterone or
18 luteinizing hormone (LH) levels were seen. Our results demonstrate that DINP does
19 not cause the adverse reproductive effects known to occur with DBP, a well-
20 established endocrine disruptor.

TDS: Testicular Dysgenesis Syndrome

1. Introduction

Formation of a testis and its subsequent production of androgens in early fetal life are prerequisites for masculinisation (Scott et al., 2009). Any disruption of these events can have adverse consequences and lead to common reproductive disorders that manifest already at birth, in puberty or in adulthood - this has been summarised in the testicular dysgenesis syndrome (TDS) hypothesis (Skakkebaek et al., 2001). A rat model of TDS has been developed and validated involving in utero exposure to Dibutyl phthalate (DBP) (Fisher et al., 2003; Kilcoyne et al., 2014; van den Driesche et al., 2012). DBP is a low molecular weight phthalate (LMW) with a straight carbon chain length in the esterified alcohols of 4 carbons (Table 1). DBP is classified and labelled accordingly as toxic to reproduction and is an established positive control substance for androgen disruption during this period of male fetal development. In utero exposure to DBP at a time which includes the so-called masculinisation programming window (MPW; embryonic day e15.5-e18.5), results in impaired androgen production, late-onset focal testicular dysgenesis and downstream male reproductive tract malformations (Carruthers et al., 2005; MacLeod et al., 2010; van den Driesche et al., 2017; Welsh et al., 2008). Recently it was demonstrated that DBP exposure specifically only in the MPW is necessary and sufficient to induce suppression of fetal testosterone, reduced anogenital distance (AGD), focal testicular dysgenesis

1 (manifesting as malformed seminiferous tubules and abnormal distribution of somatic
2 cells in focal areas) and TDS disorders such as cryptorchidism, hypospadias, reduced
3 adult testis size, and compensated adult Leydig cell failure (van den Driesche et al.,
4 2017). Reduced androgen production in this small critical window of time during
5 development is considered central to these changes, but exactly how, and its
6 necessity for causing all manifestations is not established.

24 Exposure of rats to other LMW phthalates (e.g. Diisobutyl phthalate (DIBP) and Di-
25 (2-ethylhexyl) phthalate (DEHP)) has been shown to disrupt sexual development in
26 male offspring following exposure during the MPW in a manner similar to DBP
27 (Saillenfait et al., 2006, 2008, 2011; Wolfe et al., 2005). Based on the collective data
28 for the LWM phthalates, it is considered that phthalates with straight carbon chain
29 lengths in the esterified alcohols between 3 and 6 form the active cluster for toxicity
30 to reproduction, with testicular toxicity being the most sensitive endpoint (Fabjan et
31 al., 2006). The ability of the high molecular weight (HMW) phthalate Diisononyl
32 phthalate (DINP) with straight carbon chain lengths of ≥ 7 in the esterified alcohols to
33 similarly disrupt development of the male reproductive tract and lead to TDS
34 disorders is not well supported by existing data (ECHA, 2013, ECHA RAC 2018;
35 NICNAS, 2015).

54 DINP is a member of the category of HMW phthalates and is a complex mixture of
55 diesters. There are two technically inter-changeable types of DINP available in
56
57
58

61
62
63
64
65

1 commerce: 1,2-Benzenedicarboxylic acid esterified with branched alcohols
2 consisting of C8-C10 (C9 rich) alkyl side chains (CAS No 68515-48-0), also referred
3 to as DINP1, and DINP2 (CAS No 28553-12-0), esterified with alcohols of strictly C9
4 branched and linear alkyl side chains (EU RAR, 2003; Koch et al., 2012). In DINP1
5 the alcohols typically consist of dimethyl heptanols branched at diverse positions and
6 15-25% isodecanols (Waterman et al., 1999). In DINP2 the predominant C9-isomers
7 are identified as methyl octanols and dimethyl heptanols, and 10% of the linear n-
8 nonanol. For DINP, liver toxicity in rodents is identified to be the most sensitive
9 endpoint (EFSA, 2005, 2019; ECHA RAC 2018) and accordingly, EFSA has based
10 their derived tolerable daily intake (TDI) on this endpoint. It has been suggested that
11 liver toxicity is indirectly linked to transient reductions of testicular testosterone
12 (ECHA RAC 2018; Dekant, 2020), but DINP is shown to be less potent than DBP
13 (Clewell et al., 2013b; Furr et al., 2014) in reducing testicular testosterone. Available
14 studies involving exposure to either DINP1 or DINP2 during the MPW collectively
15 show marked differences in the extent, severity and incidence of effects when
16 compared to similar doses of DBP. The studies on DINP have consistently reported
17 a lack of induction of gross male reproductive tract malformations such as
18 cryptorchidism and hypospadias (Boberg et al., 2011; Clewell et al 2013b; Gray et
19 al., 2000). Likewise, DINP has been shown to have no impact on general
20 reproductive tract development manifested as decreased relative weights in
21 androgen sensitive tissues: levator ani/bulbocavernosus muscles (LABC), seminal
22 vesicles, ventral prostate, glans penis, bulbourethral gland, and epididymis (Boberg
23 et al., 2011; Gray et al., 2000; Clewell et al., 2013b).

24 Despite the collective evidence demonstrating DINP does not induce TDS disorders,
25 the reporting of DINP's ability to impact testosterone following exposure to the

1 developing fetus (Borch et al., 2004; Clewell et al., 2013a; Furr et al., 2014; Hannas
2 et al., 2011;), albeit at much higher doses than DBP, spurred regulatory questions
3 regarding the potential of DINP to disrupt male reproductive tract development
4 (CPSC, 2018; ECHA, 2013; EFSA, 2019). The ECHA Risk Assessment Committee
5 (RAC) undertook a thorough in-depth assessment of the DINP database and
6 concluded (ECHA RAC 2018) no classification for DINP for either effects on sexual
7 function and fertility, or for developmental toxicity is warranted (according to
8 European CLP (classification, labelling and packaging of substances) Regulation
9 (EC) No 1272/2008, the EU implementation of the Globally Harmonized System
10 (GHS)). Despite this official regulatory conclusion from ECHA determining absence
11 of DINP mediated adverse effects on reproduction and development, some views
12 continue to suspect DINP of causing adverse effects on male reproductive
13 development through an endocrine mode of action.

31 While the morphological signs of TDS disorder emerge in the rat after the MPW, the
32 mechanistic changes necessary for mediating the disorder are induced (i.e.
33 programmed) by exposure in the MPW (van den Driesche et al., 2017). That is to
34 say that DBP induction of comparable testosterone deficiency due to exposure after
35 the MPW (GD19.5-20.5) does not induce TDS disorders, nor does more prolonged
36 DBP exposure (GD 13.5-21.5) induce any greater incidence of TDS disorders than
37 just treatment during the MPW (van den Driesche et al. 2017). All of the existing
38 studies assessing DINP effects on *in vivo* testosterone levels in fetal testes measure
39 impacts at a gestational time point subsequent to the MPW. Because impacts on
40 androgen production during -and not after- the MPW (Carruthers et al., 2005; Foster
41 et al., 2001; Welsh et al., 2008; van den Driesche et al., 2017) are central to TDS
42 disorders, assessing if DINP impacts testosterone during this finite window (e15.5-

18.5) in an *in vivo* model is important for reconciling the dataset for DINP.

Additionally, we were interested in assessing if changes induced during the MPW alone manifested into focal areas of testicular dysgenesis, similar to what has been seen with DBP (van den Driesche et al., 2012, 2017).

In this study we investigated effects of in utero exposure to a low dose (125 mg/kg bw/day) and a high dose (750 mg/kg bw/day) of DINP during the MPW (i.e. e15.5-e18.5 only) and compared the results with a high dose (750 mg/kg bw/day) DBP exposure using similar read-outs as published by van den Driesche et al., 2017. The high dose level of DINP (750 mg/kg bw/day) was considered appropriate based on the observation of significant reductions of maternal body weight changes as signs of moderate maternal toxicity at this dose in published studies (Hellwig et al., 1997; Masutomi et al., 2003); and the recognition that impacts on testes testosterone levels and steroidogenic gene transcription have been reported at this dose of DINP and lower (Borch et al., 2004; Clewell et al., 2013a; Furr et al., 2014; Hannas et al., 2011, 2012). Saturation of DINP metabolism and significant changes of kinetics occur between the DINP dose levels of 250 mg/kg bw/day and 750 mg/kg bw/day, where despite a 3-fold increase in dose, C_{max} and AUC_{inf} did not increase (Clewell et al., 2013a). Deviation from linearity and saturation of metabolism at 750 mg/kg bw/day was also noted in the recently developed PBPK model for DINP (Campbell et al., 2020). We narrowed the exposure window to e15.5-e18.5 to focus on the critical question of DINP's potential anti-androgenic impacts on the developing male reproductive tract and measured both hormone levels and impacts on steroidogenesis at various life stages and applied state of the art histopathology staining techniques to refine the characterization of potential changes to the testis beyond what the current DINP dataset provides. If indeed DINP can mediate TDS

1 disorders, this exposure window, as validated with DBP which is used here as a
2 positive control in this experimental model, would be sufficient to induce androgen
3 impacts and alter male reproductive tract development.

