ABSTRACT

We present a new survey of HCN (1–0) emission, a tracer of dense molecular gas, focused on the little-explored regime of normal star-forming galaxy disks. Combining HCN, CO, and infrared (IR) emission, we investigate the role of dense gas in star formation, finding systematic variations in both the apparent dense gas fraction (traced by the HCN-to-CO ratio) and the apparent star formation efficiency of dense gas (traced by the IR-to-HCN ratio). The latter may be unexpected, given the recent popularity of gas density threshold models to explain star formation scaling relations. Our survey used the IRAM 30-m telescope to observe HCN(1–0), CO (1–0), and several other emission lines across 29 nearby disk galaxies whose CO (2–1) emission has previously been mapped by the HERACLES survey. We detected HCN in 48 out of 62 observed positions. Because our observations achieve a typical resolution of ~ 1.5 kpc and span a range of galaxies and galactocentric radii (56% lie at $r_{\text{gal}} > 1$ kpc), we are able to investigate the properties of the dense gas as a function of local conditions in a galaxy disk. We focus on how the ratios IR-to-CO, HCN-to-CO, and IR-to-HCN (observational cognates of the star formation efficiency, dense gas fraction, and dense gas star formation efficiency) depend on the stellar surface density, Σ_{star} , and the molecular-to-atomic gas ratio, $\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$. The HCN-to-CO ratio is low, often $\sim 1/30$, and correlates tightly with both the molecular-to-atomic ratio and the stellar mass surface density across a range of 2.1 dex (factor of ≈ 125) in both parameters. Thus for the assumption of fixed CO-to-H₂ and HCN-to-dense gas conversion factors, the dense gas fraction depends strongly on location in the disk, being higher in the high surface density, highly molecular parts of galaxies. At the same time, the IR-to-HCN ratio (closely related to the star formation efficiency of dense molecular gas) decreases systematically with these same parameters and is $\sim 6 - 8$ times lower near galaxy centers than in the outer regions of the galaxy disks. For fixed conversion factors, these results are incompatible with a simple model in which star formation depends only on the amount of gas mass above some density threshold. Moreover, only a very specific set of environment-dependent conversion factors can render our observations compatible with such a model. Whole cloud models, such as the theory of turbulence regulated star formation, do a better job of matching our observations. We explore one such model in which variations in the Mach number driving many of the trends within galaxy disks while density contrasts drive the differences between disk and merging galaxies.

1. INTRODUCTION

It is not yet fully understood how the properties of molecular gas clouds affect their ability to form stars. A strong relation between gas density¹⁵ (n) and star formation is expected, because denser gas pockets will be more prone to collapse and will collapse more quickly. A key method to test this expectation has been to assemble observations of molecular lines with different critical densities and to compare these observations to tracers of recent star formation. Because such observations do not need to resolve individual clouds or star-forming cores, this approach may be the most practical way to systematically study the effect of gas density on star formation over large parts of the universe. In this paper, we present new observations of the HCN (1–0) transition that cover large (\sim kpc) parts of nearby galaxy disks and compare them to estimates of the recent star formation rate and CO emission, a tracer for the molecular gas content (H_2). HCN(1–0), with an effective excitation density $\gtrsim 10^4 - 10^5 \text{ cm}^{-3}$, has (along with HCO^+ (1–0)) become the most common tracer of dense gas over large parts of galaxies. By contrasting it with the bulk of the molecular gas traced by CO emission and the rate of recent star formation, we aim to gain insight into how physical conditions internal to the molecular gas, especially density, affect the star formation process.

Starting with the groundbreaking papers by Gao & Solomon (2004a,b), several studies (e.g. Graciá-Carpio et al. 2006, 2008; Busmann et al. 2008; Juneau et al. 2009; García-Burillo et al. 2012) have shown that the total star formation rate (SFR) of galaxies scales more directly (meaning more linearly) with the luminosity of molecular lines that have high excitation densities (e.g., HCN) than with bulk tracers of the molecular gas (e.g., CO). While low- J CO emission tracks star formation nearly linearly in the disks of local star-forming galaxies (e.g., Bigiel et al. 2008, Schrubba et al. 2011, and Leroy et al. 2013b, hereafter L13), the relationship becomes nonlinear (multivalued or steeper than linear) when starburst regions and merging galaxies are considered (e.g., Genzel et al. 2010; Daddi et al. 2010). Considering spirals and (ultra)luminous infrared galaxies ($L_{\text{TIR}} \geq 10^{11} L_{\odot}$; hereafter (U)LIRGs) as a single population, the SFR is a super-linear function of the bulk gas tracer CO. By contrast, Gao & Solomon (2004b) showed that total SFR scales almost linearly with the HCN(1–0) luminosity across the entire range of galaxies. In a follow-up study, Wu et al. (2005) concluded that the large parts of galaxies sampled by Gao & Solomon (2004b) and Galactic dense cores align along the same HCN(1–0)–IR relation. On the assumption that line luminosities are proportional to the mass of emitting gas, these results imply that the SFR per unit *total* molecular mass is higher in the brighter (higher SFR) systems, while the SFR per unit *dense* molecular mass is nearly constant.

Explanations of the distinct relationships between CO, recent SFR, and HCN can broadly be grouped into two classes. One group of explanations, which we refer to as “density threshold models”, broadly posit that the SFR is determined by the mass of molecular gas above a certain *threshold* density, with gas above this density forming stars at an approximately fixed rate everywhere (i.e., $\text{SFR}/M_{\text{dense}} \text{ is } \sim \text{constant}$). Gao & Solomon (2004b) and Wu et al. (2005) advocate such a view, as do Lada et al. (2010, 2012) and Evans et al. (2014)

based on studies of clouds in the Solar Neighborhood. A competing class of models, which we refer to as “whole cloud” or “turbulence regulated models,” posit that the properties of the whole star-forming cloud affect the efficiency of star formation. That is, the average density, Mach number, and other properties of the entire cloud set the local threshold for star formation, the fraction of gas above this threshold, and the speed with which star-forming gas collapses. Federrath & Klessen (2012) synthesize several such models; in this paper, we focus on comparisons to Krumholz & McKee (2005, hereafter KMK05) and Krumholz & Thompson (2007, hereafter KT07), which considered such a “whole cloud” picture in the context of observations of molecular lines with varying critical density. In these models, both the SFR per unit of total molecular mass and the fraction of dense gas increase with the average density within the clouds (\bar{n}). The Mach (\mathcal{M}) number also affects the density distribution and criteria for star formation, with a high \mathcal{M} broadening the probability distribution function of gas densities and increasing high density condensations, though its numerical effect varies somewhat with the details of the model used (Federrath & Klessen 2012).

Characterizing the relation between dense gas and star formation is critical to distinguish between these models, and, in turn, to understand how larger scale conditions in galaxies affect star formation. For example, several recent results have highlighted the potential importance of dynamical effects in explaining observed variations in the SFR per unit gas (Genzel et al. 2010; Daddi et al. 2010; García-Burillo et al. 2012; Meidt et al. 2013). For a full picture of how such large scale phenomena propagate into cloud-scale variations in the star formation process, we must first understand how physical conditions within the gas (which may be affected by large-scale conditions, e.g., see Hughes et al. 2013) affect star formation in the cloud.

Observations of a diverse sample of normal galaxy disks can help distinguish these models but such a data set has remained lacking. The pioneering surveys of dense gas in galaxies mostly offer rough averages over the entire molecular/star-forming disks or values at bright galaxy centers (e.g., Gao & Solomon 2004a; Graciá-Carpio et al. 2006, 2008; Busmann et al. 2008; Juneau et al. 2009; Krips et al. 2008; Crocker et al. 2012; García-Burillo et al. 2012). The existing handful of observations targeting dense gas in galaxy disks at cloud scales have been time-consuming and provide only small-size samples (e.g., Brouillet et al. 2005 and Buchbender et al. 2013 in M 31 and M 33, respectively). Observations comparing extragalactic observations to individual clouds in the Milky Way (Wu et al. 2005; Heiderman et al. 2010; Lada et al. 2012) have proved enlightening, but the Galactic clouds studied sample a more restricted range of conditions than nearby galaxies and also suffer from small sample sizes and narrow perspective.

To bridge these studies, we undertook a new HCN survey that targeted large parts of a significant sample of galaxy disks. From 2008 until 2011, we used the IRAM 30-m telescope to observe HCN (1–0) emission from the disks of 29 nearby star-forming galaxies. We drew our targets from the HERACLES survey, which constructed maps of CO(2–1) line emission from a set of 48 nearby galaxies (L13; first maps and survey presented by Leroy et al. 2009). With a typical resolution of ~ 1.5 kpc, each of our HCN observations blends together a large population of individual molecular clouds. We expect this averaging to attenuate the intrinsic variability and evolutionary effects visible when studying individual star-forming complexes (e.g., Schrubba et al. 2010). However

¹⁵ Throughout this paper “density” refers to volume density of H_2 molecules unless otherwise specified.

this resolution is still fine enough that we can isolate many local variables related to the physical state of the interstellar medium (ISM), for example stellar and gas surface density, interstellar radiation field, and so on. A particular emphasis of our survey is to study the disks (not just the centers) of star-forming galaxies, and so our observations span a wide range of galactocentric radii, from galaxy centers out to $\sim 75\%$ of the *optical radius* (defined as the radius of the 25 mag arcsec⁻² isophote in the B-band). This allows us to probe a wide range of local conditions and, because HERACLES builds on many surveys at other wavelengths (see Sect. 2), the data exist to readily estimate these local conditions. In the end, our HCN survey provides context for cloud-based studies in the Milky Way and Local Group galaxies, while contrasting the starbursts, whole-galaxy integrals, and bright galaxy centers targeted in previous extragalactic studies (see also Bigiel et al, *subm.*).

This paper is structured as follows. We describe our observations and the ancillary data sets in Sect. 2. In Sect. 3, we put our data in context by comparing them to star formation scaling relations obtained from unresolved observations of galaxies. In Sect. 4, we focus specifically on our data and investigate the systematic variations across galaxy disks of the star formation efficiencies and the dense gas fraction in the molecular clouds. In Sect. 5, we compare these trends with the predictions from density-threshold and turbulence-regulated models of star formation. In Sect. 6, we study how the compatibility between our observations and these models depends on the assumed CO and HCN conversion factors. In Sect. 7, we try to define a common scenario for resolved and unresolved observations. Sect. 8 summarizes the paper.

2. DATA AND PHYSICAL PARAMETERS

2.1. Data

2.1.1. A New Survey of HCN (1–0) Emission in Galaxy Disks

From 2008 through 2011, we used the IRAM 30-m telescope to observe HCN(1–0) line emission at 62 positions in 29 galaxies drawn from the HERACLES survey (Table 1). For comparison to the overall molecular reservoir, we also observed the CO(1–0) line at 58 of those positions (recall that HERACLES observed CO (2–1)). All of our targets are star-forming galaxies ($L_{\text{TIR}} < 10^{11} L_{\odot}$; hereafter SF galaxies); most of our targets are disk galaxies, though several are known starburst galaxies (e.g., we include M 82) and several of our central pointings cover nuclear starbursts. The pointings were chosen to cover a wide range in environment properties and star formation activity, while also maximizing the likelihood of detection. To this end, we targeted regions with relatively bright CO(2–1) emission in the HERACLES maps, picking a set of such regions that span a wide range in galactic radius (up to 75% of the optical radius; see maps in Appendix B). Our final set of HCN(1–0) detections spans a range of 2.1 dex (factor of ≈ 125) in both stellar surface density and molecular-to-atomic mass ratio, a range of 1.9 dex (factor of ≈ 80) in molecular gas surface density, and a range of 1.7 dex (factor of ≈ 50) in SFR surface density.

The angular resolution of the IRAM 30-m at the frequency of HCN(1–0) is $\sim 28''$, which sets our working resolution in this paper. The corresponding spatial resolution at the distances of our targets ranges from 0.4 to 3.4 kpc (rightmost column in Table 1) with an average value of ≈ 1.5 kpc.

For observations in January and December 2008 we used the old AB receivers at the 30-m telescope. In August 2009

and June 2011 we used the EMIR receiver (Carter et al. 2012; see Table 2). Whenever possible with regard to the extent of the emission and the observing schedule, we observed in wobbler-switching mode with a total ON–OFF throw of $\pm 240''$ in azimuth and a wobbling frequency of 0.5 Hz. The orientation of the wobbler throw direction is fixed in azimuth, so the throw in equatorial coordinates depends on the hour angle of the target. We used the HERACLES CO(2–1) maps to ensure that every position was observed only when the OFF positions were free of molecular line emission. Due to this constraint, wobbler-switching mode was not viable for a few positions because the throw would have intersected the galaxy. In those cases we adopted a position-switching scheme and selected a suitable OFF position with coordinates chosen based on the HERACLES maps.

We checked the focus of the telescope on planets or bright quasars at the beginning of each session and then every few hours and, if relevant, at sunset and sunrise. Every ~ 1 –1.5 hours, we corrected the telescope pointing using a point-like source close to the target galaxy. The magnitude of these corrections typically agreed with the nominal pointing accuracy of the telescope ($\sim 2''$ rms). Every 15 minutes, we obtained a standard chopper wheel calibration, which we used to place the data on the antenna temperature scale (T_{A}^*). In order to convert to main beam temperature (T_{MB}), we adopted forward and beam efficiencies from the IRAM documentation¹⁶ that were up-to-date at the time of the observations (see Table 3). The expected uncertainties in the resulting gain calibration are $\lesssim 10\%$. We checked this by observing well-known line-calibrators on a non-systematic basis. Comparing these to the 30-m telescope spectra collected by Mauersberger et al. (1989), we confirm this accuracy. As a crosscheck, we also compared our HCN(1–0) line intensities at five galaxy centers to those measured by Krips et al. (2008), also with the IRAM 30-m telescope. The measured intensities agree within $< 10\%$.

We reduced the data using the CLASS package of the GILDAS software library¹⁷. The raw spectra taken with EMIR (since 2009 onwards) are ~ 4 GHz wide. For each line at each position, we fitted a baseline to a 0.5 GHz-wide part of the spectrum centered on the line frequency Doppler shifted by using the systemic velocity of the observed galaxy. For observations taken with the AB receivers (in 2008), we used the entire 0.5 GHz bandwidth when fitting the baseline. Depending on the quality of the baseline, we fitted a polynomial baseline of degree one or three. In each case we avoided the velocity range of molecular emission from the galaxy known from the HERACLES maps. When necessary, we removed spurious spikes from the spectra. In the positions observed in 2009 ($\sim 20\%$ of the total), we also suppressed a systematic small-amplitude ripple in the HCN(1–0) spectra via flagging and linear interpolation in the Fourier transformed spectrum. For each line and position, we averaged all the spectra except those that showed egregious artifacts, poor baselines or abnormal noise levels to produce a final spectrum.

