34 Running header: Impact of bTB risk-based trading scheme  
35  
36

37 ABSTRACT

38

39 The adoption of bovine tuberculosis (bTB) risk-based trading (RBT) schemes has the  
40 potential to reduce the risk of bTB spread. However, any scheme will have cost  
41 implications that need to be balanced against its likely success in reducing bTB. This  
42 paper describes the first stochastic quantitative model assessing the impact of the  
43 implementation of a cattle risk-based trading scheme to inform policy makers and  
44 contribute to cost-benefit analyses. A risk assessment for England and Wales was  
45 developed to estimate the number of infected cattle traded using historic movement  
46 data recorded between July 2010 and June 2011. Three scenarios were implemented:  
47 cattle traded with no RBT scheme in place, voluntary provision of the score and a  
48 compulsory, statutory scheme applying a bTB risk score to each farm. For each  
49 scenario, changes in trade were estimated due to provision of the risk score to  
50 potential purchasers. An estimated mean of 3,981 bTB infected animals were sold to  
51 purchasers with no RBT scheme in place in one year, with 90% confidence the true  
52 value was between 2,775 and 5,288. This result is dependent on the estimated  
53 between herd prevalence used in the risk assessment which is uncertain. With the  
54 voluntary provision of the risk score by farmers, on average, 17% of movements were  
55 affected (purchaser did not wish to buy once the risk score was available), with a  
56 reduction of 23% in infected animals being purchased initially. The compulsory  
57 provision of the risk score in a statutory scheme resulted in an estimated mean change  
58 to 26% of movements, with a reduction of 37% in infected animals being purchased  
59 initially, increasing to a 53% reduction in infected movements from higher risk sellers  
60 (score 4 and 5). The estimated mean reduction in infected animals being purchased  
61 could be improved to 45% given a 10% reduction in risky purchase behaviour by

62 farmers which may be achieved through education programmes, or to an estimated  
63 mean of 49% if a rule was implemented preventing farmers from the purchase of  
64 animals of higher risk than their own herd.

65

66 Given voluntary trials currently taking place of a trading scheme, recommendations  
67 for future work include the monitoring of initial uptake and changes in the purchase  
68 patterns of farmers. Such data could be used to update the risk assessment to reduce  
69 uncertainty associated with model estimates.

70

71 Keywords: risk factors, risk-based trading, bovine tuberculosis, risk scores

72 **INTRODUCTION**

73

74 Bovine tuberculosis (bTB) is an infectious disease of cattle caused by the bacterium  
75 *Mycobacterium bovis* and is one of the biggest challenges facing the cattle farming  
76 industry in England and Wales. The cost of controlling bTB is the largest single  
77 component of animal health related expenditure in these countries paid by the tax  
78 payer, amounting to nearly £100 million in 2014 (Defra, 2014). The adoption of risk-  
79 based trading (RBT) has the potential to aid the management of livestock diseases by  
80 providing those participating within schemes more accurate information when  
81 purchasing animals (Defra, 2013a). However, the performance of such schemes in  
82 reducing the movement of infected cattle between farms is dependent on how well  
83 schemes are implemented and the specific rules established to permit or prevent trade.  
84 Risk scores can be implemented within assurance schemes or certification standards  
85 that are managed by industry organisations with a voluntary disclosure of the score, or  
86 assisted by government with statutory controls whereby disclosure is compulsory in  
87 order for the legal sale of cattle. Scheme rules can dictate whether or not certain  
88 batches are permitted to move between herds or zones of different risk scores, and  
89 whether a herd score is affected by the purchase of animals of a lower risk status.

90

91 Discussions were facilitated with representatives from the farming community  
92 (farmers, auctioneers, private veterinarians, government officials involved in  
93 monitoring facilities, and farmer association representatives) at seven meetings during  
94 2012-2013 in England and Wales to evaluate how informed cattle trading may vary  
95 within different schemes that could be adopted. Understanding the basis of the  
96 decisions made by farmers is crucial to the success of any functioning RBT scheme.