52 Time-mated female Wistar rats (Harlan, UK) were housed for a minimum of 1 week in
53 ventilated cages (2000P cages; Tecniplast, Buguggiate, Italy) prior to use in
54 experimental studies and were kept under standard conditions with ad libitum access
55 to sterile water and fed a soy-free breeding diet (RM3(E); SDS, Dundee, Scotland).
56
57
58
59
60
61
62
63
64
65

1 Housing conditions were carefully controlled (lights on at 07:00, off at 19:00,
2 temperature 19–21° C, humidity 45-65%, GOLD shavings and LITASPEN standard
3 bedding (SPPS, Argenteuil, France)). The dams were allocated randomly to receive
4 vehicle control (corn oil; Sigma-Aldrich Company Ltd) treatment, 750 mg/kg bw/day
5 Dibutyl phthalate (DBP; Sigma-Aldrich Company Ltd, Dorset, UK; 99% pure (GC
6 area%) according to the supplier), 125 mg/kg bw/day or 750 mg/kg bw/day Diisononyl
7 phthalate (DINP2; BASF SE, Germany, purity: ≥99.5% (GC area%)) in 1 ml/kg corn
8 oil, daily by oral gavage. The dose of DBP was based on our previous study (van den
9 Driesche et al., 2017) The high dose DINP was based on considerations of maternal
10 toxicity (Hellwig et al., 1997; Masutomi et al., 2003), toxicokinetics (Campbell et al.,
11 2020; Clewell et al., 2013a) and dose effect levels in prior studies reporting effects on
12 molecular endpoints assessed herein (Borch et al., 2004; Clewell et al., 2013a; Furr
13 et al., 2014; Hannas et al., 2011, 2012). All treatments were performed in a single
14 animal facility at the University of Edinburgh and treatments were administered
15 between 09:00-10:30 during the masculinisation programming window treatment
16 (MPW; e15.5-e18.5). Male fetuses were collected at e17.5 (within the MPW), e21.5
17 (at the end of gestation) or at postnatal day 90 (adulthood). Pregnant dams were killed
18 by CO₂ inhalation followed by cervical dislocation. Fetuses were removed, decapitated
19 and placed in ice-cold PBS (Sigma-Aldrich). Post-natal animals were housed with their
20 natural mothers from birth or in cages with a maximum of 6 animals after weaning and
21 were killed by CO₂ inhalation followed by cervical dislocation. Fetal testes were
22 removed by microdissection and fixed in Bouin's fixative for 1 hour, transferred to 70%
23 (v/v) ethanol and then processed into paraffin blocks using standard procedures.
24 Testes from the fetuses used for intratesticular testosterone measurements and adult
25 testes and epididymides used for sperm head counts were frozen on dry ice.

2.3. *Adult phenotypical analysis*

When the adult male rats were collected, their body weight was measured and they were subjected to a detailed inspection to determine testicular descent and the normality of the penis. Hypospadias and cryptorchidism were examined as described previously (Welsh et al., 2008; van den Driesche et al., 2017). Anogenital distance (AGD) was measured prior to opening of the abdomen, using digital callipers (Faithfull Tools, Kent, UK), as was the length of the penis after being dissected out. Anogenital Index (AGi) was calculated to normalize to pup or adult body weight (i.e. AGi was calculated by dividing AGD by the cube root of body weight). The testes, ventral prostate and seminal vesicles were also dissected out and weighed.

2.4. *Adult sperm motility and sperm head count*

The testis and cauda epididymis were taken from all groups and sperm motility, sperm morphology, sperm head count (cauda epididymis) and sperm head count (testis) were determined. Sperm motility examinations were carried out in a randomized sequence using the sperm from the cauda epididymis. For sperm motility the numbers of observations are: vehicle control (27 from 7 litters), 750 mg/kg bw/day DBP (DBP-750; 17 from 6 litters), 125 mg/kg bw/day DINP (DINP-125; 36 from 7 litters), 750 mg/kg bw/day DINP (DINP-750; 28 from 7 litters). Numbers for sperm head counts were the same for vehicle control and DINP groups, but different for the DBP-750 group (26 from 6 litters) because a number of adults treated with 750 mg/kg bw/day DBP had epididymal agenesis or missing epididymis. Sperm motility was assessed using methodology described previously (Slott et al., 1991),

1 and sperm head counts were similarly done according to previously published
2 studies (Meistrich, 1989). In brief, the tunica albuginea was opened with a scalpel
3 and the parenchym of the testis was isolated and weighed. The samples were
4 refrigerated in a solution of 0.1 % Triton X-100 (Merck) and stored at -20° C until
5 further processing. After thawing, the samples were homogenized in randomized
6 order for 30 seconds with a Polytron at 20 000 U/min, the homogenates were
7 collected through a Nylon sieve and the residual content in the sieve was washed
8 twice with water. The homogenization resistant spermatids were kept on a magnetic
9 stirrer running at low velocity until counting. 3 µl of the solution were counted in the
10 MAKLER chamber (20-fold magnification, counting of 100 squares) and the mean
11 value of 3 chambers counted per animal was taken.

30 *2.5. Triple immunofluorescence for Smooth Muscle Actin, 3β-HSD and Sox-9*

31 Fetal testes were removed by microdissection and fixed in Bouin's fixative for 1 hour,
32 transferred to 70% (v/v) ethanol and then processed into paraffin blocks using
33 standard procedures. Sampling at the different time points was as follows:
34
35
36
37
38
39
40

41 E17.5: Control: n = 15 from 6 litters, DBP-750: n = 15 from 6 litters, DINP-125: n = 15
42 from 6 litters, DINP-750: n = 15 from 5 litters.
43
44
45

46 E21.5: Control: n = 15 from 6 litters, DBP-750: n = 15 from 5 litters, DINP-125: n = 15
47 from 5 litters, DINP-750: n = 15 from 6 litters.
48
49
50

51 We aimed for 15 males for each timepoint by selecting 3 males per litter. In cases
52 where there were only 2 males available in a litter, we completed the number of
53 males to 15 from another litter.

In order to visualize focal dysgenesis, specific antibodies were used for co-immunolocalisation of 3 β -HSD (Leydig cell marker; antibodies-online.com), Sox-9 (Sertoli cell marker; Chemicon International, UK) and α -smooth muscle actin (α -SMA, peritubular myoid cell marker; Sigma-Aldrich, UK). Slides were washed between all incubation steps in Tris Buffered Saline (TBS) pH 7.6 (3 x 5 min) and all incubations were carried out in a humidity box (Fisher Scientific, UK). Sections were dewaxed and rehydrated using standard procedures, followed by a peroxidase block in 3% (v/v) H₂O₂ in methanol for 30 minutes. Next, the sections were blocked in normal goat serum (NGS; Vector Laboratories Inc, USA) diluted 1:5 in TBS containing 5% (w/v) bovine serum albumin (BSA) (Sigma-Aldrich; NGS/TBS/BSA), followed by incubation with the first primary rabbit antibody, anti-Sox-9, which was diluted 1:1,000 in NGS/TBS/BSA overnight at 4° C. The next day, sections were incubated with peroxidase-conjugated goat F(ab) anti-rabbit secondary antibody (GARP; Abcam UK), diluted 1:200 in NCS/TBS/BSA for 30 minutes at room temperature (RT), and followed by incubation with Tyr-Cy3 (Perkin Elmer-TSA-Plus Cyanine3 System; Perkin Elmer Life Sciences, USA) according to the manufacturer's instructions. From here onwards slides were kept in the dark. Next, the sections were subjected to antigen retrieval by boiling in a pressure cooker in 0.01 mol/l citrate buffer (pH 6.0) for 5 minutes and left to cool for 20 minutes. This was followed by another block in NGS/TBS/BSA and overnight incubation at 4° C with the second primary antibody, rabbit anti-3 β -HSD, diluted 1:1,000 in NGS/TBS/BSA. On the third day, slides were incubated with peroxidase-conjugated goat F(ab) anti-rabbit secondary antibody (Abcam) diluted 1:200 in NGS/TBS/BSA for 30 minutes at RT, followed by incubation with Tyr-fl (Perkin Elmer-TSA-Plus Fluorescein System; Perkin Elmer Life Sciences) according to the manufacturer's instructions. Sections were again blocked against peroxidase in 3%

1 (v/v) H₂O₂ in TBS plus 0.01% (v/v) Tween-20 (Sigma-Aldrich) for 20 minutes followed
2 by blocking in NGS/TBS/BSA and overnight incubation at 4° C with the third primary
3 antibody, mouse anti-SMA, diluted 1:10,000 in NGS/TBS/BSA. On the last day,
4 sections were incubated with peroxidase-conjugated goat F(ab) anti-mouse
5 secondary antibody (Abcam) diluted 1:200 in NGS/TBS/BSA for 30 minutes at RT,
6 and followed by incubation with Tyr-Cy5 (Perkin Elmer-TSA-Plus Cyanine5 System;
7 Perkin Elmer Life Sciences, Boston, MA, USA) according to the manufacturer's
8 instructions. Finally, the slides were mounted with Permafluor (Thermo Scientific, UK)
9 and fluorescent images were captured using a Nikon A1R confocal laser microscope.