From these reduced, averaged spectra, we calculate velocity-integrated intensities, expressed throughout the paper on the main beam temperature (T_{MB}) scale in units of K km s⁻¹. We derive these intensities summing over the velocity range known to contain molecular line emission from the CO (2–1) maps (the same region that we avoided in base-

Note. — Center coordinates, distance, size, and orientation of the observed sources. All values are taken from L12, when available. The remainder objects are NGC 2146 and NGC 2798 (all data taken from Schrubba et al. 2011), NGC 3034 (all from HyperLeda, Paturel et al. 2003, except distance, from Walter et al. 2002), NGC 3077 (from Walter et al. 2008), and NGC 4631 (from Irwin et al. 2011).

line fitting). We estimate the statistical error, σ_{line} , via

$$\sigma_{\text{line}} = rms_{\text{channel}} \sqrt{\delta V \Delta V}, \quad (1)$$

where rms_{channel} is the rms noise, in Kelvin, for each channel, δV is the channel width and ΔV is the width of the line window. Throughout this paper, we disregard the fine structure of HCN, which is not apparent in our observations, and quote a single integrated intensity for the $J = 1 \rightarrow 0$ transition. The two brightest fine-structure levels of the $J = 1 \rightarrow 0$ transition lie only $\sim 5 \text{ km s}^{-1}$ apart. This is comparable to our typical spectral resolution ($3.4 - 6.8 \text{ km s}^{-1}$) and three times smaller than the smallest line width (FWHM) of any detected line in our survey.

We acquired and reduced the CO (1–0) data in a similar way, although the integration times were much shorter than for HCN (1–0) because CO (1–0) is a much brighter line. In most of this paper we derive molecular surface densities from the CO(2–1) HERACLES maps (Sect. 2.2), because, unlike the CO(1–0) data, they are available at all observed positions. In Appendix A.1, we use the CO(1–0) data where available to demonstrate that the CO excitation conditions do not bias our main results.

Appendix B summarizes the results of our 30-m survey. In Figs. B1–B5, we show our 62 observed positions on the

HERACLES CO(2–1) maps of the target galaxies. Figs. B6–B19 show the final HCN(1–0) and CO(1–0) spectra. Table B1 reports the velocity integrated intensities, $I_{\text{HCN}10}$ and $I_{\text{CO}10}$, at each position, indicating statistical errors, $\sigma_{\text{HCN}10}$ and $\sigma_{\text{CO}10}$, in brackets. The quoted errors do not include the $\sim 10\%$ uncertainty that we expect in the overall flux calibration. For the analysis in this paper, we consider all spectra with $SNR_{\text{line}} \equiv (I_{\text{line}}/\sigma_{\text{line}}) \geq 4$ to be detections. As a check, we verified that in all cases the line shapes of HCN were consistent with the shape of the CO(2–1) line at matched spatial and spectral resolution (Figs. B6–B19). We applied the same check to spectra with lower signal-to-noise ratio and, based on this criterion, we promoted three HCN spectra with $3.4 \leq SNR_{\text{HCN}} \leq 3.7$ to be detections. In summary, we detect HCN(1–0) at 48 positions with a median SNR_{HCN} of ~ 9.5 . The HCN detections span ~ 2.5 dex in $I_{\text{HCN}10}$ (a factor of ≈ 330) and extend from galaxy centers up to $r_{25} = 0.75$. The detection at the largest radius occurs in NGC 6946 at a galactocentric radius of 8.5 kpc. We detect the CO(1–0) line in 57 out of 58 positions with a median SNR_{CO} of ~ 35 . When reporting non-detections, we give 4σ upper limits.

2.1.2. Ancillary Data

Our target galaxies belong to the HERACLES sample, which means that we have CO(2–1) emission mapped at

Table 2
Receiver-Backend Combinations.

Month/year	Receiver(s)	Backend
01/2008	A100+B100	1 MHz filterbank
12/2008	A100+B100	1 MHz filterbank
08/2009	E090	WILMA (2 MHz resolution)
06/2011	E090	WILMA (2 MHz resolution)

Table 3
Observed Lines

Line	Frequency (GHz)	Beam (")	$T_{\text{MB}}/T_{\text{A}}^*$	
			[2008]	[2009/2011]
HCN(1–0)	88.6	27.8	1.23	1.17
CO(1–0)	115.3	21.3	1.28	1.22

NOTE. — Line rest frequencies. Reported beam size corresponds to the FWHM of the 30-m beam. Separate $T_{\text{MB}}/T_{\text{A}}^*$ ratios are given for the 2008 and 2009/2011 campaigns, which used different receivers (see text and Table 2 for details).

$\sim 13''$ across their disks. HERACLES targets many individually well-studied nearby galaxies and was designed to overlap with other surveys that provide data across the electromagnetic spectrum. The data from these other surveys and from numerous studies of individual galaxies, provide us with an excellent characterization of the local properties of the ISM and of the star formation rates at each of our pointings. A detailed account can be found in Leroy et al. (2012, hereafter L12; see also L13). In short, we make use of the following data:

- CO(2–1) line emission, from HERACLES (L13).
- IR emission in the 3.6 – 160 μm range, from the *Spitzer* Infrared Galaxies Survey (SINGS, Kennicutt et al. 2003) and the Local Volume Legacy Survey (LVL, Dale et al. 2009).
- Continuum-subtracted $\text{H}\alpha$ emission, from SINGS, LVL, GoldMine (Gavazzi et al. 2003), and a compilation of other, smaller studies (Hoopes et al. 2001; Boselli & Gavazzi 2002; Knapen et al. 2004).
- H I line emission, from The H I Nearby Galaxy Survey (THINGS, Walter et al. 2008) and a collection of new and archival VLA data (L13 and Leroy et al., in prep.).

Except in the few cases noted below, we convolved all the available maps to our working resolution of $28''$, i.e., the resolution of our HCN data. We closely followed L12 to estimate physical parameters from them.

2.2. Physical Parameter Estimates

All surface densities in this paper are *face-on* values. For this, the equations to convert intensities measured along the line of sight to surface densities include a $\cos(i)$ factor, where i is the adopted inclination of the galaxy disks (Table 1). The cosine factor corrects for the observational bias that makes measured intensities to increase with i as the beam intersects a larger volume of the disk.

In all cases we have tried to keep the physical parameters in this paper closely linked to observed intensities. That is, total molecular surface density is a recasting of CO intensity, dense gas surface density is a linear translation of HCN intensity, and so on for H I (21-cm intensity), star formation (IR intensity from $24\mu\text{m}$), and stellar surface density (near-IR intensity). We explore additional effects related to parameter estimation in the appendix but the results of this paper can mostly be straightforwardly read in terms of observables and we plot these as an alternative axis whenever possible.

2.2.1. Molecular Surface Density

The mass surface density of molecular gas (Σ_{mol} , including helium) is commonly derived from the velocity-integrated intensity of the CO (1–0) line. For practical reasons, in this paper we derive Σ_{mol} from the HERACLES observations of the CO (2–1) line, $I_{\text{CO}21}$; we can easily convolve our full maps at higher resolution to match the HCN(1–0) beam and derive a CO(2–1) intensity for each point (while the CO 1–0 line is observed at higher resolution than the HCN 1–0 line because of its rest frequency). We then define I_{CO} as the CO(1–0) intensity inferred from the HERACLES observations on the assumption of a fixed CO(2–1)–to–CO(1–0) line ratio, R_{21} :

$$I_{\text{CO}} = \frac{I_{\text{CO}21}}{R_{21}}. \quad (2)$$

We adopt $R_{21} = 0.7$, which is the average ratio found by L13 by comparing their HERACLES CO(2–1) data with CO(1–0) data available in the literature (including the data presented in this study) at matched angular resolution. Our new observations of CO(1–0) support this characteristic ratio as appropriate for our data. In Appendix A.1, we redo large portions of our analysis with the available CO (1–0) data and confirm that the assumption of a fixed R_{21} does not bias our results.

From I_{CO} , we derive

$$\Sigma_{\text{mol}} = \alpha_{\text{CO}} I_{\text{CO}} \cos(i), \quad (3)$$

where α_{CO} is the CO–to–molecular mass conversion factor, here phrased in terms of CO (1–0). By default, we assume throughout our sample a fixed, Galaxy-like conversion factor $\alpha_{\text{CO}} = \alpha_{\text{CO}}^0 \equiv 4.4 M_{\odot} \text{pc}^{-2} (\text{K km s}^{-1})^{-1}$ (derived from a H_2 column density conversion of $X_{\text{CO}} = 2 \times 10^{20} \text{cm}^{-2} (\text{K km s}^{-1})^{-1}$ and a 1.36 helium-correction factor). We explore the impact of varying this assumption in Sect. 6.

Note that our approach to α_{CO} could simply be recast as adopting a fixed conversion factor for the CO (2–1) intensity. For an in-depth investigation into the CO-to- H_2 conversion factor in HERACLES galaxies, we refer the reader to Sandstrom et al. (2013).

2.2.2. Dense Molecular Gas Surface Density

Molecular clouds host cores and dense filaments comprised of gas with densities several orders of magnitude higher than the cloud average (\bar{n}). The emission lines of molecules with high electric dipoles (e.g., HCN, HCO^+ , CS) trace this dense component, in which collisions can thermally excite their energy levels. A conversion factor (α_{HCN}) can be defined to calculate the mass surface density of dense molecular gas (including helium), Σ_{dense} , from the HCN(1–0) intensity:

$$\Sigma_{\text{dense}} = \alpha_{\text{HCN}} I_{\text{HCN}10} \cos(i). \quad (4)$$

We initially assume a fixed $\alpha_{\text{HCN}} = \alpha_{\text{HCN}}^0 \equiv 10 M_{\odot} \text{ pc}^{-2} (\text{K km s}^{-1})^{-1}$, which Gao & Solomon (2004b) argued to be reasonable for the disks of normal, star-forming galaxies. In discussing Σ_{dense} , we consider this quantity to represent the surface density of gas at densities above a fixed cutoff, n_{dense} , where n_{dense} is of the order of the star formation threshold expected from some models and observations, i.e., $\sim 10^4 - 10^5 \text{ cm}^{-3}$. The exact value of n_{dense} does not matter for most of our analysis, as long as this density is associated with the dense, often star-forming substructures within clouds.

A potentially important issue is how n_{dense} compares with the density required to effectively excite the HCN(1–0) line (n_{eff}). For the HCN(1–0) line, the critical density at which the de-excitation rates by collisions and by spontaneous emission are equal is $n_{\text{crit}} = 1.25 \times 10^6 \text{ cm}^{-3}$ at $T_{\text{K}} = 20 \text{ K}$ (taking the rate coefficients listed in the LAMDA database¹⁸; Schöier et al. 2005). However, it is well-known from radiative transfer models (e.g., Scoville & Solomon 1974) that a line can be effectively excited at densities lower than n_{crit} thanks to opacity effects. The excitation threshold is thus sensitive to variations in the gas temperature, the velocity gradient, and the HCN abundance within the clouds. Based on a grid of models with the RADEX radiative transfer code (van der Tak et al. 2007), we find n_{eff} could be $\sim 10^4 - 10^5 \text{ cm}^{-3}$ for typical cloud conditions. With our definitions, any variation in this excitation threshold could imply a change in α_{HCN} . We explore how an α_{HCN} that varies with environment would impact our conclusions in Sect. 6.

2.2.3. Other Local Conditions Within Our Beams

Atomic gas. We assume that the 21 cm H I emission is optically thin and derive the mass surface density of atomic gas (Σ_{atom} , including helium), from the velocity-integrated intensity of the line, $I_{\text{H I}}$:

$$\frac{\Sigma_{\text{atom}}}{M_{\odot} \text{ pc}^{-2}} = 1.98 \times 10^{-2} \frac{I_{\text{H I}}}{\text{K km s}^{-1}} \cos(i). \quad (5)$$

The total mass surface density of gas, Σ_{gas} , is defined as $\Sigma_{\text{gas}} = \Sigma_{\text{mol}} + \Sigma_{\text{atom}}$ and the molecular-to-atomic ratio is $\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$. In the observed positions where HCN is detected, the molecular gas makes up $\sim 50 - 100\%$ (median 88%) of the total gas surface density.

Stars. We estimate the mass surface density of old stars from the $3.6 \mu\text{m}$ intensity, $I_{3.6}$ via:

$$\frac{\Sigma_{\text{star}}}{M_{\odot} \text{ pc}^{-2}} = 280 \frac{I_{3.6}}{\text{MJy sr}^{-1}} \cos(i), \quad (6)$$

which we consider uncertain by $\sim 50\%$ due to contamination from young stars and dust emission (Meidt et al. 2012) and uncertainties in the mass-to-light ratio (Zibetti et al. 2009; Meidt et al. 2014).

Dust Properties and IR Spectral Energy Distribution. We convolve the LVL and SINGS *Spitzer* images to a common resolution ($\sim 40''$), construct radial profiles for each galaxy, and fit the average spectral energy distribution in each ring using the dust models of Draine & Li (2007); for details of this specific processing see Leroy et al. (2012). From these models we derive several dust properties within radial bins, of which the $24 \mu\text{m}$ -to-TIR ratio, the ‘‘cirrus’’ emissivity, and the dust-to-gas mass ratio (after comparing with CO and H I

data also convolved to $40''$) are used in this paper to derive star formation rates (see below and Appendix A.2). These quantities are all ratios (rather than absolute intensities) and we assume that they hold, at least on average, at the somewhat higher working resolution of our HCN observations.

Star Formation Rate (SFR). To easily compare our results with most studies of molecular lines in galaxies, we estimate the SFR surface density (Σ_{SFR}) from the total IR intensity (I_{TIR}):

$$\frac{\Sigma_{\text{SFR}}}{M_{\odot} \text{ Myr}^{-1} \text{ pc}^{-2}} = 1.87 \times 10^{-3} \frac{I_{\text{TIR}}}{L_{\odot} \text{ pc}^{-2} \text{ sr}^{-1}} \cos(i). \quad (7)$$

Here, I_{TIR} is calculated from the measured $24 \mu\text{m}$ intensity (I_{24}) and the dust models, which produce a 24-to-TIR ratio that rigorously holds at slightly larger scales than our beam. This can alternatively be thought of as approximately using the $24 \mu\text{m}$ emission to make an aperture correction that matches the lower resolution TIR, estimated from $24 \mu\text{m}$, $70 \mu\text{m}$, and $160 \mu\text{m}$ data, to our $28''$ HCN beam.