97

98 In order to parameterise the model, estimates on the expected level of RBT scheme  
99 participation by farmers with the voluntary provision of the risk score was discussed  
100 with stakeholders, alongside compliance levels that may be achieved within a  
101 statutory scheme based on the compulsory provision of the risk score prior to  
102 purchase. From 25 interested stakeholders (farmers, valuers, and representatives from  
103 non-government organisations) when asked whether cattle farmers would prefer a  
104 voluntary or statutory RBT scheme, 76% (19/25) expressed a preference for a  
105 voluntary provision of the risk score, with all Welsh respondents opting for an initial  
106 voluntary scheme. However, concerns were frequently raised that without a statutory  
107 scheme the system may not be effectively carried out and that there may be  
108 differences in its application in different regions. It was felt that for farmers in clean  
109 areas, or those that have not experienced a recent breakdown that a statutory system  
110 may be favoured. However, for those farms that had experienced a recent breakdown,  
111 several stakeholders expressed the view that such farmers would not want to  
112 participate in any scheme that reduced the price of their animals or where they had to  
113 declare their bTB status. The engagement of farmers in RBT schemes by geographic  
114 location, and the purchasing choices given different schemes, were explored and  
115 quantitative estimates gained through a follow up questionnaire.

116

117 The aim of this research was to estimate the impact of farmers using risk scores to  
118 make more informed choices when buying cattle. The reduction in movements of  
119 infected cattle between farms over one year in England and Wales was estimated  
120 under three key scenarios: (1) cattle traded with no RBT scheme, (2) voluntary  
121 provision of the risk score, and (3) compulsory provision of the risk score in a

122 statutory RBT scheme. Additionally, the impact of changes in calculating the risk  
123 score were evaluated together with an investigating into areas of significant  
124 uncertainty in input parameters.

125

126

## 127 **METHODS**

128

129 A stochastic model implemented in Excel with the add on @Risk (version 6.1) was  
130 used to estimate the number of infected movements under each of the three scenarios.  
131 The final risk score developed using a method described in the accompanying paper,  
132 that could be practically applied, is presented in Table 1.

133

134 In this risk assessment each iteration in the model represents a random year with  
135 convergence to 4% of the mean value of each output parameter achieved with 5,000  
136 iterations using Latin Hypercube sampling. Each individual trading farm was included  
137 in the model and separately simulated for the probability of being infected (between  
138 herd infection), and if infected, the within herd prevalence was sampled for that herd  
139 size. All historical trading events in England and Wales recorded on the Cattle  
140 Tracing System (CTS) have been used (July 2010 to June 2011) to estimate the  
141 number of total movements and infected movements in one year with no RBT scheme  
142 in place. Movements to slaughter have not been included as such movements would  
143 not spread infection to new herds. It is assumed that all remaining movements involve  
144 a trade between a selling farm and a purchasing farm. The risk assessment uses  
145 distributions for certain parameters to describe any known uncertainty or variability  
146 associated with input parameters. Where uncertainty could not be quantified within a

147 distribution, separate scenario simulations were carried out to investigate the impact  
148 on model results of the level of participation by farmers, bTB between herd  
149 prevalence and purchase behaviour by farmers as detailed in the sensitivity analysis.

150

### 151 **Estimating the number of infected movements per year**

152

153 The number of infected movements per year is dependent on (1) the probability each  
154 farm which is selling cattle is bTB infected but the infection is undetected (farm either  
155 not under restriction or with specific movement license), (2) the within herd infection  
156 prevalence on that farm, (3) the proportion of animals moved from that farm in  
157 batches to other farms, and (4) the sensitivity of the pre-movement test where applied.

158 The risk pathway for the movement of infected animals off farm is provided in Figure  
159 1. Numerous parameter values were extracted from the National database SAM  
160 RADAR bTB reception database, herein referred to as SAM.

161

162 Probability farm infected with bTB,  $P_{inf}$

163

164 For each farm in the dataset the probability of the herd being bTB infected,  $P_{inf}$  was  
165 estimated using a modified freedom from infection (FFI) model (AHVLA, 2011).