26 *2.6. Hormone measurements*

27
28 Adult male animals were sacrificed by CO₂ inhalation followed by cervical dislocation
29 and straight after that blood was collected from the heart and stored on wet ice. Plasma
30 was collected by centrifugation of all samples collected at the day of sacrifice. Fetal
31 testes were homogenised in 250 µL ice cold PBS using a handheld tissue
32 homogeniser (Thomas Scientific). The homogenates were centrifuged at full-speed
33 and the supernatant was used for intratesticular testosterone measurements as
34 described below. Fetal intratesticular testosterone, adult plasma testosterone and LH
35 measurements were done by the Specialised Assay Laboratory at the MRC Centre for
36 Reproductive Health, Edinburgh, UK. The testosterone ELISA was performed by
37 coating 96-well plates (Greiner Bio-One GmbH, Frickenhausen, Germany) with 100 µl
38 of donkey anti-rabbit IgG (Jackson ImmunoResearch Inc, West Grove, USA) per well
39 at a dilution of 1:500 in ELISA coating buffer (100 mM Na Bicarbonate, pH 9.6) covered
40 and incubated in a fridge at 4° C overnight. Before use the plates were washed 2 times

with wash buffer (0.05 M Tris/HCl + 0.05 % Tween 20, pH 7.4). Next, 250 μ l of blocking buffer (PBS pH 7.4 containing 0.5% BSA) was added to each well and incubated for 1 hour at room temperature whilst shaking before being washed 2 times with wash buffer. Standards, samples and controls (20 μ l per well) were added to each well, followed by 80 μ l of testosterone-HRP conjugate (Astra Biotech GmbH, Berlin, Germany) at 1:20,000 in assay buffer (PBS pH 7.4 containing 0.1% BSA and 250 ng/ml cortisol), followed by 50 μ l of rabbit anti-testosterone-19 antibody (AMS Biotechnology, USA) 1:200,000 in assay buffer. Plates were incubated at room temperature for 2 hours on a microtiter plate shaker (IKA®, Schuttler MTS4, IKA Labortechnik, Staufen, Germany), then washed 5 times with assay wash buffer and 120 μ l of substrate solution (3,3',5,5'-Tetramethylbenzidine, Millipore Corporation, Temecula, CA, USA) was added to each well. Plates were incubated at room temperature without shaking in the dark. After 20 min., the reaction was stopped by adding 80 μ l of 2N H₂SO₄ solution (Sigma-Aldrich Company Ltd., Dorset, UK). Finally, plates were read on a plate reader at 450 nm. Plasma LH levels in adult rats were measured as described previously (McNeilly et al., 2000).

Standard curves were prepared with a total of 8 different concentrations (24.3, 8.1, 2.7, 0.9, 0.3, 0.1, 0.03 and 0 ng/ml). Samples, standards and controls were included in duplicate. Inter- and intra-assay coefficients of variation (CV) were calculated from two controls of low and high testosterone in duplicate in each of eight assays. The inter-assay CV for low and high pools respectively were 11.4% and 9.1%; the intra-assay CV were 8.9% and 5.6%. The lower limit of detection was calculated at 0.2 ng/ml.

2.7. Measurement of Leydig cell aggregation

1 Measurement of Leydig cell aggregate size in the fetal testis was done as described
2 previously (Mahood et al., 2007; van den Driesche et al., 2012). Briefly, testes from
3 the different treatment groups (n=15 from 5-6 litters per treatment group) were serially
4 sectioned and three representative sections from each testis then selected and
5 immunostained for 3 β -HSD (antibodies-online.com; 1:500) on a Leica BOND-MAX
6 automatic immunostaining machine using the BOND Polymer Refine Detection (Leica,
7 UK). The three sections chosen were those corresponding to approximately 25, 50,
8 and 75% intervals through the serially sectioned testis. Sections immunostained for
9 3 β -HSD were not counterstained, so as to provide sufficient homogeneity, high
10 contrast, and low background to allow computer-assisted thresholding and
11 subsequent computer-assisted counting of Leydig cell (3 β -HSD-immuno-positive)
12 aggregates and determination of Leydig cell aggregation area. Slides were scanned
13 using a Zeiss Axioscan Z1 whole slide scanner at 20x magnification using a Hitachi
14 HV-F202SCL camera, following intensity-based tissue detection a 0.2% onion skin
15 focusing strategy was applied and slides scanned. Fiji image analysis software was
16 used for quantification (Schindelin et al., 2012). A custom macro was designed that
17 used thresholding to identify the whole tissue section and quantify total pixel area. A
18 Gaussian blur (sigma 2) filter was applied to smooth the images and reduce noise.
19 Thresholding was then used within the tissue regions to identify aggregates of
20 immuno-positive cells. The 3 β -HSD staining permitted the identification of cluster
21 borders and the measurement of the total area of each cluster volume was quantified.
22 Leydig cell aggregates were expressed as percentage of total Leydig cell area. Leydig
23 cell aggregates were then assigned arbitrarily to one of two groups: small aggregates,
24 accounting for \leq 5% of the total Leydig cell aggregate area per testis, and large
25 aggregates, which individually accounted for \geq 5.1% of total Leydig cell aggregate area

2.9. Statistics

Values are expressed as mean \pm SEM. Comparison of treatment effects used one-way ANOVA followed by the Bonferroni post test when multiple treatment groups were compared. These analyses used GraphPad Prism (version 8; GraphPad Software Inc., San Diego, CA). The presented data used each litter as the unit, rather than the animal.

3. Results

No generalized adverse effects of the DBP or DINP treatments were observed in the exposed females. The litter size or sex ratio was not significantly affected by the treatments (data not shown).

3.1. Reproductive tract analysis in adult rats exposed to DBP or DINP during the MPW

Similar to previously published results (van den Driesche et al., 2017), gestational exposure to 750 mg/kg bw/day DBP during the MPW resulted in significant effects in adult males on anogenital distance (AGD), anogenital index (AGi), average testis weight, penis length, penis weight, ventral prostrate weight and seminal vesicle weight (Table 2). In contrast, neither high dose (750 mg/kg bw/day) nor low dose (125 mg/kg bw/day) DINP exposure during the MPW resulted in any adverse effects on the male reproductive tract in adulthood (Table 2). Likewise, only adult animals exposed to 750 mg/kg bw/day DBP during the MPW, and not exposed to either dose of DINP, showed

1 a significant reduction in both sperm motility and sperm head count ($P < 0.001$; Figure
2 2C and 2D, respectively).

32 *3.3 Effects of in utero exposure to DBP and DINP during the MPW on testosterone*
33 *and luteinizing hormone production*

34
35
36
37
38 Previously we observed induction of “compensated Leydig cell function” in adult males
39 exposed during the MPW to 750 mg/kg bw/day DBP, as indicated by a statistically
40 significant increase in circulating luteinizing hormone (LH) levels and concomitant
41 significantly increased LH/testosterone ratio (van den Driesche et al., 2017). In the
42 current study, while exposure to 750 mg/kg bw/day DBP resulted in decreased
43 testosterone together with increased LH production and concomitant increase in the
44 LH/testosterone ratio in adults, the effects did not reach statistical significance. Small
45 changes in adult circulating testosterone levels without any effect on LH production
46 and no effects on the LH/testosterone ratio (Figure 2E-F) seem not meaningful.

However, only when the data were analysed using individual animal values of the adults rather than litter means, a small, but statistically significant positive effect of in utero exposure to 750 mg/kg bw/day DBP on circulating LH levels was observed, resulting in an increased LH/testosterone ratio ($P < 0.05$; data not shown). Similar to the litter mean data, this effect was not observed in either 125 or 750 mg/kg bw/day DINP treatment groups when the data were analysed as individual animals (data not shown).

3.4. *Effects of in utero exposure to DBP or DINP during the MPW on the fetal testis*

We isolated fetuses exposed in utero to either vehicle control, 750 mg/kg bw/day DBP, 125 or 750 mg/kg bw/day DINP at embryonic day e17.5 and e21.5. Similarly to the effects observed in adulthood (Table 2), only exposure to 750 mg/kg bw/day DBP during the MPW had significant effects on AGD ($P < 0.001$; Figure 3A), average testis weight ($P < 0.001$; Figure 3B), and intratesticular testosterone ($P < 0.001$; Figure 3C) at GD21.5, which confirms previously published data (van den Driesche et al., 2012, 2017). No effects were observed after in utero exposure to either DINP dose. At e17.5 (towards the end of the MPW) only exposure to 750 mg/kg bw/day DBP, caused a significant reduction in intratesticular testosterone production ($P < 0.001$; Figure 3D). No effects were observed on intratesticular testosterone production on e17.5 following exposure to DINP.

[Figure 3]

1 The quantitative mRNA expression of the steroidogenic synthesis genes *StAR*,
2 *Cyp11a1* and *Cyp17a1* was significantly reduced after exposure to 750 mg/kg bw/day
3 DBP at e17.5 ($P < 0.05$; Figure 4A-C), however at e21.5 this reduction had returned to
4 control levels (Figure 4D-F). Exposure to either 125 mg/kg bw/day or 750 mg/kg
5 bw/day DINP did not have any effect on *StAR*, *Cyp11a1* and *Cyp17a1* expression at
6 either e17.5 or e21.5 (Figure 4).

21 *3.5. In utero exposure to DBP, not DINP, during the MPW causes fetal testicular* 22 *dysgenesis* 23 24

25 The fetal testicular morphology was investigated using triple immunofluorescence for
26 3β -HSD (fetal Leydig cell marker), Sox-9 (Sertoli cell marker) and SMA (peritubular
27 myoid cell marker). Similarly, to what we have described previously (van den Driesche
28 et al., 2017), in utero exposure to 750 mg/kg bw/day DBP during the MPW results in
29 large dysgenetic areas, which consist of a mixture of fetal Leydig cell aggregations
30 and ectopically localized Sertoli cells (Figure 5B, asterisk). Fetal testes isolated from
31 fetuses that were exposed to either 125 or 750 mg/kg bw/day DINP during the MPW
32 looked morphologically similar to control testes at e21.5 (compare Figures 5C, D with
33 5A).

bw/day DINP, using similar methods as previously described (Mahood et al., 2007; van den Driesche et al., 2012). The fetal testis was serial sectioned and sections at roughly 25%, 50% and 75% of the testis were used for automatic immunostaining procedures (Figure 6A, B). This allowed for quantification of the 3 β -HSD immunostained areas using software analysis (see Methods) and thereby a systematic determination of testicular dysgenesis in the fetal testis samples. As shown in Figures 6C and 6D, in utero exposure to 750 mg/kg bw/day DBP resulted in a significant reduction in the percentage of small fetal Leydig cell aggregates and a significant increase in large fetal Leydig cell aggregates (which is a measurement for testicular dysgenesis). At e17.5 and e21.5 either dose of DINP did not result in any significant differences in the percentage of small or large Leydig cell aggregates when compared with vehicle control exposed animals (Figure 6C, D). Interestingly, we did notice a small, but significant effect when we compared the 125 with 750 mg/mg bw/day DINP exposure groups at e21.5, with the higher DINP dose reflecting a reduction in small and an increase in large fetal Leydig cell clusters at e21.5 when compared with the low dose DINP exposure group (Figure 6D).