Equation 7 corresponds to the calibration by Murphy et al. (2011, see also Kennicutt & Evans 2012) and we prefer this approach because it links us cleanly to previous work comparing HCN and CO, which has focused mostly on the integrated IR luminosity as a star formation rate tracer. This allows our results to be seamlessly read in terms of IR luminosity surface density, even though we label them ‘‘SFR.’’ In Appendix A.2, we take advantage of the ancillary data set and build alternative SFR tracers ($\text{H}\alpha$, $24 \mu\text{m}$, and a linear combination of both) to confirm that the choice of star formation rate tracer has a minimal impact on our results. All the SFR calibrations in this paper assume a Kroupa (2001) IMF.

2.3. Extragalactic Reference Sample

We compare our data to observations of molecular lines in 106 SF galaxies and (U)LIRGs compiled by García-Burillo et al. (2012, hereafter GB12). GB12 combined published data with new observations using the IRAM 30-m telescope. GB12 present CO(1–0) and HCN(1–0) luminosities for all of their targets, estimating these from higher-order transitions in a few high-redshift objects. Their sample includes both upper limits (non-detections) and lower limits for objects without full mapping. In principle, we derive the total SFR (in $M_{\odot} \text{ Myr}^{-1}$) for these targets from the total IR luminosity (L_{TIR}) again using Equation 7. However, following Graciá-Carpio et al. (2008), we rather use $1.3 \times L_{\text{FIR}}$ instead of L_{TIR} , where L_{FIR} is the far IR luminosity. This allows us to avoid AGN-driven contamination of L_{TIR} in the brightest (U)LIRGs, while it hardly changes the estimated SFR in objects powered by star formation. In particular, once the most conspicuous AGN sources are removed, the $L_{\text{TIR}}/L_{\text{FIR}}$ ratios of the GB12 sample show a small scatter of 0.05 dex rms (12%) around a median value of ≈ 1.3 . Since we lack TIR data for some GB12 objects, we also use $(1.3 \times L_{\text{FIR}})$ rather than L_{TIR} to classify them as either SF galaxies or (U)LIRGs (Sect. 1). In principle, this affects the classification of only five galaxies.

For simplicity and in order to present the data as directly as possible, we assume the constant conversion factors quoted in Sect. 2.2 to derive (dense) molecular masses from the measured line luminosities. This is a non-trivial assumption, given the ample evidence that these factors are a few times lower in (U)LIRGs than in SF galaxies (e.g., see Bolatto et al. 2013,

¹⁸ <http://home.strw.leidenuniv.nl/~moldata/>

for a review). The main influence of these factors on our first-order analysis is likely to be some offset between (U)LIRGs and SF galaxies. We return to the topic of conversion factors in Sect. 6. An additional concern is the unobscured SFR, which is not perfectly accounted for by the IR luminosity and could make up a significant fraction of the total SFR in SF galaxies, thus causing additional offsets (GB12).

For the 83 objects that have measured sizes for the star-forming/molecular disk, we convert luminosity/flux measurements to estimates of the average Σ_{dense} , Σ_{mol} , and Σ_{SFR} . We divide the total molecular (dense) mass or SFR in each galaxy by its disk area. The measured sizes are typically given as FWHM values of the light distribution, so that we quote $\langle \Sigma \rangle = M/(\pi \text{FWHM}_{\text{maj}}^2/4)$. Here, FWHM_{maj} would be the Full Width at Half Maximum along the the major axis of the star-forming/molecular disk. This definition is equivalent to that of the *face-on* surface densities derived from our data (Sect. 2.2). When calculating $\langle \Sigma \rangle$, we implicitly neglect any aperture correction to account for the fraction of the mass inside the FWHM, which would be a factor of 0.5 for a two-dimensional Gaussian and potentially as low as ~ 0.15 for an exponential disk. It is also driven by the total mass and so may be viewed as somewhat closer to the peak Σ value than the value likely to be found at any given locale in the galaxy (in the same way that the ratio between the total area below a Gaussian curve and its FWHM approximately gives its peak value). For the example of a face-on exponential disk, the surface density $\langle \Sigma \rangle$ is, in fact, ~ 4 times the peak value of the exponential because the aperture correction (i.e., the mass outside the FWHM) is so large. For a Gaussian, the number approaches ~ 1.4 . Most SF galaxies likely fall somewhere in this range (e.g., Young et al. 1995). We return to this source of bias when we compare our sampling of galaxy disks to these unresolved data (Sect. 3). For now, we caution the reader that $\langle \Sigma \rangle$ derived in this way is biased somewhat high.

2.4. Analysis tools

We parameterize the relations between pairs of variables using power-law fits, which we use to capture general trends in the data. We derive the best fit power law from total-least-square minimization, typically in the log-log space, excluding non-detections and assuming equal uncertainties along both axes. Quoted uncertainties in the fit outputs are 1σ levels analytically derived from the equations of error propagation. Our lower/upper limits are typically compatible with the solutions that we find, so we do not expect that their exclusion biases the fit outputs. Given the irregular sampling of our targets, we caution that care should be taken before extrapolating our fits to other regimes or data sets.

We also find it useful to measure the strength of the correlations between pairs of variables in a non-parametric way, which we do using Spearman’s rank correlation coefficient (r_s ; hereafter rank coefficient). Throughout this paper, rank coefficients do not consider limits (i.e., non-detections). We measure the significance of r_s by its p-value, i.e., the probability that the absolute value of the rank coefficient for uncorrelated data could be equal or higher than the measured value by chance. Throughout this paper, we consider that a correlation is significant when the p-value of its rank coefficient is lower than 2.5%.

We performed most of the data analysis within the environment of statistical computing R (R Development Core Team 2013).

Table 4
Rank Correlations for (Dense) Molecular – SFR Scalings

	M_{dense} vs. SFR	M_{mol} vs. SFR	Σ_{dense} vs. Σ_{SFR}	Σ_{mol} vs. Σ_{SFR}
<i>this paper</i> +GB12	0.96*	0.96*	0.97*	0.97*
<i>this paper</i>	0.89*	0.95*	0.88*	0.87*
GB12	0.89*	0.86*	0.92*	0.89*
GB12 – SF only	0.54*	0.55*	0.95*	0.92*
GB12 – (U)LIRG only	0.82*	0.83*	0.91*	0.89*

NOTE. — Rank correlation coefficients relating star formation and gas surface densities (Fig. 1) for various groupings of our data and the GB12 data. Star symbols indicate significant correlations (p-value < 2.5%).

3. COMPARISON WITH UNRESOLVED OBSERVATIONS: STAR FORMATION SCALING RELATIONS

Our HCN detections span a range in HCN (1–0) luminosity (within the beam) of $\sim 3 \times 10^4 - 2 \times 10^7$ K km s⁻¹ pc². Thus, they span the luminosity gap between individual Galactic clouds (up to $\sim 1 \times 10^4$ K km s⁻¹ pc² in Wu et al. 2005) and entire galaxy disks (down to $\sim 1 \times 10^7$ K km s⁻¹ pc² in GB12). This reflects that, at our working resolution of ~ 1.5 kpc, we probe ensembles of clouds at sub-galactic scales. Because this scale has been barely explored in previous studies, we begin our analysis by comparing in Fig. 1 our data (gray circles) to unresolved observations of galaxies drawn from GB12 (colored symbols; see Sect. 2.3).

The top row of Fig. 1 plots the total SFR in our pointings (within the 28'' beam) and in the GB12 galaxies as a function of the (dense) molecular mass traced by HCN (M_{dense} ; left-hand column) and CO (M_{mol} ; right-hand column). The bottom row shows the same information, but in terms of surface densities of SFR and (dense) gas mass. These surface density scaling relations are often called Kennicutt-Schmidt (KS) plots, and the accompanying power-law fits (“KS laws”) are a common tool for empirical studies of the relations between star formation and the ISM. We remind that, for sake of simplicity, we adopt fixed CO and HCN conversion factors for both SF galaxies and (U)LIRG. Thus, these are also luminosity-luminosity scaling relations and we include axes showing the corresponding IR and line luminosities.

As expected from previous studies, in all four panels of Fig. 1 the SFR shows a good correspondence with the (dense) molecular gas traced by the HCN and CO emission. We also see this in Table 4, which lists the rank coefficients for the plots in Fig. 1 considering various groupings of our data and the GB12 data. All of these correlations are significant (p-value < 2.5%) and high ($\gtrsim 0.8$ for total SFR/masses, except for the subset of SF galaxies from GB12; $\gtrsim 0.9$ for surface densities), thus reflecting the tight correlations seen in the figures. Unexpectedly, the rank coefficients of the SFR-vs- M_{dense} and SFR-vs- M_{mol} relations, on the one hand, and of the Σ_{SFR} -vs- Σ_{mol} and Σ_{SFR} -vs- Σ_{dense} relations, on the other, are very similar for every data set. Although the slopes of the relations vary, implying differences in the physics at play for different molecular tracers, the CO and HCN lines appears to be almost equally good at predicting the SFR at these scales. We caution the reader that this result may not hold at different scales and/or different data samples.

Fig. 1 shows that our data extend the range of gas masses and surface densities spanned by unresolved observations. In terms of total gas masses (top row), our brightest points,

Figure 1. *Top row:* Total SFR (Σ_{SFR}) as a function of the mass of molecular (*left*) and dense (*right*) molecular gas for pointings in galaxy disks (this paper, gray points) and unresolved star-forming galaxies (red) and (U)LIRGs (blue) from GB12. *Bottom row:* Surface density of recent SFR (Σ_{SFR}) as a function of the surface density of total (*left*) and dense (*right*) molecular gas for the same data sets. The top and right-hand axes of each panel display the data in terms of observed quantities. Open symbols indicate limits in the direction of the attached arrows. The equations in the figures report power-law fits to our data (gray line), the GB12 sample (green line), and all the data (brown line). Errors at 1σ -level in the fit parameters are indicated. For comparison, the yellow area shows a fixed ratio (power law index 1) with a factor of 2 scatter.

mostly vigorously star-forming galaxy centers, lie right below the least active SF galaxies (dark red circles). In terms of surface densities (bottom row), there is a partial overlap between them. Pointings at larger galactocentric radii, where the lines are typically fainter (Sect. 4), have masses and surface densities as much as two and one order of magnitude lower than the galaxies in the GB12 sample, respectively. Recall that we expect the surface densities estimated from the unresolved (GB12) observations to be biased somewhat high by the lack of an aperture correction (Sect. 2.3). Correcting by these fac-

tors, which should affect both axes, would tend to increase the GB12 overlap with our data set in terms of surface density.

The bottom-row panels of Fig. 1 might support the idea that (U)LIRGs and SF galaxies form distinct star formation sequences (Genzel et al. 2010, Daddi et al. 2010, GB12). With or without aperture correction applied to the unresolved observations, our data and the SF galaxies from GB12 align along a continuous and monotonous sequence. In contrast, the (U)LIRG sample lies parallel, but seemingly offset to higher Σ_{SFR} for the same (dense) gas surface density. The offset is

particularly noticeable in the $\Sigma_{\text{SFR}} - \Sigma_{\text{mol}}$ plane, and would be even larger if we assumed lower-than-Galactic CO and HCN conversion factors for the (U)LIRG subsample of GB12.

In the four panels of Fig. 1, adding our data to the GB12 sample has the effect of lowering the best-fit power law indices. However, the reason for this change differs between the left-hand and right-hand panels. In the $\Sigma_{\text{SFR}} - \Sigma_{\text{mol}}$ plane (similarly in the $SFR - M_{\text{mol}}$ plane), the global power-law index drops from ~ 1.4 to ~ 1.2 because our data (power-law index of 1.01 ± 0.08) reinforce the linear trend shown by the SF galaxies in the GB12 sample (index of 0.97 ± 0.07 ; fit not shown in the plots). By contrast, in the $\Sigma_{\text{SFR}} - \Sigma_{\text{dense}}$ plane (similarly in the $SFR - M_{\text{dense}}$ plane) the global index changes from ~ 1.1 to ~ 1.0 when our data are included because our data by themselves follow a significantly sublinear relation (index of 0.69 ± 0.06). In this plot, the SF galaxies alone are fitted by a higher index of 0.88 ± 0.06 . This highlights a main conclusion of this paper: that, perhaps surprisingly, *the apparent efficiency with which dense gas forms stars seems to vary systematically across our sample of galaxy disk pointings*. The sense of the variation is that regions with lower dense gas fractions and lower dense gas surface densities tend to have a higher apparent rate of star formation per unit dense gas.

In summary, despite the continuity between our data and SF galaxies, Fig. 1 suggests that the star formation laws for the dense molecular gas are not the same at galactic and subgalactic scales. This is not illogical, given that many of the new conclusions in this paper come from data points with low surface density. These typically correspond to off-center positions and, because they are relatively faint in line emission, they will not dominate the total galaxy luminosity. Our results thus suggest that the average star formation properties of molecular clouds vary across galaxy disks. We investigate this topic in detail in the following sections, focusing on our new data set. Doing so, we take advantage of the fact that our data set resolves disk galaxies into discrete regions and targets the well-characterized HERACLES (i.e., THINGS and SINGS) galaxies.

4. DENSE GAS FRACTION AND STAR FORMATION EFFICIENCY ACROSS GALAXY DISKS

4.1. Normalized Quantities: f_{dense} , SFE_{mol} , and SFE_{dense}

In this section, we combine our HCN observations with ancillary data of the observed pointings (Sect. 2.1.2). We explore how the beam-averaged properties of the dense gas in unresolved molecular clouds depend on local conditions within a galaxy. Doing so, it is crucial to bear in mind that, because the molecular interstellar medium in galaxy disks can be sparse and clumpy at our typical spatial resolution, neither beam-integrated masses (“luminosities”) nor beam-averaged surface densities (“intensities”) can be straightforwardly translated into intrinsic cloud properties (see extended discussion in Leroy et al. 2013a). For example, in the simplistic assumption that the beam had an area A and probed N identical spherical clouds of mass m_{cloud} and projected area a_{cloud} , we would find that

$$M = m_{\text{cloud}} \times N, \quad (8)$$

$$\Sigma = \Sigma_{\text{cloud}} \times a_{\text{cloud}} \times \frac{N}{A}, \quad (9)$$

where $\Sigma_{\text{cloud}} \equiv m_{\text{cloud}}/a_{\text{cloud}}$ is the intrinsic surface density in a

cloud and M and Σ are the mass and surface density measured at beam scales¹⁹.