166 This model has been previously developed to estimate the probability that a given  
167 herd was free of infection given its test and disease history,  $P(free)$  (Martin et al.,  
168 2007) and is described in the accompanying paper. There is considerable uncertainty  
169 associated with the probability of a herd being infected with bTB which is  
170 investigated in the sensitivity analysis. For each iteration, each selling farm is either

171 infected or not, modeled as a Bernoulli random variable, based on the probability of  
172 infection per year estimated for that farm.

$$P_{inf} \sim \text{Binomial}(1, 1 - P(\text{free}))$$

173

174 Number of animals infected,  $N_{inf}$

175 The number of infected animals in a herd is dependent on the within herd bTB  
176 prevalence and the number of animals within that herd. From a review of the  
177 literature, the within herd bTB prevalence applicable to undetected infected herds of  
178 varying herd size in England and Wales was not available. To calculate, we first  
179 estimated the annual number of infected animals in herds,  $Inf_{year}$ , where routine  
180 whole herd testing had been carried out in 2011. Where disease is not suspected,  
181 whole herd tests are conducted with the single intradermal comparative cervical  
182 tuberculin test (SICCT) test. Given the mean sensitivity of the SICCT test,  $Se_{mean}$ ,  
183 together with the total number of test positive reactors identified in whole herd tests  
184  $S_{year}$  (SAM) in England and Wales, the negative binomial distribution was used to  
185 describe the total annual number of infected animals in tested herds:

$$186 \quad Inf_{year} \sim \text{Negbin}(S_{year} + 1, Se_{mean}) + S_{year},$$

187

188 The estimated within herd prevalence for individual herds,  $P_{prev}$  was then sampled  
189 from the surveillance dataset, representing those herds assumed to be infected, such  
190 that the cumulative estimated number of infected animals per year across herds  
191 equalled the expected number infected per year  $Inf_{year}$ . This subset included herds  
192 where no reactors had been found ( $S=0$ )

193 
$$P_{prev} \sim \frac{Negbin(S+1, Se)+S}{h},$$

194 where  $S$  denotes the number of reactors per surveillance herd identified by the SICCT  
 195 test in 2011 (SAM),  $Se$  is the sensitivity of the SICCT test, and  $h$  is the total number  
 196 of animals tested in that surveillance herd (SAM). The negative binomial distribution  
 197 was truncated to ensure that the number infected in an individual herd (reactors and  
 198 false negatives) was not greater than the total number of animals tested in that  
 199 surveillance herd. The distribution of bTB within herd prevalence was generated from  
 200 500,000 iterations to ensure convergence to 4% of the estimated mean. Results were  
 201 filtered to include only those iterations where the observed 2011 England and Wales  
 202 reactor herds were included in the subset and are provided in Table 2.

203

204 The distribution of the sensitivity of the SICCT test at the herd level was described  
 205 using the Beta distribution with values of  $\alpha = 6.66$  and  $\beta = 6.37$  (Downs et al., 2011).  
 206 At the national level,  $Se_{mean}$ , a mean sensitivity of 0.511 was used for the SICCT  
 207 test. The estimated prevalence of bTB on infected farms, not previously suspected of  
 208 disease, decreases with increasing herd size, following the same trend as the  
 209 prevalence of detected reactors on infected farms. Note, this is not the probability of a  
 210 farm being infected, but the level of infectivity on farms that are infected. Separate  
 211 cumulative probability distributions representing the uncertain within herd prevalence  
 212 by herd size were applied in the model. Given the estimated within herd prevalence, a  
 213 binomial distribution was used to estimate the variable number of infected animals on  
 214 each infected farm from the total number of animals on farm:

$$N_{Inf} \sim Binomial(Herdsize, P_{prev})$$

215 where  $Herdsize$  was the average number of animals on farm (SAM).