[Figure 6]

4. Discussion

The results of our study support that DINP does not elicit the events necessary and sufficient for inducing TDS as seen with DBP such as reduced reproductive organ size (testes, prostate, seminal vesicles, penis), cryptorchidism, hypospadias, nor reduced AGD. In order to set our results into perspective some aspects merit a more detailed discussion.

4.1. *Exact Timing of the exposure*

Consistent with previously published findings (van den Driesche et al. 2012, 2017), our study demonstrates that exposure to DBP within the MPW only results in focal dysgenesis that manifests histologically after the MPW and after cessation of DBP exposure. This dysgenesis is associated with reduced androgen production in the MPW (Figure 3), and associated with effects on the male reproductive tract (Table 2 and Figure 2) including hypospadias (via disruption of genital tubercle development); cryptorchidism (via disruption of testis descent); and reduction in AGD and AGi that is maintained into adulthood (via disruption of androgen mediated proliferation/cell migration of perineal tissue). The temporal mismatch between inhibition of steroidogenesis in the MPW and the manifestation of the abnormal testicular histopathology days later, indicates that DBP induces focal dysgenesis via a 'programming' that occurs during the MPW. However, it is well established that the temporal window of importance for androgen in mediating male reproductive development extends beyond the MPW and DBP has been shown to reduce testosterone following exposures initiated after the MPW (van den Driesche et al., 2012). In this study we aimed to untangle the events mediated during the MPW from those initiated or impacted later in development by focusing attention on the ability of DINP to induce focal dysgenesis via the 'programming' and steroidogenesis impacts that occur during the MPW. Studies assessing effects of DINP on male reproductive tract development (Figure 7) have reported effects on testosterone (Borch et al., 2004; Clewell et al., 2013a; Furr et al., 2014; Hannas et al., 2011) and steroidogenesis gene expression (Adamsson et al., 2009; Hannas et al., 2011, 2012;

Li et al., 2015) at doses of 750 mg/kg bw/day and lower, and Leydig cell aggregates at doses as low as 300 mg/kg bw/day (Clewell et al., 2013b). If indeed DINP is a lower potent inducer of testicular dysgenesis it was reasonable that exposure to 750 mg/kg bw/day during this necessary and sufficient window of exposure would lead to detectable molecular effects at e17.5 and cellular effects at e21.5. Failure to observe any effects of DINP using the sensitive techniques employed herein, suggests that DINP is unable to induce TDS through a similar 'programming' mechanism as DBP.

DEHP and DBP have been shown to also impact rat development in OECD guideline developmental toxicity studies (i.e. OECD TG414) in which exposures stop prior to the MPW, i.e. exposures during GD6-15 per the former OECD TG414 as published in 1981 (the guideline was modified in 2001 to include exposures extending beyond organogenesis). Effects in these developmental toxicity studies are not specific to the male reproductive tract but also include malformations such as neural tube defects and cleft palate. Studies with DINP (Figure 7, depicted in blue) do not induce these effects. In our opinion this points out a toxicodynamic distinction between LMW phthalates from DINP on the fetus worth emphasizing.

[Figure 7]

4.2. Steroidogenesis

Phthalates leading to adverse antiandrogenic effects are shown to interfere with the steroidogenic pathways of the testes (Plummer et al., 2007). Testosterone biosynthesis starts from cholesterol via a multistep process involving cholesterol transport to the mitochondria of the steroidogenic cell and enzymatic conversion into

1 the active steroid hormone (Thompson et al., 2004). If impacts on steroid
2 biosynthesis precede the testosterone reductions leading to disrupted male
3 development, the timing of steroidogenic impacts would have to be prior to the
4 critical reduction in fetal testosterone that occurs during the MPW and has been
5 associated with induction of TDS disorders (van den Driesche et al., 2017). The
6 steroidogenic acute regulatory protein, StAR, is involved in the transport of
7 cholesterol, the precursor of testosterone, in the cell into the mitochondria (Johnson
8 et al., 2007). In this study, the quantitative mRNA expression of *StAR*, and
9 of *Cyp11a1* and *Cyp17a1* (involved in cholesterol conversion to testosterone) was
10 significantly reduced after exposure to DBP at e17.5 ($P < 0.05$; Figure 4A-C), however
11 at e21.5 this reduction had returned to control levels (Figure 4D-F). The return to
12 control levels at e21.5 may reflect a “rebound” after the DBP treatment window
13 stopped at e18.5, which gave the fetal testes time to recover the gene expression
14 levels that were measured at e21.5. In contrast, DINP did not demonstrate an impact
15 on fetal testicular mRNA levels of genes involved in steroidogenesis (*Cyp11a1*,
16 *Cyp17a1*) or cholesterol transport (*StAR*) on either e17.5 or e21.5. DINP has been
17 reported in the literature to impact expression of these genes following in utero
18 exposure on e14-e18 (Hannas et al., 2011, 2012). Possible differences in
19 experimental design may be responsible for the different outcomes. Hannas et al.,
20 2011, 2012, exposed the more sensitive Sprague Dawley rats slightly longer (e14-
21 e18) and employed testes extraction at e18. Two other studies have also reported
22 DINP-mediated effects on steroidogenesis gene expression. Adamsson et al., 2009,
23 reported a statistically significant increase in *Cyp11a1* and no change on *StAR*,
24 whereas Li et al., 2015, reported a decrease in both genes. The exposure paradigms
25 for both of these studies varied from one another and from our study design (Figure

1 7). The dose used herein was comparable to the highest dose in Adamsson et al.,
2 2009, while Li et al., 2015, dosed up to 1000 mg/kg bw/day. Neither Adamsson et al.,
3 2009, nor Li et al., 2015, observed a change in corresponding steroidogenesis
4 protein levels following exposure to DINP. In the experimental model herein, the
5 contrast between the outcomes of DBP, which reduces the expression of the three
6 genes significantly on e17.5, and DINP, which has no effect on gene expression,
7 provides compelling support that DINP does not reduce mRNA levels of
8 steroidogenic genes in fetal testes during the critical MPW.

21

22 The data on intratesticular testosterone levels mirrored that of the mRNA expression
23 data for steroidogenesis genes. Exposure to DBP showed a statistically significant
24 reduction in intratesticular testosterone at e17.5 which was maintained, however with
25 lesser magnitude, at e21.5. The reduced magnitude of effect on intratesticular
26 testosterone reduction at e21.5 compared to e17.5 (Figure 3C, D) is consistent with
27 a 'rebound' effect following cessation of exposure (van den Driesche et al., 2012.
28 2017). In contrast, DINP showed no effect on intratesticular testosterone at either
29 timepoint (Figure 3 C, D). There are many possible explanations for why the ability of
30 DINP to impact testosterone may not have been observed. A difference in androgen
31 sensitivity among rat strains has been reported, with Sprague Dawley rats being
32 more sensitive to steroidogenic impacts than the Wistar rat strain (Wilson et al.,
33 2007). However, the studies reporting a reduction in testosterone following DINP
34 exposure (Borch et al., 2004; Clewell et al., 2013a; Furr et al., 2014; Hannas et al.,
35 2011; Li et al., 2015) versus those that do not report a dose responsive effect on
36 testosterone (Adamsson et al., 2009; Boberg et al., 2011; Clewell et al., 2013b) do
37 not correlate to strain (Figure 7), meaning the strain used is an unlikely explanation

1 for the lack of effect shown here. The length of time between cessation of the DINP
2 exposure and the testosterone measurement could also be an important
3
4 consideration for why no effect on testosterone was observed. Adamsson et al.,
5
6 2009, who did not detect a change in intratesticular testosterone, measured on e19.5
7
8 following DINP exposure e13.5-17.5, proposed the 'rebound' effect as responsible
9
10 for the lack of observed effect on intratesticular testosterone. The 'rebound' effect
11
12 could account for the lack of effects on testosterone found in this study at GD21.5
13
14 (Figure 3), but would not explain the lack of effect during the MPW at e17.5. Also
15
16 note that DBP exposure during the MPW is shown here (Figure 3D) and elsewhere
17
18 (van den Driesche et al., 2017) to reduce intratesticular testosterone days after
19
20 exposure has ceased (although to a lesser extent). Therefore, the 'rebound' effect
21
22 does not account for all of the observations in this study. DINP has been
23
24 demonstrated to be a lower potency steroidogenesis inhibitor compared to DBP and
25
26 other LMW phthalates to impact steroidogenesis in an ex vivo model of testicular
27
28 testosterone production, where testes are outside of homeostatic controls for a
29
30 period of hours before testosterone levels are assessed (Furr et al., 2014; Hannas et
31
32 al., 2011). Therefore, the dose, duration of exposure, or nature of measurement may
33
34 explain why no effect on testosterone was observed herein. However, taking a very
35
36 simplistic view, studies with longer duration of exposure to higher (Boberg et al.,
37
38 2011) or comparable doses of DINP (Clewell et al., 2013b) than used here did not
39
40 observe dose dependent changes in intratesticular testosterone; while impacts on
41
42 intratesticular testosterone (Clewell et al., 2013a) and ex vivo testicular testosterone
43
44 production (Hannas et al., 2011) have been reported in studies at doses lower than
45
46 750 mg/kg bw/day. As discussed further below, an alternative explanation for our
47
48 findings is that DINP exposure during the MPW does not inhibit steroidogenesis or it
49
50
51
52

1 does not inhibit steroidogenesis to an extent great enough to overcome homeostatic
2 controls which are necessary for eliciting downstream TDS disorders.
3
4
5
6

7
8 As mentioned previously, DBP has been shown to reduce intratesticular testosterone
9 levels following exposure during the MPW (e15.5-18.5) as well as following exposure
10 after the MPW (e19.5-20.5), however, the fetal testosterone deficiency induced after
11 the MPW is not associated with induction of TDS disorders (van den Driesche et al.,
12 2017). Therefore, the timing of androgen reduction matters. The studies that assess
13 effects of DINP on male reproductive tract development intertwine the evaluation of
14 effects mediated during the MPW (i.e. programming event) with those that are
15 initiated or impacted later in development due to the duration of the exposures
16 employed (see Figure 7). Interpretation of these data is further complicated by a lack
17 of standardization of what developmental time point measurements are taken.