Because we work at a fixed angular resolution, beam-integrated masses (M) are strongly dependent on the source distance, that determines the number of clouds captured by the beam (N) to a significant extent. This observational bias is partially corrected when working with surface densities. However, because our observations span a large range of galactocentric radii, we expect large variations in the N/A ratio, which measures the “filling factor” of clouds per unit area. These filling factor variations, which may largely affect Σ_{SFR} , Σ_{mol} , and Σ_{dense} in the same way, can drive surface density correlations (e.g., see Sect. 3 and Table 4), masking more subtle changes in intrinsic cloud properties.

The simplest way to eliminate the N/A factor, assuming that it acts approximately equally on all surface density terms, is to represent our data in terms of three surface density *ratios* that are also frequently used in the literature: the dense gas fraction ($f_{\text{dense}} \equiv \Sigma_{\text{dense}}/\Sigma_{\text{mol}}$), the star formation efficiency of the molecular gas ($SFE_{\text{mol}} \equiv \Sigma_{\text{SFR}}/\Sigma_{\text{mol}}$, i.e., the inverse of the molecular gas depletion time, with dimension of time^{-1}), and the star formation efficiency of the dense molecular gas ($SFE_{\text{dense}} \equiv \Sigma_{\text{SFR}}/\Sigma_{\text{dense}}$). These three parameters are related through the following equation:

$$SFE_{\text{mol}} = SFE_{\text{dense}} \times f_{\text{dense}}. \quad (10)$$

If all the star formation and molecular emission arises from the same set of clouds inside a beam, then these ratios capture the average intrinsic cloud properties over the population within the beam, independent of any filling factor variations.

Our simple approach to physical parameter estimation means that for most of this paper these ratios have direct observational analogs. The ratio of HCN-to-CO emission maps to the dense gas fraction, the ratio of infrared to HCN emission maps directly to the dense gas star formation efficiency, and the ratio of infrared to CO emission maps to the overall molecular gas star formation efficiency.

4.2. Environmental Trends

After exploring a variety of ISM parameters, we found that the systematic variations of f_{dense} , SFE_{dense} , and SFE_{mol} in our sample are best captured by correlations with the molecular-to-atomic ratio, $\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$, and the stellar mass surface density, Σ_{star} . These two quantities also have the advantage of being independent of one another and representing extremely simple functions of the available data, which allows us to confirm with little analysis that those correlations are not spurious. We stress, however, that many other ISM parameters that are relevant to our study are highly covariant with $\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$ and Σ_{star} (e.g., metallicity, midplane pressure), so that we cannot rigorously ascertain what ultimately drives the trends discussed below. The reader should keep in mind that both $\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$ and Σ_{star} decline with increasing galactocentric radius, so that the lower values in Fig. 2 typically correspond to outer positions in the disks.

Fig. 2 shows f_{dense} ($\propto I_{\text{HCN}}/I_{\text{CO}}$; top row), SFE_{dense} ($\propto I_{\text{IR}}/I_{\text{HCN}}$; middle row) and SFE_{mol} ($\propto I_{\text{IR}}/I_{\text{CO}}$; bottom row) as a function of $\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$ (left column) and Σ_{star} (right column). The Figure shows several well-defined, systematic

¹⁹ As usual in extragalactic studies, we assume that the cloud-cloud velocity dispersion prevents clouds in the foreground from absorbing the emission of those behind them.

Table 5
Rank coefficients for f_{dense} , SFE_{dense} , and SFE_{mol} as a function of local conditions in the galaxy

	f_{dense}	SFE_{dense}	SFE_{mol}
r_{25}	-0.59*	0.43*	-0.07
$\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$	0.75*	-0.72*	-0.22
Σ_{star}	0.67*	-0.53*	0.09

NOTE. — Stars symbols indicate significant correlations (p-value < 2.5%) For a typical number of 45 fully detected data points, p-values are \leq 50%, 10%, 5%, 2.5%, 1%, and 0.1% for $|r_s| \geq$ 0.10, 0.25, 0.30, 0.34, 0.39, and 0.49, respectively.

trends across the ~ 2.1 dex (a factor of ≈ 125) spanned by both ISM parameters. As either $\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$ or Σ_{star} increases, f_{dense} increases by a factor of ≥ 4 (fitted power-law indices ~ 0.3 ; see equations in the top corners of the panels), whereas SFE_{dense} decreases by a factor of ~ 8 (power-law indices ~ -0.4). In contrast, SFE_{mol} appears virtually independent of $\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$ and Σ_{star} within the scatter, in rough agreement with more detailed studies in HERACLES galaxies (L13). These trends are confirmed in Table 5, where we list the corresponding rank coefficients. Clearly, $\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$ and Σ_{star} show strong (anti)correlations with f_{dense} and SFE_{dense} but no significant correlations with SFE_{mol} .

Fig. 2 argues strongly that some intrinsic properties of molecular clouds vary systematically across galaxy disks. For our default assumption of fixed CO and HCN conversion factors, we find that f_{dense} and SFE_{dense} show opposite trends, in the sense that the SFE_{dense} decreases and f_{dense} increases as we move from low- Σ_{star} , low $\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$ disks towards high Σ_{star} , high $\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$ galaxy centers. From Equation 10, this renders SFE_{mol} almost uncorrelated with the local conditions considered here. In Appendix A, we demonstrate that these results are robust against changes in the CO transition used to trace molecular gas (i.e., $J = 1 - 0$ instead of $J = 2 - 1$) or in the chosen SFR tracer.

Cast in observational terms, our results show that the ratio of HCN-to-CO intensity ($\propto \Sigma_{\text{dense}}/\Sigma_{\text{mol}}$) increases systematically from a typical value of $\approx 1/30$ (in K) in the disks of normal star-forming galaxies to a higher ratio of $\approx 1/10$ in actively star-forming galaxy centers and starbursts, i.e., a factor of ≈ 3.5 increase over the two orders of magnitude in Σ_{star} and $\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$ that we study. At the same time, the IR-to-HCN ratio ($\propto \Sigma_{\text{SFR}}/\Sigma_{\text{dense}}$) drops, by a factor of ≈ 6 over the same range, so that active galaxy centers appear to display systematically less infrared emission (thus, lower star formation rate) per unit dense gas emission. These two trends cancel, though not entirely, so that the ratio of IR-to-CO ($\propto \Sigma_{\text{SFR}}/\Sigma_{\text{mol}}$) varies more weakly over the same range, systematically changing by less than a factor of 2.

Broadly, these results have two straightforward interpretations: either SFE_{dense} and f_{dense} indeed change as described, or physical conditions within the molecular clouds change systematically in such a way that the conversions of CO and HCN intensity to total and dense molecular gas produce the trends that we observe. In either case, the observations imply that the physical conditions in the molecular ISM, and in molecular clouds specifically, change systematically across galaxy disks, but in a way that conspires to yield only weak

apparent variations in the SFR per unit molecular gas. We explore these two interpretations in the next sections.

5. COMPARISON TO STAR FORMATION MODELS

Because dense gas is believed to play a pivotal role in star formation, our results on f_{dense} and SFE_{dense} have implications for some of the most common models of star formation applied to galaxies. In this section, we compare our observations to examples of the two broad classes of current models: first (Sect. 5.1), the straightforward density-threshold model by Gao & Solomon (2004a,b) and Wu et al. (2005); second (Sect. 5.2), turbulent whole cloud models (KMK05; KT07; Federrath & Klessen 2012). We specifically focus on the theory of turbulence-regulated star formation discussed by KMK05 and KT07, but refer the reader to a wider summary of whole-cloud models by Federrath & Klessen (2012). The alternative model by Narayanan et al. (2008) is based on hydrodynamical simulations of entire galaxies, but shares a similar framework and results in similar predictions to the KMK05.

5.1. Density Threshold Models

In a density threshold model, the star formation rate in a region depends chiefly on the available mass of molecular gas above a certain volume density. The simplest form of such a model, and the most commonly adopted in extragalactic research, assumes an environment-independent, fixed star formation efficiency of the dense gas traced by, e.g., the HCN(1–0) line (our SFE_{dense}). Such a view offers a simple explanation for the almost linear correlation between the HCN(1–0) and IR luminosities of galaxies found in the early studies by Gao & Solomon (2004a,b). That relation contrasts with the (globally) superlinear relation between the CO(1–0) and IR luminosities when (U)LIRGs are included. Within this paradigm, the IR-molecular relations in galaxies emerge because of a higher f_{dense} in the IR-brighter objects. In support of a density threshold model for star formation, Wu et al. (2005) concluded that galaxies and Galactic dense cores with $L_{\text{TIR}} > 10^{4.5} L_{\odot}$ (as required to get reliable SFR estimates from the IR continuum) align along the same HCN(1–0)–IR relation. Other studies of Galactic clouds based on different observational methods have been found in qualitative agreement (Lada et al. 2012; Heiderman et al. 2010; Evans et al. 2014), favoring this simple picture in which the dense gas reservoir is the main determinant of the star formation rate.

At face value, our results in galaxy disks are clearly at odds with these simple threshold models. We find that the SFE_{dense} at kiloparsec scales systematically varies by a significant factor of ≈ 6 across ~ 2 dex in $\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$ and Σ_{star} . We do find that f_{dense} systematically increases by a similar factor moving from galaxy disks to galaxy centers, but the interplay of the two quantities means that SFE_{mol} remains constant across the disks within the scatter. The apparently varying SFE_{dense} in our observations means that the ability of dense gas to form stars must depend on environment and thus, presumably, on conditions in the host molecular cloud. This is at direct odds with the basic assumption of threshold models.

One can envisage more complex density-threshold models that could fit our resolved observations in galaxy disks. In principle, a model that allowed for variations in the density threshold and/or in the star formation timescale of the dense gas could solve the discrepancies (e.g., see Federrath & Klessen 2012). However, making such adjustments quickly moves one into a gray area: if a density threshold depends sensitively on conditions in the parent molecular cloud and

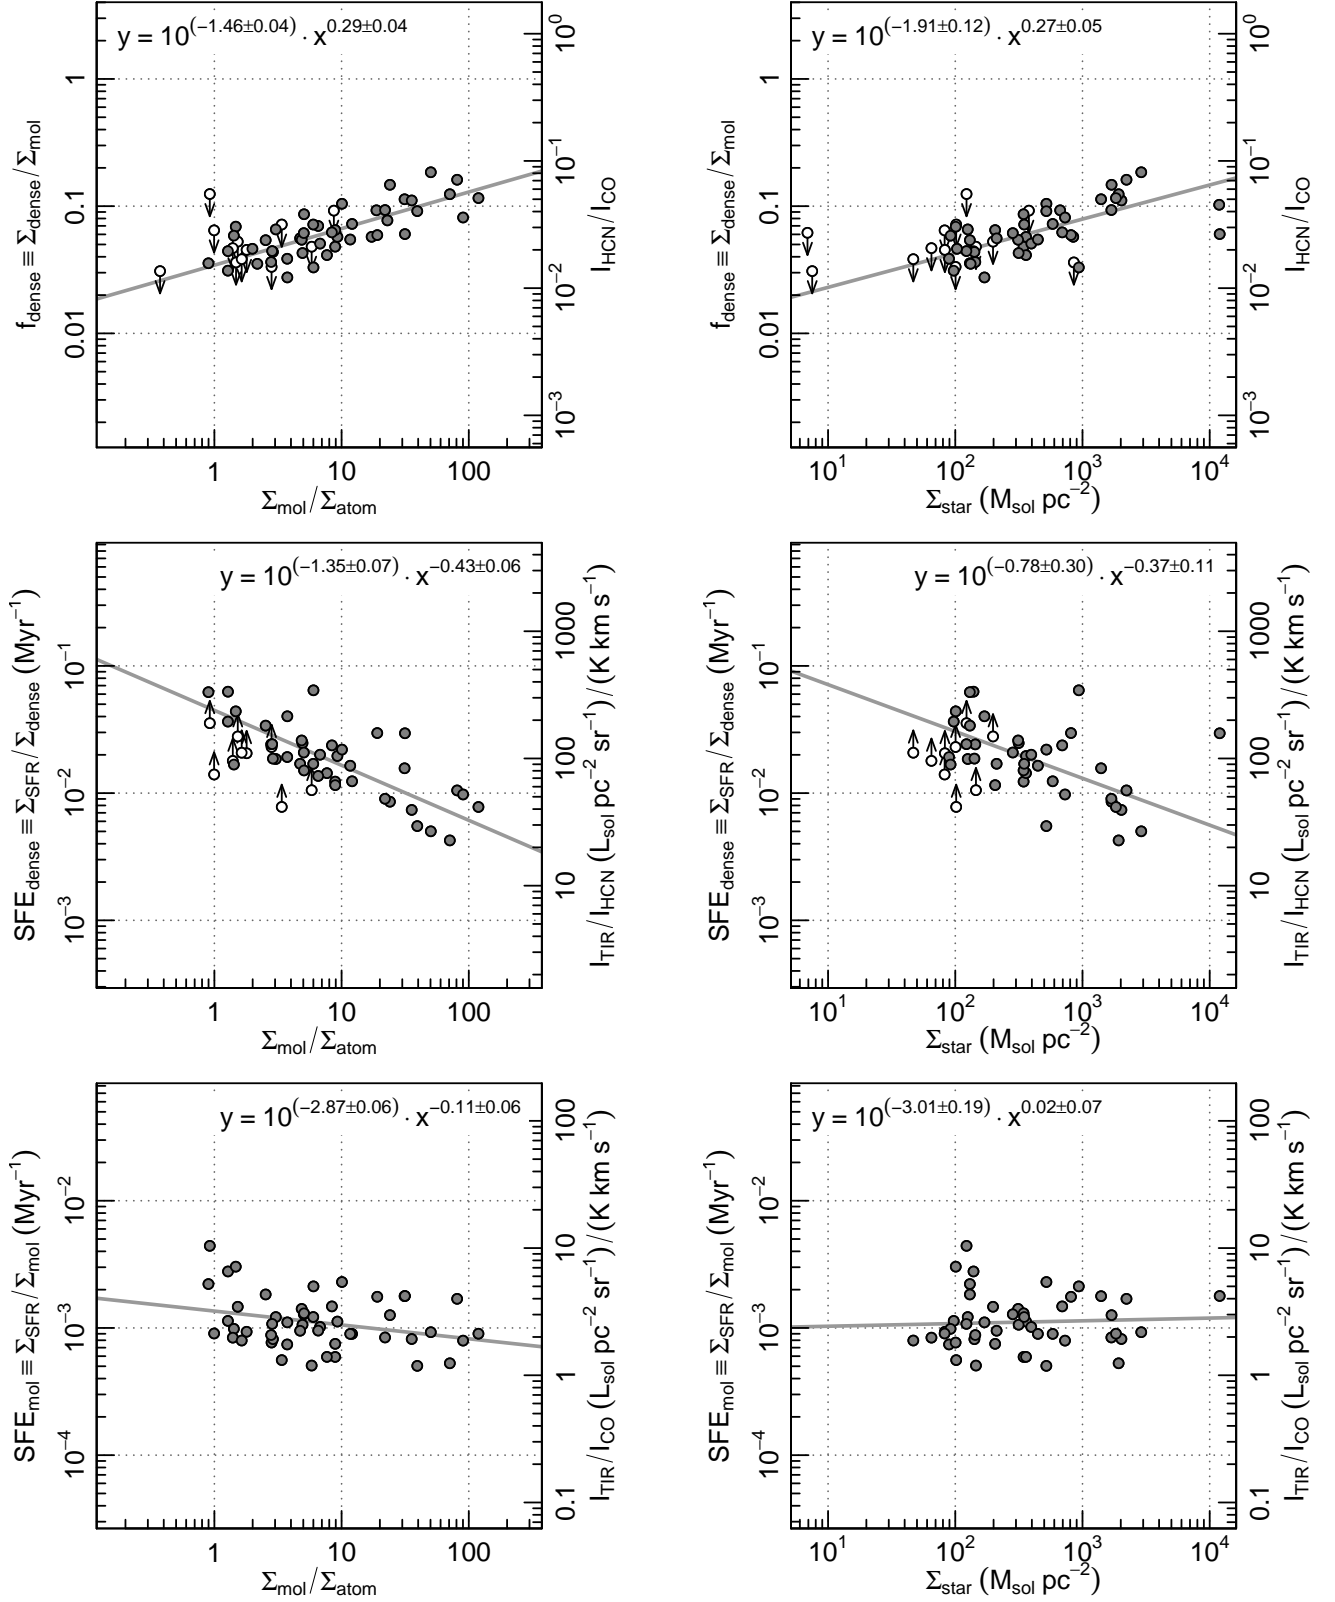

Figure 2. Dependence on environment in our observations. From top to bottom, the dense gas fraction f_{dense} (top row), the star formation efficiency of dense gas SFE_{dense} (middle row), and the star formation efficiency of molecular gas SFE_{mol} (bottom row) as a function of: the molecular-to-atomic ratio ($\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$, left-hand column) and the stellar mass surface density (Σ_{star} , right-hand column). The right-hand axis of each panel display the data in terms of observed quantities. Filled and empty symbols correspond to detections and non-detections, respectively. The solid line shows our best fit to the data (Sect. 2.4). Its equation is reported in the top right corner.

host galaxy, then it increasingly resembles the whole-cloud models. Alternatively, systematic variations in how CO and HCN trace the molecular and dense molecular medium could partly account for the observed trends, salvaging a more universal density-threshold model. In Sect. 6.2, we explore whether our observations could be consistent with a simple density-threshold model given plausible variations in the conversion factors.

5.2. The Turbulence Regulated Whole-Cloud Model

“Whole cloud models” offer an alternative to the universal density threshold view. Here we use this term to refer to models in which conditions throughout a molecular cloud ultimately affect the efficiency with which dense gas forms stars. These models have been contrasted with threshold models in the literature several times, with recent Milky Way results invoked to support a simple density threshold (Evans et al. 2014), while arguments using low resolution extragalactic data used to argue for whole cloud models (e.g., Krumholz & Thompson 2013). Even considering only analytic models, a wide suite of whole cloud models exist in the literature (Federrath & Klessen 2012). These almost all consider the star formation efficiency per free fall time, SFE_{ff} , as the fiducial quantity and so encode a fundamental dependence on density (e.g., McKee & Ostriker 2007). SFE_{ff} further depends in most models on the virial parameter, Mach number, magnetic field, and turbulent character within the clouds.

5.2.1. KMK05 Model Overview

With such a wide set of free parameters, it is outside the scope of our paper to compare our data to the full set of models or possible cloud conditions. Indeed, because in our survey we have very limited knowledge of the cloud population at sub-beam scales, we lack many of the measurements needed for such a comparison. Instead, the main thrust of our treatment of whole cloud models is to ask: can such models plausibly create the kind of correlated variations in SFE_{dense} and f_{dense} that we see in our data? To do so, we focus on one of the earliest whole cloud models, the theory of turbulence-regulated star formation put forward by KMK05. In a later paper, KT07 combined their theoretical treatment with a simple radiation transfer model²⁰ that implicitly provides the conversion factors between gas masses and the observed molecular line luminosities (e.g., HCN(1–0)). To simplify the comparison, we refer here to the original equations by KMK05 and treat conversion factors as fixed.

In the KMK05 theory, the star formation within a virialized molecular cloud with a lognormal distribution of densities depends primarily on the average gas density (\bar{n}) and the intracloud turbulence. The latter is parameterized by the Mach number, \mathcal{M} . The sense of the dependence is that \bar{n} sets the characteristic timescale for star formation, the free-fall time, so that a high density implies more efficient star formation per absolute time interval. Meanwhile in the KMK05 model, a higher degree of intracloud turbulence, i.e., a higher \mathcal{M} , tends to inhibit star formation²¹.

For our purposes, the KMK05 model boils down to the following Equations (complemented by Equation 10):

$$SFE_{\text{mol}} = \epsilon_{\text{SF}} \frac{(\mathcal{M}/100)^{-0.32}}{\tau_{\text{ff}}(\bar{n})}, \quad (11)$$

$$f_{\text{dense}} = \frac{1}{2} \left[1 + \operatorname{erf} \left(\frac{\sigma_{\text{PDF}}^2 - \log(n_{\text{dense}}/\bar{n})}{2^{3/2}\sigma_{\text{PDF}}} \right) \right], \quad (12)$$

$$\sigma_{\text{PDF}}^2 \approx \log \left(1 + \frac{3\mathcal{M}^2}{4} \right). \quad (13)$$

Here, τ_{ff} is the free-fall timescale evaluated at the average volume density (\bar{n}), which is proportional to $1/\sqrt{\bar{n}}$; ϵ_{SF} is an efficiency parameter of the order of $\sim 1.4\%$ that depends on the virial state of the clouds; σ_{PDF} is the width of the lognormal probability distribution function of gas density within a cloud, determined by the Mach number (\mathcal{M}).

The KMK05 model has two key features. First, unlike a simple threshold model, whole cloud models predict both f_{dense} and SFE_{mol} , and by extension SFE_{dense} . Although these models have more free parameters, they also attempt to explain more of the star formation process; by contrast, the density threshold models push the topic of regulating star formation into the formation of dense gas, which they do not address. Second, the KMK05 model has two different mechanisms to alter f_{dense} : the fraction of dense gas increases along with both the average density, \bar{n} , and the turbulent Mach number, \mathcal{M} . The latter dependence occurs because a higher Mach number broadens the density PDF (Eq. 13). Consequently, for a fixed average density, it also increases the mass of gas with densities above the cutoff for the HCN-traced gas, n_{dense} (this happens as long as $n_{\text{dense}} > \bar{n}$, which is always expected for plausible conditions; see Sect. 2.2). In the KMK05 model, the variations in \bar{n} and \mathcal{M} affect the star formation efficiencies in different ways, however:

- If \bar{n} increases, τ_{ff} decreases, enhancing SFE_{mol} . In contrast, the product $f_{\text{dense}} \times \tau_{\text{ff}}$ changes little across a plausible range in \bar{n} , which would render SFE_{dense} almost constant.
- If \mathcal{M} increases, f_{dense} increases, while SFE_{mol} would moderately decrease. Combining these, SFE_{dense} would experience a more significant drop (due to the additional $1/f_{\text{dense}}$ factor).

Based on this model, KT07 (see also Sect. 7) posit that an increase by 2-3 orders of magnitude in \bar{n} along the IR sequence of galaxies could mostly explain the different power-law indices for the IR-CO(1–0) and IR-HCN(1–0) relations in galaxies. While a high Mach number in (U)LIRGs compared to normal SF galaxies could also come into play, KT07 argue that this parameter would likely play a secondary role.

5.2.2. Results

Because we do not know the detailed structure of molecular clouds within our beams, the agreement between our data and Equations 11-13 depends on some assumptions about four parameters that are not strongly constrained *a priori*: the CO and HCN conversion factors, the density cutoff for HCN emission (n_{dense}), and ϵ_{SF} . To match the region of $SFE_{\text{mol}}-SFE_{\text{dense}}-f_{\text{dense}}$ parameter space spanned by our observations, we set n_{dense} to $2.8 \times 10^5 \text{ cm}^{-3}$, as assumed by KT07, but adopt a ϵ_{SF} efficiency parameter that is 1/5 times the value preferred by them. The same mismatch in ϵ_{SF} was noted by GB12.

²⁰ Code available at <http://www.uchicago.edu/~krumholz/codes/>

²¹ Note that this feature is not shared by some other models, in which higher Mach numbers tend to drive higher rates of star formation rates; see Federrath & Klessen (2012).

Figure 3. Comparison between the $SFE_{\text{mol}}-f_{\text{dense}}$ (left-hand panel) and $SFE_{\text{dense}}-f_{\text{dense}}$ (right-hand panel) relations in our data and in the KMK05 model. The top and right-hand axes of each panel display the data in terms of observed quantities. For the data, symbols are the same as in Fig. 1. The power-law fit equation (gray line) is shown in the top-right corner. The model predictions are represented by colored lines. To obtain the purple curves, labelled by the assumed M in the left-hand panel, we fix the Mach number and vary the average gas density. To obtain the orange lines, labelled by the assumed \bar{n} in the right-hand panel, we fix the average density and vary the Mach number.

Figure 3 displays our data in the $SFE_{\text{mol}}-f_{\text{dense}}$ (left) and $SFE_{\text{dense}}-f_{\text{dense}}$ (right) planes, with power-law fits shown as grey lines. We overlay the curves predicted for realistic conditions when we vary either \bar{n} (fixed $M = 25, 50,$ and 100 , from top to bottom; purple) or M (fixed $\bar{n} = 10, 10^2, 10^3,$ and 10^4 cm^{-3} , from left to right; orange). Thus the purple and orange grid shows a plausible parameter space from the KMK05 overlaid on our observations.

Figure 3 shows that our data are better described by the orange tracks obtained by varying the Mach number (M) while holding the average density constant at $\approx 100 \text{ cm}^{-3}$. The mismatch between our data and the curves for constant M (purple) is particularly apparent in the right-hand panel, which shows that the spread in SFE_{dense} that we measure is hard to reproduce only by varying the average density of otherwise identical clouds. As a simple way to quantify this (dis)agreement, we fitted the data in each panel with curves predicted by the KMK05 model, fixing either \bar{n} or M while leaving the other parameter free. In the $SFE_{\text{dense}}-f_{\text{dense}}$ space, the best-fit curve for fixed M has a four times higher reduced- χ^2 than the best-fit curve for fixed \bar{n} (in the $SFE_{\text{mol}}-f_{\text{dense}}$ plane the fits have more comparable quality).

Thus a simple comparison to the whole-cloud models of KMK05 shows that, with reasonable inputs (and after adjusting the ϵ_{SF} parameter), the models span a range of $SFE_{\text{mol}}-SFE_{\text{dense}}-f_{\text{dense}}$ parameter space that can match our data well. For the specific functional forms of the KMK05 models, our data are well fit by an implementation of the models in which clouds are significantly more turbulent, but not much denser, near the galaxy centers than in the disks. If this were the case, the trends that we find across galaxy disks would be different from those between SF galaxies and (U)LIRG, which appear to be chiefly driven by an enhancement in \bar{n} (see Sect. 7). However, we caution that the specific numerical dependencies of the KMK05 model do differ from other, more re-

cent, analytic models, including those that otherwise adopt the KMK05 approach but treat the free fall time on multiple scales. Broadly, the wider parameter space spanned by whole cloud models can accommodate our data in a way that a simple threshold cannot.

6. THE EFFECT OF CONVERSION FACTORS

So far, we have assumed fixed, Milky Way-like conversion factors for CO and HCN. Under this assumption, our data strongly favored whole-cloud models over a universal density threshold. An alternative hypothesis would be that the changing physical conditions within our clouds mainly change the conversion between CO and total molecular gas mass or HCN and dense molecular gas mass. Though an exhaustive study of the conversion factor is well beyond the scope of this paper, here we test a suite of plausible conversion factor variations and investigate how they could alter the simple picture discussed above. Specifically, we build a grid of plausible conversion factors for CO and HCN and, at every point of the grid, we check whether our data, combined with these conversion factors, exhibit basic agreement with either of our two models.

6.1. Background

Significant deviations in α_{CO} from its Milky Way value have been predicted and observed in galaxies, both at global and smaller scales (see the review by Bolatto et al. 2013). Broadly, α_{CO} appears to exhibit two main behaviors. First, α_{CO} seems to increase with decreasing metallicity (or dust-to-gas ratio), as CO emission becomes confined to a smaller fraction of a molecular cloud. Second, α_{CO} tends to drop in extreme star forming environments (e.g., galaxy centers, (U)LIRGs, and starbursts) where the gas is more turbulent and more excited. Bolatto et al. (2013) suggested that this second trend could be usefully parameterized as a decrease in α_{CO}

with increasing total mass surface density ($\Sigma_{\text{tot}} = \Sigma_{\text{star}} + \Sigma_{\text{gas}}$), although Σ_{tot} may not be its ultimate physical driver.

Compared with α_{CO} , the HCN conversion factor, α_{HCN} , has been much more poorly characterized. There are, however, practical reasons to expect that the two conversion factors follow each other to some extent. First, α_{HCN} must be lower in some (U)LIRGs than in SF galaxies to ensure that $f_{\text{dense}} < 1$. More physically, if α_{HCN} emerges from a turbulent, opaque medium — even if it makes up only a portion of a typical cloud — we expect similar dependences on the degree of turbulence and excitation. Second, the density above which the HCN(1–0) line is effectively emitted could vary as certain cloud properties change (e.g., average density, temperature, turbulent velocity gradient). This would also make α_{HCN} , that converts the line luminosity into gas mass above a fixed density cutoff, vary (Sect. 2.2).