31

32 Interpreting the meaning of reported outcomes on DINP without carefully considering
33 the dynamics and temporality of biology during fetal development confounds
34 interpretation and may be obscuring the meaning of reported observations. None of
35 the existing studies on DINP (Figure 7) limited exposure to the MPW only, nor
36 measured intratesticular testosterone during the MPW. The absence of a DINP-
37 mediated effect on intratesticular testosterone levels on e17.5 observed herein, is
38 consistent with the body of evidence reporting a lack of induction of gross male
39 reproductive tract malformations such as cryptorchidism and hypospadias following
40 DINP exposures (Boberg et al., 2011; Clewell et al., 2013b; Gray et al., 2000).
41
42
43
44
45
46
47
48
49
50
51
52
53

54 Absence of an impact on testosterone at e17.5 and e21.5 following exposure during
55 the MPW is also consistent with the body of evidence indicating DINP does not
56 induce changes to AGD. AGD is a sensitive indicator of in utero androgen levels and
57
58
59
60
61
62
63
64
65

1 a shortened AGD serves as a useful correlative biomarker for reduced fetal
2 androgen levels in the MPW (Schwartz et al., 2019; Welsh et al., 2008; van den
3 Driesche et al., 2017). The majority of studies on DINP report no statistically
4 significant change on AGD following in utero exposure (Clewell et al., 2013a; Gray et
5 al., 2000; Li et al., 2015; Masutomi et al., 2003). Of the two studies that report a
6 statistically significant finding, Boberg et al., 2011, reported a small but statistically
7 significant AGD decrease in males exposed to 900 mg/kg bw/day DINP. The
8 biological and toxicological relevance of this reported finding are questionable
9 however, due to the small magnitude (~5%) of the change, reported challenges in
10 reproducing the statistical significance upon reanalysis of the raw data (Chen et al.,
11 2017), and published methodology modifications (Boberg et al., 2016) indicating
12 AGD was measured by different technicians on different days (as rapid pup growth
13 and technician variability can affect AGD measurements, randomization of animals
14 across days and technicians is important for informing significance of outcomes).
15 Clewell et al., 2013b, reported a statistically significant decrease of AGD (both
16 scaled for body weight and absolute) on postnatal day 14 at the highest DINP dose
17 (11,400 ppm), but not at postnatal days 2 and 49. AGD is highly dependent on
18 animal size, and the postnatal day 14 animal weights for males in this dose group
19 were also statistically different than controls. Given that anogenital differences
20 induced by anti-androgenic influences in utero should be apparent at birth, the
21 difference observed at postnatal day 14 without a correlative difference at postnatal
22 day 2 suggest the postnatal day 14 observation was unlikely due to an anti-
23 androgenic effect. The findings reported here that DINP does not impact
24 testosterone levels on e17.5 add more collective weight to the conclusion that DINP
25 is not anti-androgenic during the MPW.

4.3. Leydig cell aggregates

As expected from the results of a previous study with 500 mg/kg bw/day (van den Driesche et al., 2012), in utero exposure to 750 mg/kg bw/day DBP resulted in statistically significant decreases in small and increases in large Leydig cell aggregates on both time points (e17.5 and e21.5) compared to controls. However, in contrast with DBP, in utero exposure to DINP did not result in any significant differences in the percentage of small or large Leydig cell aggregates when compared with vehicle control exposed animals (Figure 6C, D). The relevance of the small, but significant effect noted when comparing the 125 to the 750 mg/mg bw/day DINP exposure group at e21.5 remains unclear. This reduction in small and the corresponding increase in large fetal Leydig cell clusters at e21.5 could also be within the variation of the method used (Figure 6D).

4.4 Effects on Sperm

The findings reported herein are similar to those in previous studies on DINP reporting a lack of statistically significant or dose-related effects of DINP on testicular descent, penile development and AGD in adult animals following in utero exposure to DINP during the MPW (Boberg et al., 2011; Clewell et al., 2013b; Gray et al., 2000). Neither the current study (Figure 2) nor the study by Boberg et al., 2011, found an effect on sperm count in adult males (see also Chen et al., 2017 for reanalysis of the statistics reported in Boberg et al., 2011). In contrast, no effect was observed on sperm motility in this study, whereas Boberg et al., 2011 reported a decrease in sperm motility at doses of 600 mg/kg bw/day and higher. However, the

1 sperm motility in the untreated controls did not reach the minimum value of 70%
2 motility which OECD (Guidance Document No. 43, 2008; Seed et al., 1996). A key
3 difference in our study design is the window of exposure. We stopped exposure at
4 e18.5 whereas Boberg et al., 2011, extended the exposure window to postnatal day
5 17. Exposure to DBP during the MPW alone is shown herein to be sufficient to
6 impact sperm count and motility (Figure 2 C, D). However, considering the timeline
7 for germ cell development and postnatal development of sperm, timing of exposure
8 could be important for explaining the differences seen with DINP between studies.
9 For example, during normal testis development at e21.5 germ cells are migrating
10 outwards to gain contact with basal lamina where they differentiate into
11 spermatogonia. As shown by Lara et al., 2017, DBP shows a much greater
12 disruption of this migration and increased germ cell aggregation following exposure
13 from e19.5-20.5 or e13.5-20.5, with significantly more germ cells migrating and
14 reduced aggregation observed following exposure during the MPW alone. This is
15 consistent with germ cell aggregation being an effect induced later in gestation,
16 supporting that timing of exposure as possibly important for detecting effects on
17 sperm. Considering the low percentage of motile sperm in the controls of the Boberg
18 et al., 2011, study, the known sensitivity of sperm to experimental conditions (Seed,
19 et al., 1996) and importance of optimized computer assisted counting measurements
20 (Schleh et al, 2013), it is also possible that the reported outcomes by Boberg et al.,
21 2011, are a nuance of the experimental approach.

5. Conclusion

1
2
3 Overall, the results of this systematic comparison provide convincing evidence on
4 the differences between the effects occurring with the LMW DBP (positive control)
5 and the HMW DINP. In contrast to what was seen with DBP, DINP did not cause
6 cryptorchidism or hypospadias. There was no effect on AGD/AGi. Leydig cell
7 aggregates on e17.5 and e21.5 did not increase. There was no reduction of
8 intratesticular testosterone, no effects on sperm motility and sperm count and no
9 effects on adult testosterone and LH levels were seen. In this experimental model,
10 DINP does not cause adverse reproductive effects and endocrine effects like DBP.
11 Our findings are similar to those in previous studies on DINP reporting a lack of
12 statistically significant or dose-related effects of DINP on testicular descent, penile
13 development and AGD in adult animals following in utero exposure to DINP during
14 the MPW (Boberg et al. 2011; Clewell et al., 2013b; Gray et al., 2000).

Table 1: Structures and abbreviations of phthalates in this study

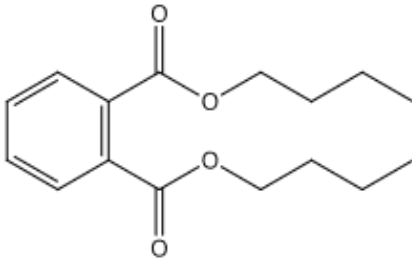

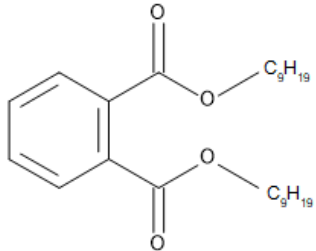

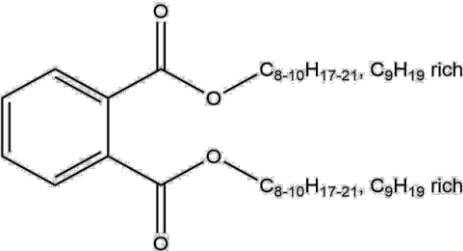

Chemical Name	Abbreviation	CAS No	Structure
Dibutyl phthalate	DBP	84-74-2	
Diisononyl phthalate	DINP (DINP2)	28553-12-0	
1,2-Benzenedi-carboxylic acid, di-C8-10, branched alkyl esters, C9-rich	DINP (DINP1)	68515-48-0	

Table 2. Effects of in utero exposure to vehicle control, 750 mg/kg bw/day DBP (DBP-750), 125 mg/kg bw/day DINP (DINP-125) and 750 mg/kg bw/day DINP (DINP-750) from e15.5-18.5 on adult reproductive phenotype

	Control	DBP-750	DINP-125	DINP-750
Body weight (g)	408.03 ± 9.70	383.30 ± 11.38	399.23 ± 6.90	417.97 ± 4.64
AGD (mm)	44.80 ± 0.94	35.67 ± 1.48 ^a	43.598 ± 0.55	44.36 ± 0.44
Anogenital index	6.04 ± 0.09	4.91 ± 0.19 ^a	5.92 ± 0.08	5.93 ± 0.05
Average testis weight (g)	1.96 ± 0.04	0.97 ± 0.13 ^a	1.99 ± 0.02	1.94 ± 0.04
Penis length (mm)	10.94 ± 0.22	9.17 ± 0.21 ^a	10.66 ± 0.07	10.51 ± 0.19
Penis weight (g)	0.148 ± 0.006	0.109 ± 0.004 ^a	0.138 ± 0.003	0.134 ± 0.005
Ventral prostate weight (g)	0.48 ± 0.03	0.40 ± 0.02 ^a	0.49 ± 0.03	0.49 ± 0.02
Seminal vesicle weight (g)	0.73 ± 0.03	0.33 ± 0.03 ^a	0.71 ± 0.02	0.69 ± 0.03

Results are expressed as litter means ± SEM. n = 7 for control, DINP 125 mg/kg bw/day and DINP 750 mg/kg bw/day groups, and n = 6 for the DBP 750 mg/kg bw/day group.