We adopt a simple, *ad hoc* approach to gauge the interplay of conversion factors, models of star formation, and our observations. To do so, we simply assume that, to some very coarse approximation, both α_{CO} and α_{HCN} may vary as some power law function of Σ_{star} , that is:

$$\alpha_{\text{HCN}}(\Sigma_{\text{star}}, \gamma_{\text{HCN}}) = \alpha_{\text{HCN}}^0 \left(\frac{\Sigma_{\text{star}}}{100 M_{\odot} \text{ pc}^{-2}} \right)^{\gamma_{\text{HCN}}}, \quad (14)$$

$$\alpha_{\text{CO}}(\Sigma_{\text{star}}, \gamma_{\text{CO}}) = \alpha_{\text{CO}}^0 \left(\frac{\Sigma_{\text{star}}}{100 M_{\odot} \text{ pc}^{-2}} \right)^{\gamma_{\text{CO}}}. \quad (15)$$

Here, the prefactors are set to the default Galaxy-like HCN and CO conversion factors defined in Sect. 2.2. Equations 14 and 15 are reminiscent of the empirical law proposed by Bolatto et al. (2013) to match a set of α_{CO} values culled from the literature, including those estimated by Sandstrom et al. (2013) across the disks of HERACLES galaxies. Bolatto et al. (2013) specifically proposed $\gamma_{\text{CO}} = -0.5$ above a total mass surface density of $100 M_{\odot} \text{ pc}^{-2}$ in addition to an exponential metallicity dependent term. We neglect the metallicity term because our survey focuses heavily on the metal-rich parts of the HERACLES sample (we checked that this term would hardly affect our results if included). We approximate $\Sigma_{\text{tot}} \sim \Sigma_{\text{star}}$ because, in our sample, the total surface density is almost always dominated by Σ_{star} (usually by a factor of $\gtrsim 3$). Finally, we have formally dropped the Σ_{tot} threshold advocated by Bolatto et al. (2013) because essentially all of our detections have Σ_{star} above this value (see Figure 2).

We emphasize that Equations 14 and 15 represent a coarse approach to the variability of conversion factors. The detailed study of HERACLES galaxies by Sandstrom et al. (2013) suggests that α_{CO} in an individual galaxy can be better described by a flat profile over most of the disk and an abrupt drop near its center and we do not expect disk surface density to be the only (or even main) physical driver of conversion factor variations. Nevertheless, power laws offer a useful tool for the kind of exploratory calculations that we carry out in this section. These are already highly approximate due to the lack of observational and theoretical constraints on α_{HCN} and a power law formalism allows us to treat α_{HCN} and α_{CO} in a similar way with only a minimal set of free parameters (γ_{CO} and γ_{HCN}). Moreover, we are specifically interested in how conversion factor variations could “rescue” a density threshold model. Fig. 2 shows that, at least in the specific case of our set of pointings, α_{HCN} should roughly behave as a power-law function of Σ_{star} in order to cancel the systematic gradients in IR-to-HCN that we observe.

We can consider a grid of plausible γ_{CO} and γ_{HCN} , with “plausible” defined according to the following rules:

- i) Most evidence in the literature point to lower conversion factors in regions of higher surface density (galaxy centers and (U)LIRGs), so we assume $\gamma_{\text{CO}} \leq 0$.
- ii) We expect the fraction of gas in the molecular phase, traced by $\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$, to increase with the depth of the gravitational potential well, traced by Σ_{star} . We find that we require $\gamma_{\text{CO}} > -0.82$ to ensure that this ratio and Σ_{star} are positively and significantly correlated and we consider only values above this value.
- iii) We expect that f_{dense} increases along with the HCN/CO line ratio. We find this happens when $\gamma_{\text{HCN}} - \gamma_{\text{CO}} > -0.42$. That is, the $\alpha_{\text{HCN}}/\alpha_{\text{CO}}$ ratio cannot be so low at galaxy centers that we actually have *lower* dense gas fractions for higher HCN/CO ratios.
- iv) We require that less than 5% of our positions have a nominal $f_{\text{dense}} > 1$, which is unphysical (even widespread $f_{\text{dense}} \sim 1$ is implausible). For this, we find that the condition $\gamma_{\text{HCN}} - \gamma_{\text{CO}} < 0.58$ is necessary. That is, the $\alpha_{\text{HCN}}/\alpha_{\text{CO}}$ ratio cannot be so high at galaxy centers that all of the molecular gas is in the dense phase.

The four conditions stated above define a rectangular region in the $(\gamma_{\text{CO}}, \gamma_{\text{HCN}} - \gamma_{\text{CO}})$ plane that encapsulates plausible variations in the CO and HCN conversion factors. The changes in γ_{CO} and γ_{HCN} will modify the mutual relations between f_{dense} , SFE_{mol} , and SFE_{dense} inferred from our observations. Thus, exploring this parameter space, we study the compatibility between our observations and models as a function of possible conversion factor variations. In this analysis, we keep α_{CO}^0 and α_{HCN}^0 in Equations 14 and 15 fixed. Any change in these parameters would globally shift the data points, which is irrelevant for the comparison between observed and predicted trends that we carry out below.

6.2. Density Threshold Models

The key assumption of the simple density-threshold hypothesis supported by, e.g., Gao & Solomon (2004b) and Wu et al. (2005) is that SFE_{dense} is fixed within the scatter. In Figure 4, the orange-colored area within the thick black contour is the region of the $(\gamma_{\text{CO}}, \gamma_{\text{HCN}} - \gamma_{\text{CO}})$ parameter space where this could be fulfilled: inside it, SFE_{dense} (derived from our data and the conversion factors at each point) would not significantly correlate with Σ_{star} , nor with $\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$. Essentially, this region stretches along the straight lines for which $-0.55 \lesssim \gamma_{\text{HCN}} \lesssim -0.35$, which is the α_{HCN} required to cancel out the gradients in SFE_{dense} found in Sect. 4. We remark that, to cancel these gradients, α_{HCN} should roughly behave as such a power law when restricted to our sample of pointings, regardless its true functional form.

In more detail, the region without systematic variations in SFE_{dense} consists of three different sections where the threshold model has a decreasing predictive power for our sample of pointings. In the first section, labeled “A” in the figure, SFE_{mol} and f_{dense} are mutually correlated and show systematic variations with respect to either $\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$ or Σ_{star} . Thus, *a priori*, systematic increases in SFE_{mol} could be ascribed to increases in f_{dense} , as expected for a threshold model. Section “A” corresponds to values of $-0.7 \lesssim \gamma_{\text{CO}} \lesssim -0.3$, i.e., compatible with the $\gamma_{\text{CO}} = -0.5$ value in Bolatto et al. (2013),

Figure 4. Compatibility between our data and the density-threshold models across the $(\gamma_{CO}, \gamma_{HCN} - \gamma_{CO})$ region defined by our boundary conditions (see text; we only represent $\gamma_{HCN} - \gamma_{CO} < 0.35$ to keep the plotting box square). Within the orange area, the observations and the density-threshold model are compatible (SFE_{dense} is neither significantly correlated with Σ_{star} nor with $\Sigma_{mol}/\Sigma_{atom}$; see text for details). The purple contours enclose the regime there are systematic variations in either SFE_{mol} and f_{dense} , but both variables are either anticorrelated or not significantly correlated at all. The purple crosses indicate the intersection between this regime and the region where SFE_{dense} shows no systematic variations. This defines section “C”, while sections “A” and “B” are located at either side of it.

and to variations in α_{HCN} that are largely in lockstep with those in α_{CO} ($|\gamma_{HCN} - \gamma_{CO}| \lesssim 0.2$), perhaps in response to the same physical mechanisms. The significant correlation between f_{dense} and SFE_{mol} arises because the Σ_{star} dependent term in α_{HCN} flattens SFE_{dense} , whereas the steep trend in f_{dense} is barely affected as variations in α_{HCN} and α_{CO} cancel each other out.

In a second section, labeled “B”, the systematic gradients in f_{dense} , SFE_{dense} , and SFE_{mol} across galaxy disks all cancel out. This leaves the density threshold theory plausible, but essentially unprobed within the scatter of our data. Section “B” corresponds to only weak variations in α_{CO} across galaxy disks, but much stronger gradients in α_{HCN} . Essentially, α_{HCN} varies in such a way that it cancels the observed variations in the IR-to-HCN and HCN-to-CO ratios, whereas the trend in the IR-to-CO ratio remains unchanged.

Finally, there is a third region, labelled “C”, where there are systematic variations in either SFE_{mol} and f_{dense} , but both variables are either anticorrelated or not significantly correlated at all. In this case, f_{dense} could not be considered a major driver of SFE_{mol} , which would rather be regulated by an hypothetical *hidden* variable. Therefore, even though SFE_{dense} would remain constant, the density threshold model would not be not predictive of SFE_{mol} .

6.3. The Turbulence-Regulated Model

To illustrate the impact of changing γ_{HCN} and γ_{CO} on the KMK05 model, we consider two extreme cases: one in which we keep \bar{n} fixed while varying M and one in which we fix M and vary \bar{n} (see Sect. 5.2.1 and Fig. 3 for an illustration

of such models). Of course, in a real system both quantities may vary and, as discussed above, the KMK05 model represents only one implementation of a turbulence-regulated whole-cloud model. The essential features of the models, which our data should reproduce to be compatible with the theory in a region of $(\gamma_{CO}, \gamma_{HCN} - \gamma_{CO})$ space, are:

- For the fixed M case, both f_{dense} and SFE_{mol} should increase when \bar{n} increases; that is, we require a significant positive correlation between f_{dense} and SFE_{mol} .
- For the fixed \bar{n} case, as Figure 3 shows, f_{dense} increases when M increases, whereas SFE_{mol} decreases more mildly; as a result, we expect either an anticorrelation between f_{dense} and SFE_{mol} , or even no significant correlation given the observational uncertainties.

We implement these qualitative behaviors as requirements on the p-value of the rank correlation coefficient between f_{dense} and SFE_{mol} and show the valid regions in $(\gamma_{CO}, \gamma_{HCN} - \gamma_{CO})$ space in Fig. 5. Fig. 5 shows that almost all of the plausible $(\gamma_{CO}, \gamma_{HCN})$ parameter space can be covered by some variant of the turbulence-regulated model. Under the assumption of fixed \bar{n} (left-hand panel), our observations agree with this theory when $\gamma_{CO} \gtrsim -0.2$ or $\gamma_{HCN} - \gamma_{CO} \lesssim -0.2$. This includes the case of fixed conversion factors ($\gamma_{CO} = \gamma_{HCN} = 0$) adopted throughout the first part of the paper. If M remains fixed while \bar{n} varies (right-hand panel), observations and models agree within the complementary region, but also in a small patch at $\gamma_{CO} \simeq 0$ and $\gamma_{HCN} - \gamma_{CO} \simeq -0.4$. This is the patch where the CO and HCN conversion factors conspire to eliminate all gradients (f_{dense} , SFE_{mol} , and SFE_{dense}) from our sample. Of course, inasmuch as this conspiracy yields a homogenous population of star-forming clouds throughout the sample, our observations could be compatible with any cloud-scale star formation theory.

6.4. Conclusions

Our exploration of plausible α_{CO} and α_{HCN} shows that compatibility with a simple density-threshold model of star formation places specific, non-trivial requirements on the behavior of the CO and HCN conversion factors. Essentially, α_{HCN} must vary in a way that cancels out the observed variation in the IR-to-HCN ratio and its value must be fairly tightly coupled to α_{CO} . By contrast, the turbulence-regulated whole cloud model of KMK05 can be compatible with almost any region of α_{CO} - α_{HCN} space that we explore. To some degree, this reflects the larger suite of free parameters in the whole cloud models, but this does not entirely invalidate the contrast: it may very well be that more physics, and so more free parameters, are needed to explain the observations.

7. DISCUSSION

We interpret our results to offer a challenge to simple density threshold models, though not to conclusively rule them out. Whole-cloud models like KMK05 have more success explaining our observations because they can span a wider part of SFE_{mol} - f_{dense} - SFE_{dense} space. We discuss shortly the implications of combining each of these models with our data and the unresolved observations from GB12.

7.1. Implications for Density Threshold Models

Density-threshold models found support in the remarkable linear IR-HCN(1–0) relation found by Gao & Solomon

Figure 5. Compatibility between our data and the KMK05 model for variation in the Mach number (left-hand panel) and in the average density (right-hand panel). Each panel covers the $(\gamma_{\text{CO}}, \gamma_{\text{HCN}} - \gamma_{\text{CO}})$ region defined by our boundary conditions. The orange area indicates the $(\gamma_{\text{CO}}, \gamma_{\text{HCN}} - \gamma_{\text{CO}})$ values for which observations and theory are compatible (see text for details).

(2004a) and Wu et al. (2005), which encompassed systems covering $\sim 7 - 8$ dex in L_{TIR} . This correlation represents almost the only extragalactic observational support for such a model. In plots that span such an enormous range in luminosity, our data do broadly “fill in” the previously missing part of this correlation. However, in detail our data also exhibit clear, systematic variations in the IR-to-HCN luminosity ratio. That is, luminosity-luminosity plots or power law fits spanning many decades would miss significant, systematic environmental trends that appear as “scatter” around the luminosity-luminosity scaling. We suspect that along with intrinsic cloud-cloud scatter (Ma et al. 2013) and observational uncertainties, the wide range in measured SFR/L_{HCN} ratios (> 2 dex and ~ 1.4 dex in Galactic cores and galaxy averages, respectively; Wu et al. 2005, GB12) may be driven by the same systematic variations that we see in this survey.

Other studies have highlighted variable SFE_{dense} : recent studies at whole-galaxy scales have pointed out that the average SFE_{dense} of (U)LIRGs is at least 3-4 times higher than that of SF galaxies (GB12, see also Gao et al. 2007), unlike what Gao & Solomon (2004a) concluded. Our own fit to the GB12 data implies that the average SFE_{dense} would increase as $L_{\text{TIR}}^{0.27 \pm 0.04}$. Moreover, studying the center of our own Milky Way galaxy using ammonia lines, Longmore et al. (2013) demonstrated this high surface density region of a normal disk galaxy to show a systematically low SFE_{dense} , the same sense of the trend (SFE_{dense} anticorrelates with Σ_{star}) that we observe in this paper.

For a fixed HCN-to-dense gas conversion factor, these results are clearly at odds with the assumption of a fixed SFE_{dense} that underlies threshold models. We show that our resolved observations could be compatible with a fixed (within the scatter) SFE_{dense} if α_{CO} and α_{HCN} varied in some plausible way. However, we emphasize that doing so would remove the major extragalactic argument for a simple density

threshold: the simple correlation of HCN and IR luminosity. Moreover, an *ad hoc* tuning of α_{HCN} cannot address the higher apparent SFE_{dense} in (U)LIRGs, since the basic expectation is that their α_{HCN} should be lower than that of SF galaxies. Applying such a correction would exacerbate, rather than alleviate, the difference in SFE_{dense} between both kinds of galaxies (for details, see GB12); but see Papadopoulos et al. (2012) for an alternative discussion of conversion factors in (U)LIRGs.

7.2. Turbulence-Regulated Models and a Simple Observational View

Whole cloud, turbulence-regulated models can produce a wide range of points in the $SFE_{\text{mol}} - f_{\text{dense}} - SFE_{\text{dense}}$ space. The specific model of KMK05 therefore appears able to reproduce our data for almost all assumptions about conversion factors, though recall that, as in GB12, we had to rescale the absolute scale of the star formation rate in the model (i.e., the efficiency parameter ϵ_{SF}). We saw that, for the case of fixed conversion factors, our data agree particularly well with an implementation of the KMK05 model in which the average cloud density remains approximately fixed while the turbulent Mach number increases with increasing stellar surface density.

This primary dependence on the Mach number may seem at odds with the normal explanation for increased SFE_{mol} in galaxy centers, which would attribute the contrast between galaxy disks and (U)LIRGs mainly to gas density. We address this in Fig. 6, where we combine our data with the GB12 data in the mostly observational spaces $\Sigma_{\text{SFR}}/I_{\text{CO}}$ vs. $I_{\text{HCN10}}/I_{\text{CO}}$ (left-hand panel) and $\Sigma_{\text{SFR}}/I_{\text{HCN10}}$ vs. $I_{\text{HCN10}}/I_{\text{CO}}$ (right-hand panel), where Σ_{SFR} is estimated linearly from the IR. This figure encapsulates our best current observational understanding of HCN, CO, and star formation in galaxies. In both panels, the combined data sets span a contiguous region of the param-

Figure 6. Comparison between observations and the KMK05 model: $\Sigma_{\text{SFR}}/I_{\text{CO}}$ (left-hand panel) and $\Sigma_{\text{SFR}}/I_{\text{HCN}10}$ (right-hand panel) as functions of $I_{\text{HCN}10}/I_{\text{CO}}$ in our data and the GB12 extragalactic sample (note that intensity and luminosity ratios are formally identical, which allows us to include in this figure those galaxies of the GB12 sample that lack an estimate of the molecular disk area). Symbols as in Fig. 1. For the sake of visualization, limits are not displayed. The purple lines correspond to lines of constant Mach number $\mathcal{M} = 25, 50$ and 100 , as indicated by the labels of the same color. They are obtained by increasing the average gas density (\bar{n}) from 10 cm^{-3} to 10^5 cm^{-3} in steps of 0.5 dex. The gray lines correspond to constant \bar{n} conditions, as indicated by the brown labels (for clarity, only one in two lines is labeled). The space between them is colored in green-orange-red hues, with reddish ones corresponding to higher densities. To convert (dense) gas masses into line luminosities, we assume the default HCN and CO conversion factors of this paper. The gray area in the background indicates the range of observables that can be reproduced by the KT07 model, where non-fixed HCN and CO conversion factors are derived from a simple radiative transfer code coupled to the KMK05 cloud model. The upper and lower envelopes of this area correspond to the *normal* and *starburst* set of parameters defined by KT07. They assume Mach numbers of 30 and 80 , respectively.

eter space²². Remarkably, there is no obvious separation between (U)LIRGs and SF galaxies (i.e., no hint of bimodality), unlike what Fig. 1 suggested. Fig. 6 shows that, for SF galaxies in both our sample and GB12, there is no strong correlation between $\Sigma_{\text{SFR}}/I_{\text{HCN}10}$ and $I_{\text{HCN}10}/I_{\text{CO}}$ (right-hand panel). Such a correlation exists, but only in the contrast between SF galaxies and (U)LIRGs and more weakly within the (U)LIRG sample. At the same time, both sets of SF galaxies (ours and GB12) show a wide range in $\Sigma_{\text{SFR}}/I_{\text{HCN}10}$, including an anticorrelation with $I_{\text{HCN}10}/I_{\text{CO}}$ that becomes much clearer and unambiguous when we consider the Σ_{star} as the independent variable in our own sample.

Colored regions in the background compare all data to the predictions of the KMK05 model. These are the same shown in Fig. 3, except that predicted surface densities of (dense) molecular are converted to line intensities via our default fixed conversion factors. The regions with constant \bar{n} are colored from green to red, with red hues indicating higher densities, for the sake of visualization.

In the $I_{\text{HCN}10}/I_{\text{CO}}$ vs. $\Sigma_{\text{SFR}}/I_{\text{CO}}$ plot (left-hand panel), the collection of data from SF disks through (U)LIRGs tend to follow the purple lines (constant Mach number), with most but not all of them spreading between $\mathcal{M} = 25$ and $\mathcal{M} = 100$. Therefore, as we move from SF galaxies to (U)LIRGs, $I_{\text{HCN}10}/I_{\text{CO}}$ and $\Sigma_{\text{SFR}}/I_{\text{CO}}$ would mostly increase because \bar{n} changes from 100 cm^{-3} (solid line near the bottom-left cor-

ner) to $\sim 10^4 \text{ cm}^{-3}$. In this plot, changes in \mathcal{M} would be secondary and would mostly introduce scatter around the main trend.

The $I_{\text{HCN}10}/I_{\text{CO}}$ vs. $\Sigma_{\text{SFR}}/I_{\text{HCN}10}$ plot in right-hand panel provides us with a complementary view. Here, the most relevant trend comes from considering only our resolved observations of SF disks (gray dots), which spread out roughly along lines of fixed \bar{n} , mostly between $\bar{n} = 10^{1.5} \text{ cm}^{-3}$ and $\bar{n} = 10^{2.5} \text{ cm}^{-3}$ (green-yellowish areas). Therefore, as we move across galaxy disks towards their centers, $I_{\text{HCN}10}/I_{\text{CO}}$ would increase and $\Sigma_{\text{SFR}}/I_{\text{HCN}10}$ would decrease mostly because \mathcal{M} increases from 25 to > 50 . Changes in \bar{n} would play a secondary role here. A less prominent but significant trend is found when SF galaxies and (U)LIRGs are globally compared. In this case, the average difference in SFE_{dense} between the two families would mostly stem from a difference in the Mach number.

Thus the KMK05 model provides a qualitative picture that can reasonably account for the observations. We caution that the quantitative details of this picture are far from settled, however. Firstly, we had to rescale their model to produce the comparison grids, and the exact numbers remain imperfect matches to typical average cloud properties: e.g., typical Milky Way clouds have $\mathcal{M} \approx 10$ and a volume averaged density $\bar{n} \sim 100 \text{ cm}^{-3}$ (e.g., Heyer et al. 2009), not perfect matches to the models. Secondly, a significant fraction of data points lie outside the generous $25 - 100$ range in Mach numbers that we have assumed to generate the comparison grids. Finally, the model requires the clouds to be less turbulent in (U)LIRGs than in SF galaxies, which is not the sense seen in observations. Still the sense of the trends seems reason-

²² The only outlier is APM 08279+5255, a luminous BAL quasar at redshift $z \approx 3.9$ with an exceptionally high $L_{\text{HCN}}/L_{\text{CO}}$ ratio. Multitransition studies of this source has shown that its HCN excitation is driven by IR pumping to a significant extent (Weiß et al. 2007), in which case the line luminosity is not a reliable tracer of gas mass.

able: several studies suggest that clouds in galaxy centers are denser but also more turbulent than those in the galactic disks (e.g., Oka et al. 2001; Rosolowsky & Blitz 2005; Leroy et al., submitted).

These inconsistencies between the KMK05 model and the extragalactic data might stem from our crude assumption of fixed CO and HCN conversion factors for all data points. They might be partly alleviated by solving the radiative transfer independently in each pointing/source to calculate more accurate conversion factors. To illustrate this, we plot in Fig. 6 as a grey background the predictions from the KT07 model, which combines the KMK05 model with a basic radiative transfer model. The gray area is limited by two sets of cloud conditions defined by KT07: one tries to reproduce typical conditions in SF galaxies, and assumes, in particular, $\mathcal{M} = 30$ (upper envelope); the second represents conditions in starburst galaxies, and assumes $\mathcal{M} = 80$ (lower envelope). In both cases the average gas density (\bar{n}) is left as the only free parameter. We globally shifted the predictions in the vertical direction to better match the data clouds. The most apparent result is that, once the radiative transfer is taken into account, the model can explain the observed range in $\Sigma_{\text{SFR}}/I_{\text{CO}}$ and $\Sigma_{\text{SFR}}/I_{\text{HCN}10}$ ratios with a narrower range of Mach numbers (30–80).

In spite of this relative improvement, the KT07 model neither reproduces the data to a satisfactory extent, though. E.g., it still requires a too broad range of Mach numbers and it predicts clouds in (U)LIRGs to be less turbulent than those in SF galaxies. These two flaws might stem from the simplifications in the radiative transfer code used by KT07 (see the paper for details). They may also be solved by combining radiative transfer models with the more recent turbulent models in Federrath & Klessen (2012) and following. In general, the assumption of virialized clouds with lognormal density PDF implicit in the KMK05 model does not necessarily hold in the disturbed ISM of many (U)LIRGs.

7.3. Simple Predictions and Logical Next Steps

The contrast of our data with both models indicates logical next steps. First, while the CO-to-H₂ conversion factor has received substantial attention, the conversion between HCN and the dense gas mass remains far more uncertain. Especially the dependence of this value on environment is very uncertain. We expect HCN (1–0) and similar high critical density, low excitation lines (e.g., HCO⁺ (1–0), CS (2–1), or HNC(1–0)) to be the most accessible tracers of dense gas in external galaxies for the foreseeable future. A quantitative understanding of how α_{HCN} and similar quantities depend on environment will be essential. New observations, e.g., of optically thin isotopologues over a wide range of environments, are clearly needed (e.g., Papadopoulos et al. 2012).

Along similar lines, the success of the “whole cloud” models hinges on the properties of individual turbulent molecular clouds. These properties, including average density and Mach number, can be measured and compared among environments. In the same way that knowing α_{HCN} will provide a rigorous constraint on threshold models, folding cloud properties into the comparison to whole-cloud models will vastly constrain the area of viable parameter space. A number of current mm-wave facilities are able to resolve individual clouds at the distances of many of our targets (e.g. Colombo et al. 2014).

8. SUMMARY

We have used the IRAM 30-m telescope to observe the HCN(1–0) line in 62 positions (48 detections) across the disks of 29 nearby galaxies also targeted by the HERACLES CO(2–1) survey. Combining these data with previous multiwavelength observations, we study the relations between the dense molecular gas traced by the HCN emission ($n \gtrsim 10^4 - 10^5 \text{ cm}^{-3}$), the bulk of the molecular gas (traced by the CO data), and the star formation rate (SFR; traced by infrared emission). We highlight that:

- Unlike most previous studies of HCN in galaxies, our observations span a wide range of galactocentric radii (from galaxy centers up to $\sim 80\%$ of the optical radius) at linear resolution (~ 1.5 kpc on average) that isolates local properties of a galaxy disk while still averaging over a large population of clouds. This allows us to probe a wide range in environmental parameters.
- We compare our data set to a compilation of unresolved observations of star-forming (SF) galaxies and (U)LIRGs (from GB12). Our resolved observations seamlessly expand the range of surface densities sampled by HCN studies of extreme systems to lower values. They also fill in an intermediate, so far largely unexplored, luminosity regime in the HCN-IR luminosity correlation found by Gao & Solomon (2004b); Wu et al. (2005).

We focus our analysis on three parameters: the dense gas fraction ($f_{\text{dense}} \propto \text{HCN}/\text{CO}$), the star formation rate per unit of dense molecular gas ($SFE_{\text{dense}} \propto \text{SFR}/\text{HCN}$) and the star formation rate per unit of molecular gas ($SFE_{\text{dense}} \propto \text{SFR}/\text{CO}$). The last two are often referred to as the “star formation efficiency” of the dense and total molecular gas. We study how these quantities relate to conditions in the disk. We focus on the molecular-to-atomic mass ratio ($\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$) and the stellar mass surface density (Σ_{star}) as useful indicators of the local conditions in the disk. Both quantities are highly covariate with galactocentric radius. We find that:

- For the simplest assumption of fixed luminosity-to-mass conversion factors for CO and HCN, we find that f_{dense} ($\propto \text{HCN}/\text{CO}$) tightly correlates with both $\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$ and Σ_{star} (Spearman’s rank coefficients 0.67 and 0.75). Across ~ 2.1 dex in both disk structure parameters, f_{dense} systematically varies by a factor of ~ 4 .
- In contrast, $SFE_{\text{dense}} \propto \text{IR}/\text{HCN}$ anti-correlates with $\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$ and Σ_{star} (rank coefficients -0.72 and -0.53), systematically decreasing by a factor of $\sim 6 - 8$ as we move from disk positions towards galaxy centers. The two trends cancel each other out, so that SFE_{mol} shows no systematic variation with either $\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$ nor with Σ_{star} . This implies that, to some degree, the apparent constancy of SFE_{mol} known from previous studies arises from a conspiracy, as the sub-resolution cloud populations must vary systematically to produce the changing HCN-to-IR and HCN-to-CO ratios.

We compare our results to two families of standard models of star formation in galaxies:

- First, we consider a simple density-threshold model, which, in its simplest version, assumes that the SFR is proportional only to the mass of dense gas above a

certain density threshold traced by the HCN emission (thus, a fixed SFE_{dense}). Such studies have been motivated by local studies of Galactic clouds and the apparent linear correlation of HCN and IR across many decades in luminosity. Such a model is clearly at immediate odds with the apparent systematic variation in SFE_{dense} across galaxy disks. Further, it predicts a strong, direct dependence of SFE_{mol} on f_{dense} that our data do not immediately show. For fixed conversion factors, our data do not appear compatible with a simple threshold model and contradict one of the main observational pieces of evidence used to argue for such data.

- In order for our observations to agree with a simple density threshold model, the HCN-to-dense gas mass conversion factor, α_{HCN} , must vary in such a way as to cancel out the observed variations in the HCN-to-IR ratio. We explore the topic more quantitatively and show that only a very restricted range of possible combinations of CO and HCN conversion factors can satisfy such a model.
- We contrast the density threshold model with “whole cloud models,” focusing on the theory of turbulence-regulated star formation formulated by KMK05 as an example (see also KT07 and, for a wider view of such models, Federrath & Klessen 2012). In the KMK05 model, SFE_{mol} increases with the average density of the molecular gas (\bar{n}), whereas it is inhibited to some degree by increased turbulence (high Mach number, \mathcal{M}). Meanwhile, f_{dense} increases with both \bar{n} and \mathcal{M} . We find that, for fixed conversion factors, the KMK05 model can reproduce our data well, provided that the increase in f_{dense} towards galaxy centers is driven by variations in \mathcal{M} rather than in \bar{n} . This good agreement exists for almost the full range of plausible conversion factors that we consider, reflecting the flexibility of the models.