^a p<0.001 (ANOVA – Bonferroni)

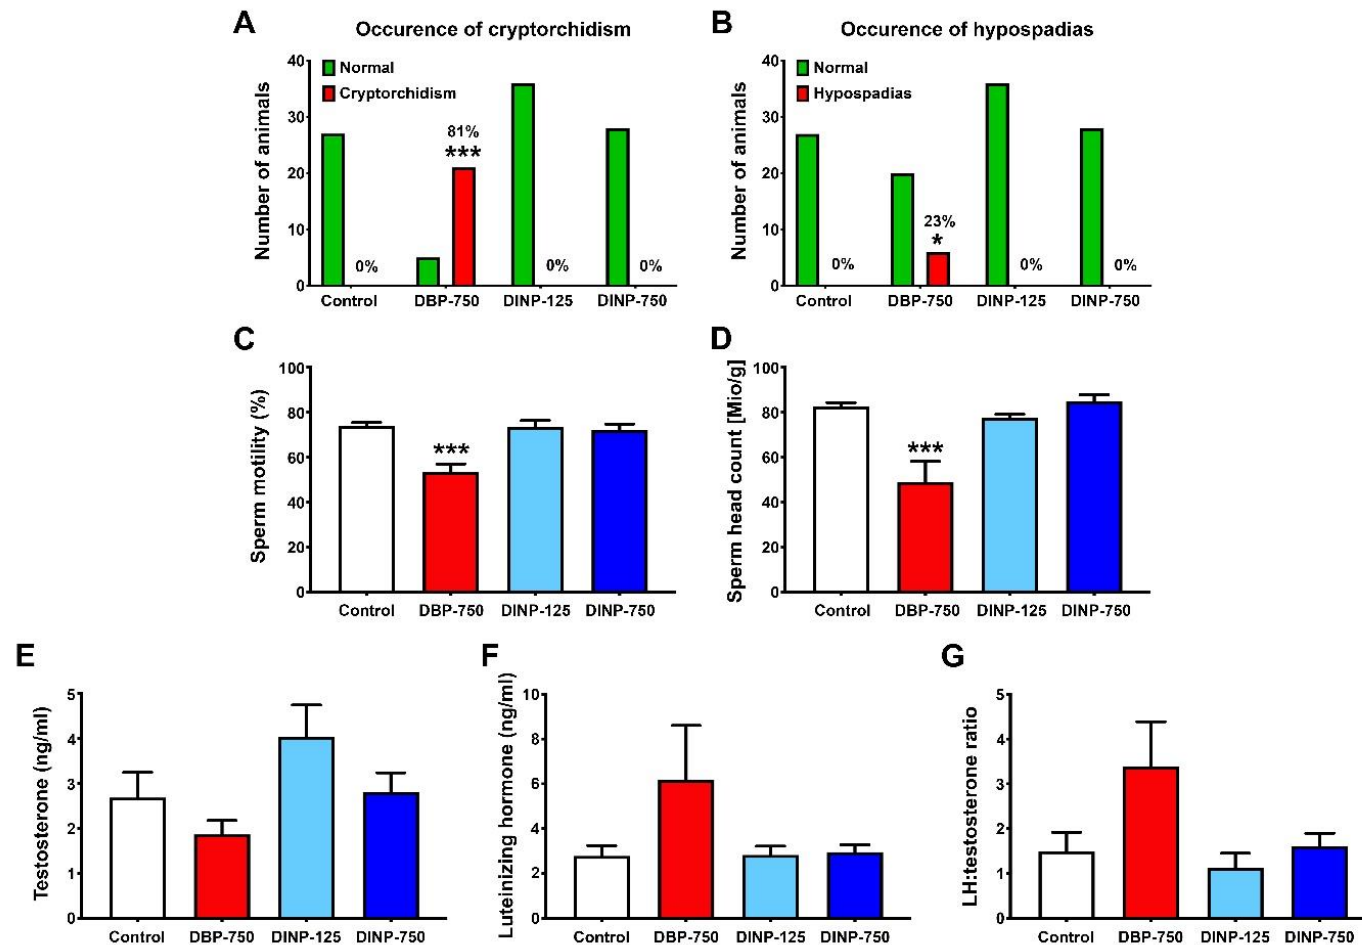

Figure 2. In utero exposure to Dibutyl phthalate (DBP, 750 mg/kg bw/day) in the masculinisation programming window (e15.5-e18.5), but not to low (125 mg/kg bw/day) or high (750 mg/kg bw/day) doses of Diisononyl phthalate (DINP) induces TDS-like symptoms in adulthood. Values are Litter Means \pm SEM (n = 7 for control, n=6 for DBP-750, n = 7 for DINP-125, n=7 for DINP-750). *p<0.05, ***p<0.001 in comparison with respective controls.

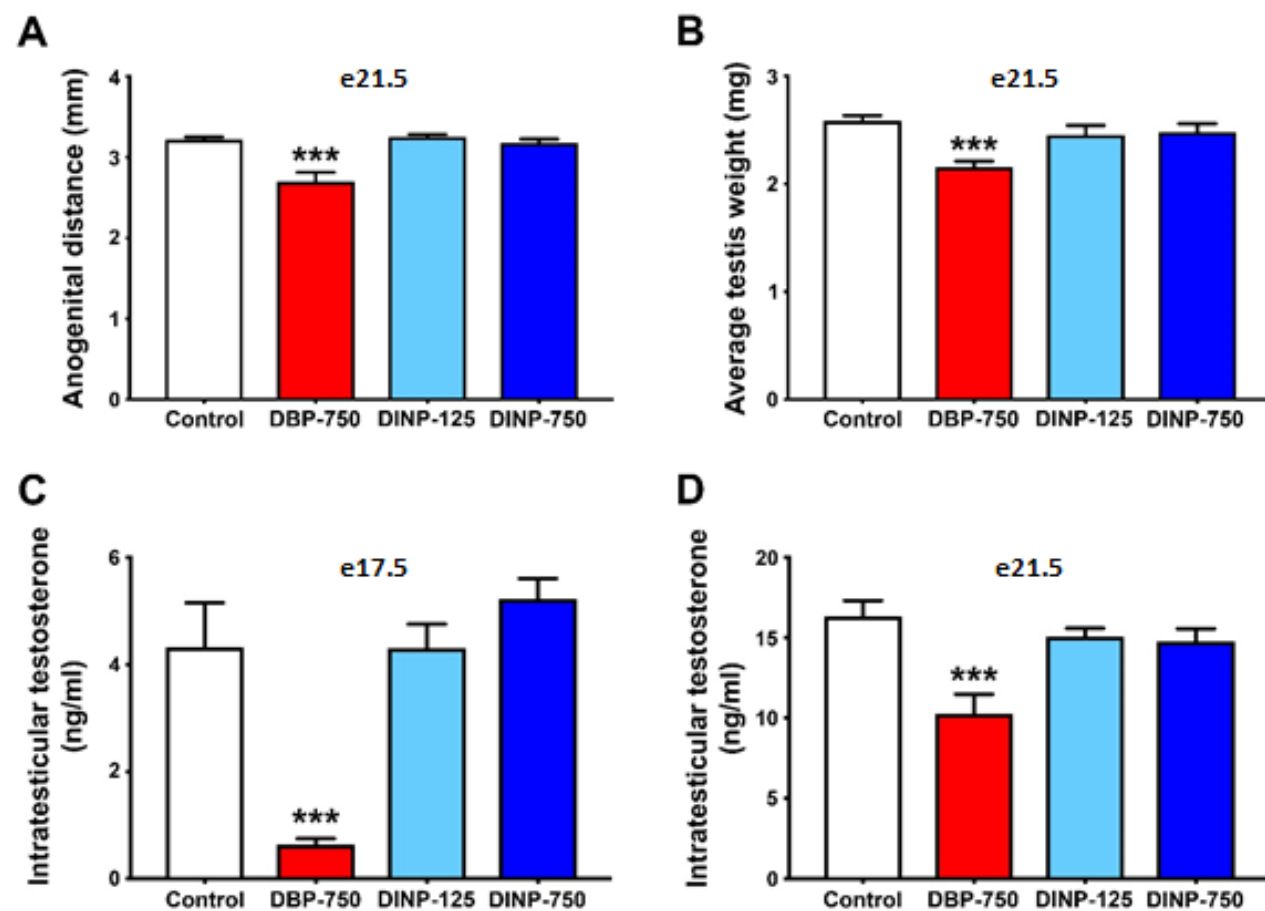

Figure 3. In utero exposure to Dibutyl phthalate (DBP, 750 mg/kg bw/day) in the masculinisation programming window, but not to low (125 mg/kg bw/day) or high (750 mg/kg bw/day) doses of Diisononyl phthalate (DNP) induces effects on testosterone and anogenital distance (AGD) in male fetuses. Effects from in utero exposure vehicle (Control), DBP (750 mg/kg bw/day), DNP (125 or 750 mg/kg bw/day) on (A) AGD at e21.5 (Values are Litter Means \pm SEM n = 7 for control, n=6 for DBP-750, n = 6 for DNP-125, n = 6 for DNP-750), (B) average testis weight at e21.5 (Values are Litter Means \pm SEM n = 7 for control, n=6 for DBP-750, n = 6 for DNP-125, n = 6 for DNP-750), (C), intratesticular testosterone at e17.5 (Values are Litter Means \pm SEM n = 7 for control, n=6 for DBP-750, n = 6 for DNP-125, n = 6 for DNP-750, and (D) intratesticular testosterone at e21.5 (values are Litter Means \pm SEM (n = 4 for control, n=7 for DBP-750, n = 4 for DNP-125, n = 6 for DNP-750 at e17.5). ***p<0.001 in comparison with respective controls.

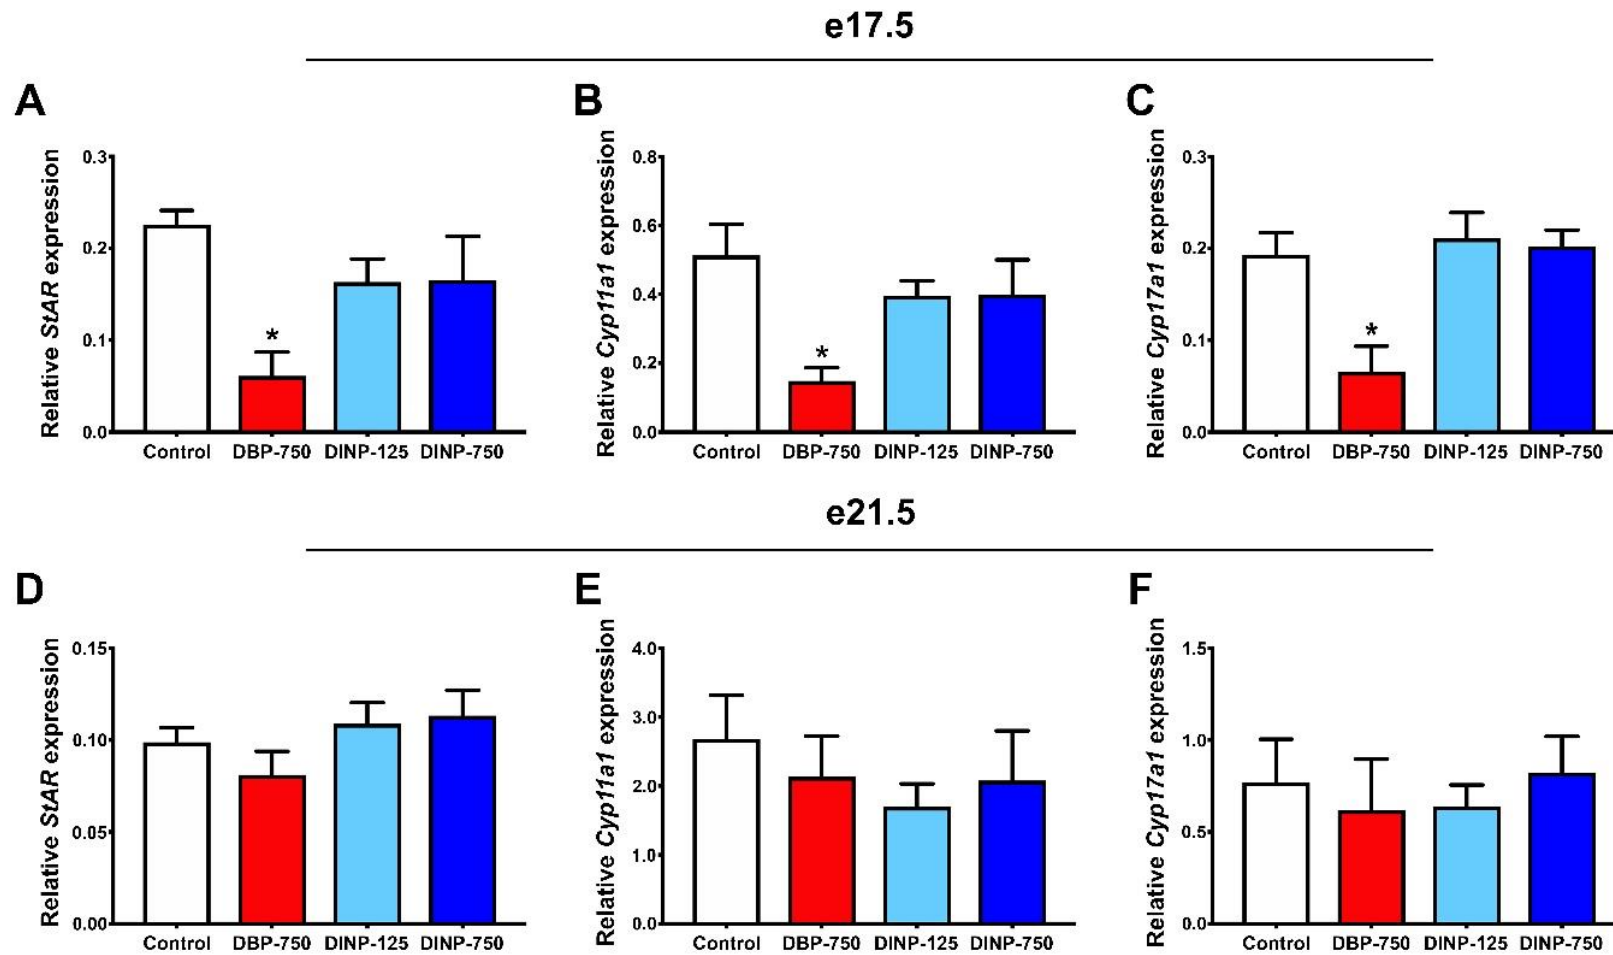

Figure 4. Quantitative mRNA expression of steroidogenic genes in e17.5 and e21.5 testes after exposure to vehicle (Control), Dibutyl phthalate (DBP-750 mg/kg bw/day), Diisononylphthalate (DINP-125 or 750 mg/kg bw/day). (A, D) Steroidogenic acute regulatory protein (*StAR*), (B, E) cytochrome P450, family 11, subfamily a, polypeptide 1 (*Cyp11a1*), (C, F) cytochrome P450, family 17, subfamily a, polypeptide 1 (*Cyp17a1*). Dams were exposed from embryonic day (e) 15.5-17.5 (A-C) or e15.5-18.5 (D-F). Values are Litter Means \pm SEM (n = 3 litters per treatment group). *p<0.05 in comparison with respective controls.

Figure 5. Triple immunofluorescence labelling of fetal testes at e21.5 following exposure during the male programming window to vehicle (Control), Dibutyl phthalate (DBP-750 mg/kg bw/day), Diisononylphthalate (DINP- 125 or -750 mg/kg bw/day).

3β-HSD (green; fetal Leydig cell marker), Sox-9 (red; Sertoli cell marker), SMA (blue; α-smooth muscle actin, peritubular myoid cell marker). The asterisk in panel B illustrates focal dysgenesis in the DBP 750 mg/kg bw/day (DBP-750) treatment group. Scale bar = 200 μm.