We interpret these results to represent a challenge to simple density threshold models, though they do not rule them out. The simple correlation between IR and HCN luminosity spanning from starbursts to Galactic cores has represented an important piece of support for such models, our survey of galaxy disks shows that the main sites of star formation in the local universe do not obey such a simple relation (see also a dedicated study of M 51 by Bigiel et al, in prep.).

The appendices report more details of the observations and investigate the effects of varying how we trace the SFR and molecular gas on our conclusions, showing that they remain robust to substitution of CO transition or SFR tracer.

APPENDIX

A. ALTERNATIVE CO AND SFR TRACERS

A.1. Checking Σ_{mol}

By default in this paper, we assume a fixed CO(2–1)–to–CO(1–0) line ratio $R_{21} = 0.7$ to estimate Σ_{mol} directly from the intensity of the CO(2–1) line (Equation 3). There is evidence that R_{21} could systematically vary across galaxy disks to some extent, however (see Leroy et al. 2009 for the case of HERACLES galaxies; also references therein). In particular, R_{21} could be up to ~ 1.5 times higher near some galaxy centers, as the gas excitation tends to be more efficient. By neglecting these variations, we could be overestimating Σ_{mol} near galaxy centers. Thanks to our complementary observations of CO(1–0) (Sect. 2.1.1), available for most of the observed positions, we can confirm that the assumption of a fixed R_{21} has a minimal effect on our results. To do this, we derive an alternative Σ_{mol} after substituting $R_{21} = 0.7$ in Equation 2 with the line ratio derived from the CO(1–0) and CO(2–1) observations in each observed position. The CO(2–1) spectral cubes were previously convolved to the angular resolution of the CO(1–0) observations ($22''$) to account for aperture effects. This implicitly assumes that the R_{21} ratio is similar at $22''$ and $28''$ resolution.

Fig. A1 shows f_{dense} , SFE_{dense} and SFE_{mol} as a function of $\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$ when Σ_{mol} is derived from CO(1–0) (grey dots) and CO(2–1) (blue crosses). The plots where the variables are plotted against Σ_{star} are similar to these, so we do not show them here. In each panel, the cloud of blue crosses was slightly adjusted so that the two data clouds have the same median along both axes. This allows us to better compare the trends that we find for both CO transitions. It is apparent in Fig. A1 that those trends are nearly identical in each case. The fitted power laws are the same as those in Fig. 2 within the errors, although they tend to be slightly steeper when Σ_{mol} is derived from the CO(1-0) intensity (i.e., by $\lesssim 0.1$). This is consistent with a small increase in R_{21} towards the galaxy centers. Table A1 shows that the rank coefficients discussed in Sect. 4 are marginally sensitive to the chosen CO transition. The only noteworthy difference is that the correlation between SFE_{mol} and Σ_{star} is more significant for CO(1–0).

A.2. Checking Σ_{SFR}

Thanks to the our ample ancillary data set, we can confirm that the trends in SFE_{dense} and SFE_{mol} found in Sect. 4 are robust against the choice of the SFR tracer. To illustrate this, we obtained simple SFR estimates from the $H\alpha$ ($I_{H\alpha}$) and $24\ \mu\text{m}$ intensities, adopting the calibrations quoted by Kennicutt & Evans (2012). These were respectively determined by Murphy et al. (2011) and Rieke et al. (2009). In addition, we followed L12 to combine $H\alpha$ and $24\ \mu\text{m}$ data into a hybrid SFR estimate that takes into account the unobscured and obscured star formation they respectively trace:

$$\frac{\Sigma_{\text{SFR}}(\text{L12})}{M_{\odot} \text{ Myr}^{-1} \text{ pc}^{-2}} = 634 \frac{I_{H\alpha}}{\text{erg s}^{-1} \text{ sr}^{-1} \text{ cm}^{-2}} \cos(i) + 1.3 \frac{J_{24}^{\text{cirrus-corrected}}}{400 \text{ MJy sr}^{-1}} \cos(i). \quad (\text{A1})$$

In Equation A1, the measured $24\ \mu\text{m}$ intensity is corrected for the contribution from dust heated by pervasive radiation fields (“cirrus”) unrelated to recent star formation. The cirrus component is proportional to the mass surface density of dust and a certain emissivity. Both parameters are derived from the dust models mentioned in Sect. 2.2. A detailed comparison of different SFR tracers in the context of the HERACLES survey can be found in L12 and L13.

We plot in Fig. A2 the two star formation efficiencies against the molecular-to-atomic ratio, but now using the three alternative SFR tracers: the $24\ \mu\text{m}$ continuum (left-hand column), the hybrid L12 calibration (middle column), and the $H\alpha$ line (right-hand column). The plots against Σ_{star} , not shown here, are similar to these. For the sake of comparison, we represent the results for our default SFR tracer (TIR) by means of blue crosses. These data points have been vertically shifted in each panel so that their

Figure A1. f_{dense} (left-hand panel), SFE_{dense} (middle panel) and SFE_{mol} (right-hand panel) as a function of the molecular-to-atomic ratio. For grey dots, Σ_{mol} is derived from CO(1–0) data as indicated in the text. For blue crosses, it is derived from the HERACLES CO(2–1) spectra.

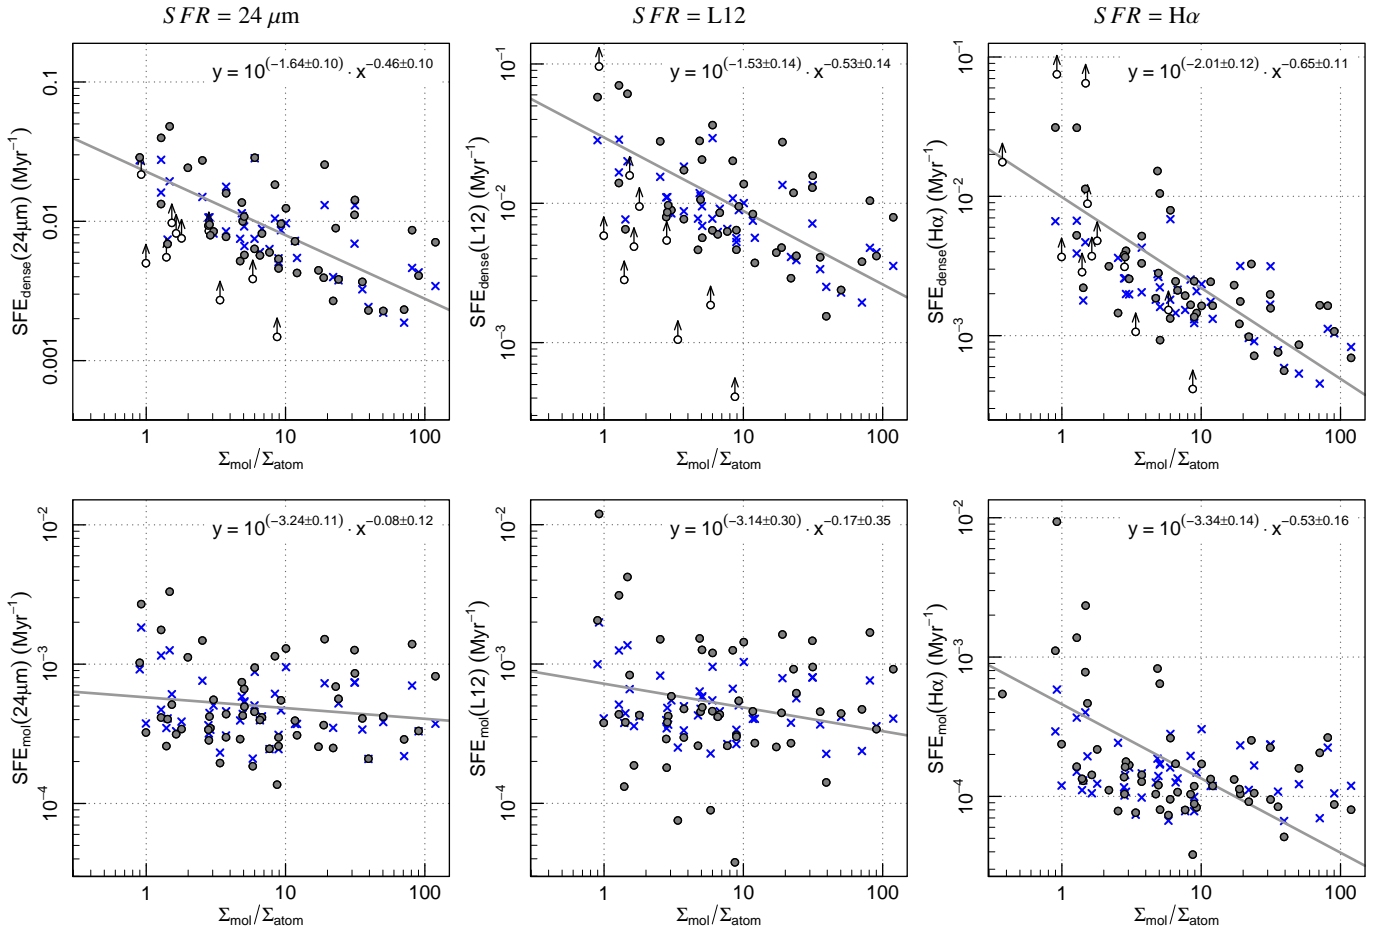

Figure A2. SFE_{dense} (top row) and SFE_{mol} (bottom row) as a function of the molecular-to-atomic ratio. From left to right, the SFR is derived from the $24\ \mu\text{m}$ emission, a linear combination of $24\ \mu\text{m}$ and $H\alpha$ intensities (L12), and the $H\alpha$ emission.

median Σ_{SFR} is the same as that of the grey dots. This allows us to focus on trends, letting aside the relative calibration between the different tracers.

The SFR calibrators have different levels of intrinsic scatter and are sensitive to different components of star formation. Some mild changes in the power-law fits can be expected, since the fraction of unobscured (i.e., $H\alpha$ -traced) star formation is known to increase towards fainter regions (L12). In spite of all this, blue crosses and grey dots show similar trends (e.g., as captured by the fitted power-law indices) in most cases. We find only two noteworthy features, in the $SFE_{\text{mol}}(\text{L12})$ and in the $SFE_{\text{mol}}(\text{H}\alpha)$ panels:

- A few data points increase the dispersion in $SFE_{\text{mol}}(\text{L12})$ at relatively low $\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$. On the one hand, there are three

Table A2
Rank coefficients for SFE_{dense} and SFE_{mol} as a function of local parameters, when different SFR tracers are used to estimate Σ_{SFR}

	TIR (default)		$24\mu\text{m}$		L12		$\text{H}\alpha$	
	SFE_{dense}	SFE_{mol}	SFE_{dense}	SFE_{mol}	SFE_{dense}	SFE_{mol}	SFE_{dense}	SFE_{mol}
r_{25}	0.43*	-0.07	0.36*	-0.05	0.35*	-0.13	0.68*	0.34*
$\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$	-0.72*	-0.22	-0.56*	-0.08	-0.51*	0.01	-0.72*	-0.43*
Σ_{star}	-0.53*	0.09	-0.41*	0.12	-0.37*	0.22	-0.58*	-0.20

positions whose $SFE_{\text{mol}}(\text{L12})$ is well below the mean. They have an abnormally high cirrus correction²³ in Equation A1 and their $\Sigma_{\text{SFR}}(\text{L12})$ is also the lowest in our sample, $\lesssim 2 \times 10^{-3} M_{\odot} \text{ Myr}^{-1} \text{ pc}^{-2}$. These SFR levels are similar to the $\lesssim 1 \times 10^{-3} M_{\odot} \text{ Myr}^{-1} \text{ pc}^{-2}$ threshold below which hybrid SFR estimators may become unreliable (L12). On the other hand, there are a few positions whose $SFE_{\text{mol}}(\text{L12})$ is well above the mean. They have some of the highest $\text{H}\alpha$ -to- $24 \mu\text{m}$ intensity ratios in our sample. We discuss them in the next point.

- The $\text{H}\alpha$ -bright positions mentioned above tilt the otherwise flat fit to $SFE_{\text{mol}}(\text{H}\alpha)$. Our sample does not include enough $\text{H}\alpha$ -bright positions to assess a possible difference in SFE_{mol} between the two SFR regimes dominated by obscured and unobscured star formation. In particular, the unobscured star formation only amounts to $\sim 5\% - 55\%$ (median 30%) of the total SFR(L12) in positions detected in HCN. In our case, pure IR and the L12 values likely provide more reliable estimates of the total SFR. Furthermore, in their thorough study of HERACLES galaxies L13 found that the environmental trends in the molecular depletion time (i.e., the inverse of SFE_{mol}) were not significantly sensitive to the chosen SFR tracer.

Something similar is found when paying attention to the rank coefficients between the star formation efficiencies and the ISM parameters, which are listed in Table A2. On the one hand, SFE_{dense} remains strongly and significantly correlated with $\Sigma_{\text{mol}}/\Sigma_{\text{atom}}$ and Σ_{star} in all cases. On the other hand, SFE_{mol} remains uncorrelated with the ISM parameters, except when $\text{H}\alpha$ is chosen as SFR tracer.

²³ Their cirrus emissivity is normal, but the $\Sigma_{\text{dust}}/I_{24\mu\text{m}}$ ratio is high.

B. DATA

We summarize here the results of our observations. Figs. B1–B4 show the location of the observed positions on the HERACLES CO(2–1) maps of the target galaxies. The HCN(1–0) and CO(1–0) final spectra are shown in Figs. B6–B19. The velocity-integrated intensities of the two lines are listed in Table B1.

NOTE. — Errors at 1σ -level are written within brackets. We give 4σ values for non-detections. We omit position 3 in NGC 4321, which was only observed in CO(1–0).

Figure B1. Map of the HERACLES CO(2–1) velocity-integrated intensity in NGC 0628, NGC 2146, NGC 2403, NGC 2798, NGC 2903, and NGC 2976 at $28''$ resolution. These illustrative maps were obtained by a crude integration over all velocity channels, so they might not be accurate at low levels. The contours correspond to 1%, 5%, 10%, 25%, 50%, 70%, and 90% of the maximum map value. The observed positions are indicated by numbers surrounded by $28''$ -wide circles. The solid and dashed ellipses correspond to R_{25} and 5 kpc galactocentric radii, respectively.