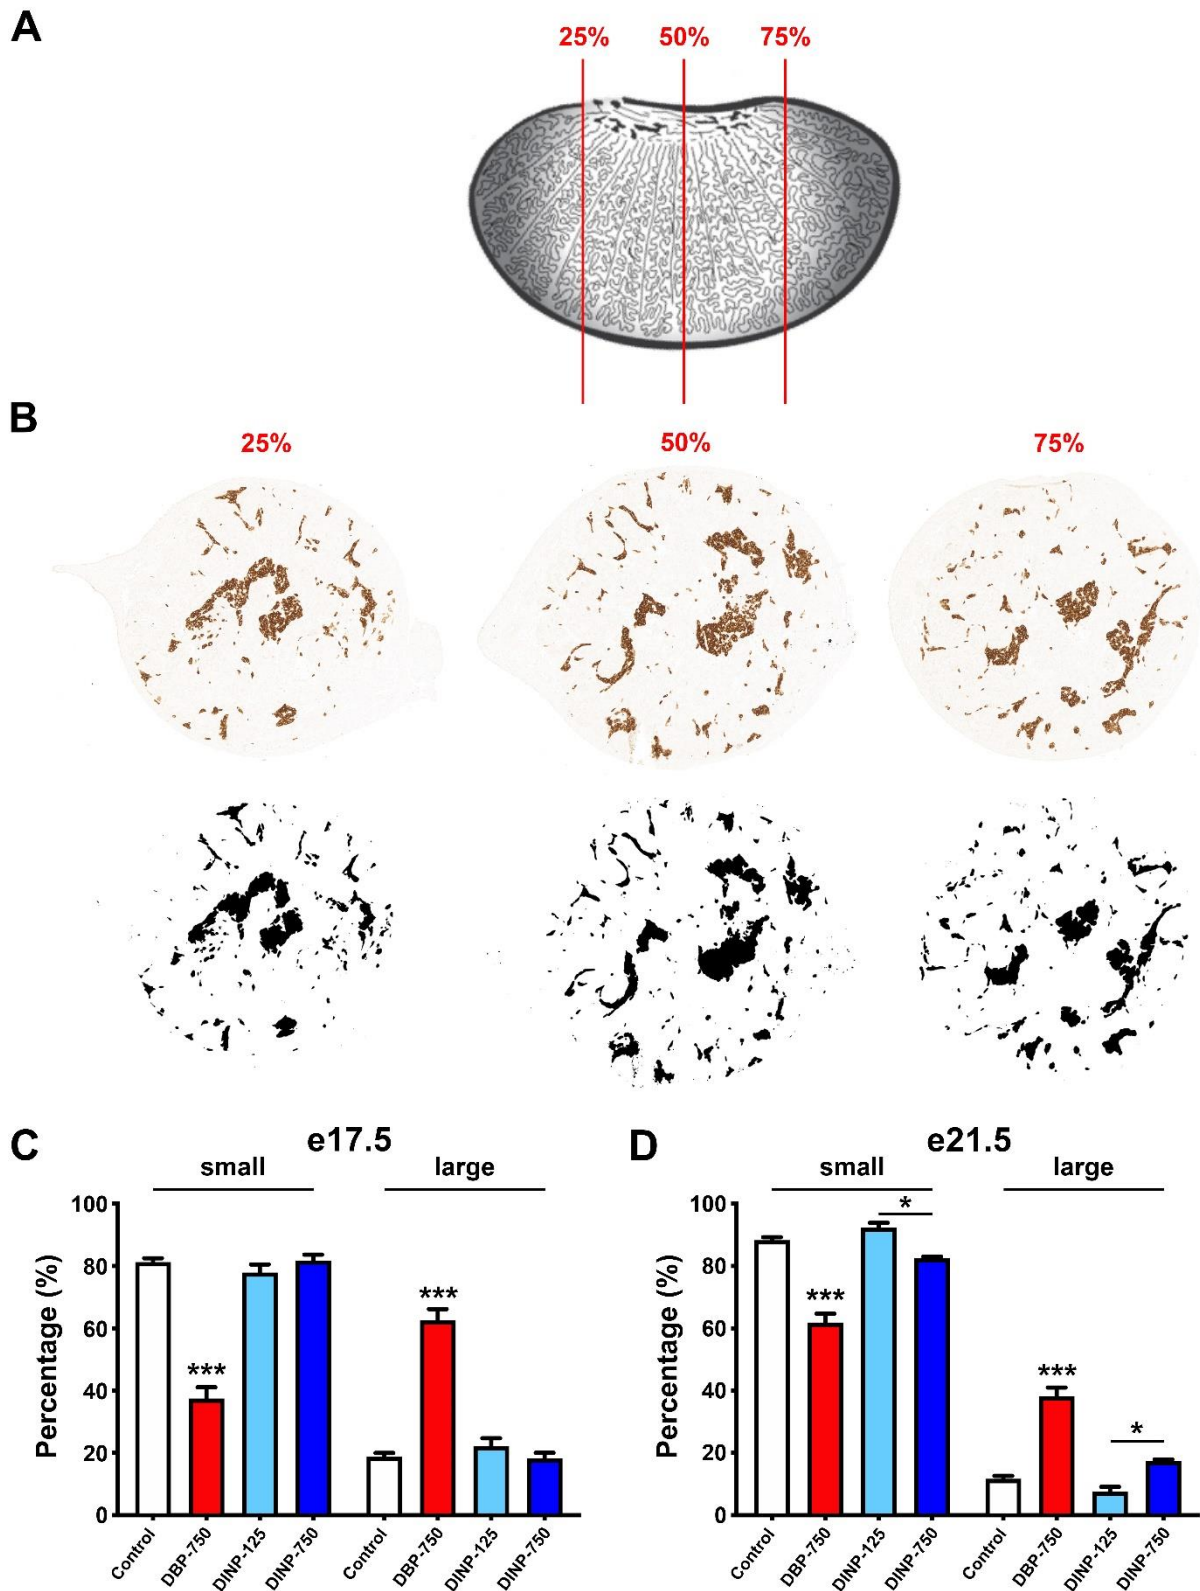

Figure 6: Quantitative evaluation of Leydig cell aggregates in e17.5 and e21.5 testes after exposure during the male programming window (MWP) to vehicle (Control), Dibutyl phthalate (DBP, 750 mg/kg bw/day), Diisononylphthalate (DINP, 125 or 750 mg/kg bw/day).

(A) Schematic diagram to illustrate the collection of the sections at 25, 50 and 75%, which were included in the systematic analysis in order to get a representative average for each testis.

(B) Examples of the immunostaining with 3 β -HSD (1st row), corresponding transformed, background corrected pictures for automatic counting (2nd row). For technical details see the Materials and Methods.

(C) Quantitative Assessment of Leydig cell aggregates. Values are Litter Means \pm SEM (n = 6 for control, n=6 for DBP 750 mg/kg bw/day (DBP-750), n = 6 for DINP 125 mg/kg bw/day (DINP-125), n = 5 for DINP 750 mg/kg bw/day (DINP-750) at e17.5 and e21.5). *p<0.05 when DINP-125 and DINP-750 groups are compared, ***p<0.001 in comparison with controls.

MPW e15.5-18.5

Figure 7. Developmental Toxicity Studies with DINP. The duration and timing of exposure for published studies on DINP are depicted here in relation to select male rat developmental milestones. Studies involving exposures encompassing the male programming window (MPW) are depicted in green. Studies involving exposure prior to the MPW are depicted in blue. # denotes study was performed in Wistar rats; * denotes study was performed in Sprague Dawley rats. Postnatal day (PND), AGD (anogenital distance), e (embryonic day)

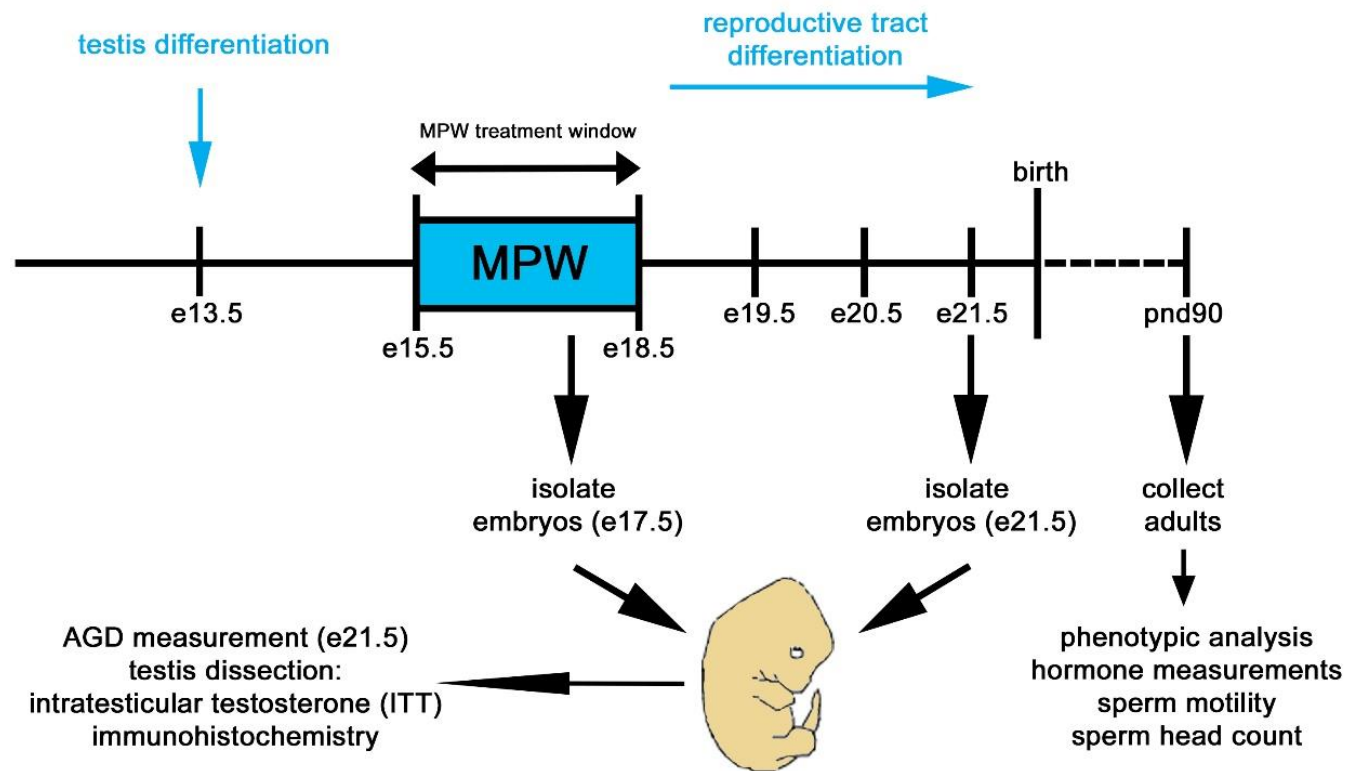

Figure 1: Study design: Indicated with blue arrows are testis differentiation in the rat (starting at embryonic day e13.5 and reproductive tract differentiation (from e18.5 onwards). The masculinisation programming window (MPW, e15.5–e18.5) is indicated with the blue box. Three different experiments were performed. The treatment window that was used in the two fetal studies was during the MPW, from e15.5–e17.5 for e17.5 fetal isolations; and from e15.5–e18.5 for e21.5 fetal isolations. The following observations were made: anogenital distance (AGD) was measured (in e21.5 fetal isolations only), testes were dissected and weighed (testes of e17.5 fetal isolations were not weighed), 1 testis was fixed for subsequent immunohistochemistry and 1 testis was frozen on dry ice for subsequent intratesticular testosterone (ITT) measurement. In a third experiment, pregnant rats were treated from e15.5–e18.5 and male animals were collected in adulthood at postnatal day (pnd) 90. Blood was taken for hormone measurements, the animals were phenotypically analysed, sperm motility was determined and testis samples were collected for sperm head counts.

Declaration of interests

The authors from the University of Edinburgh declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

The authors declare the following financial interests/personal relationships which may be considered as potential competing interests:

Drs. Angelika Langsch, Christine Palermo and Rainer Otter are employed by producers of DINP