216

217 Allocation of infected animals to off movements or remaining on farm,  $N_{Inf_{total}}$   
 218  
 219 Each selling farm may move animals off to a number of different locations during one  
 220 year. Paired movements between all farms between July 2010 to June 2011 was  
 221 extracted using the Cattle Tracing System (CTS). The estimated number of infected,  
 222  $N_{inf}$  being allocated to these different batches moved off farm, or remaining on the  
 223 farm, was assumed not to be dependent on animal infection status. The probability of  
 224 any one infected animal being allocated to a batch was therefore equal to the number  
 225 of animals sold in that batch divided by the original total number of animals in the  
 226 herd. For most farms there was more than one batch movement sold per year.  
 227 Therefore, a multinomial distribution was implemented as a set of nested binomial  
 228 distributions to describe the between year variability for allocation of infected animals  
 229 to batches or remaining on farm:

$$N_{Inf_{total}} \sim Multinomial(N_{Inf}, \{P_{farm}, P_{batch1}, P_{batch2} \dots P_{batchn}\})$$

$$N_{Inf_{total}} = N_{inf_{farm}} + N_{inf_{batch1}} + N_{inf_{batch2}} \dots + N_{inf_{batchn}}$$

230 where  $N_{Inf_{farm}}$  is the number of infected animals allocated to remain on farm, and  
 231  $N_{Inf_{batchn}}$  the number allocated to batch n. Where the selling farm is located within  
 232 an area subject to annual or bi-annual bTB tests (areas of high bTB incidence), all  
 233 cattle over 42 days of age require a pre-movement test to be taken 60 days prior to  
 234 movement. Within the risk assessment it is assumed that all animals originating from  
 235 farms located in the high risk area are tested and. This is a simplification as there are  
 236 movements which would be exempt from testing including animals under 42 days and  
 237 those licensed between Approved Finishing Units (AFUs) and certain farms under  
 238 restriction. It was assumed that each infected animal had the same likelihood of

239 testing positive in the absence of any latent period included in the model. A binomial  
240 random variable with the number of infected animals in that batch and the sensitivity  
241 of the SICCT test,  $Se$ , was sampled for the variability associated with a positive pre-  
242 movement test. Given any positive results it was assumed that the entire batch was not  
243 sold. Detection of positive animals in the pre-movement test would result in trading  
244 restrictions placed on the farm thereafter. However, given that all movements occur in  
245 one annual time step with no chronological order, the assumption was made that batch  
246 results were independent from other batch results for that source farm. This  
247 simplification made does not affect the comparison of RBT schemes because the entire batch  
248 is removed from all schemes for that iteration.”

249

### 250 **Estimating the impact of a voluntary scheme**

251

252 This scheme was based on the risk score of the seller ( $S_{score}$ ), being made available  
253 voluntarily to auctioneers and purchasers prior to purchase by the seller. The risk  
254 score of the purchaser ( $P_{score}$ ), may influence which animals they buy. The risk  
255 pathway for one selling farm is shown in Figure 1 and was used to estimate the  
256 infected and uninfected animals in each batch. This risk pathway was extended with  
257 an example batch as shown in Figure 2 to take account of whether or not the  
258 purchaser participates in a scheme and, given participation, whether or not the  
259 purchaser accepts the risk score of the seller. A ‘failed initial movement’ occurs when  
260 the purchaser does not accept the sellers risk score.

261

262 Probability of participating in a trading scheme,  $P_{scheme}(P_{score}, P_{region})$

263

264 The percentage of farmers that would be likely to purchase through a voluntary RBT  
265 scheme was discussed at seven meetings with stakeholders during 2012-2013 in  
266 England and Wales, with a follow up questionnaire (available from corresponding  
267 author). There were 17 quantitative estimates received. Stakeholders felt that there are  
268 many dependencies to be factored into estimates generated including the individual  
269 bTB status and circumstances of the purchaser and how successfully the scheme was  
270 rolled out. For Wales, it was deemed that the level of uptake of an RBT scheme would  
271 differ by region. Therefore, different estimates for uptake were calculated for regions  
272 defined as Low risk and High risk. Estimates were also stratified by purchasers risk  
273 score as it was thought that incurring a breakdown in recent years would influence the  
274 purchasing farmers' behaviour. The effect of differences in the purchasing relating to  
275 farm herd type was also raised. For example finishing farms (animals fattened for  
276 slaughter) were considered less likely to be concerned about the bTB risk of animal  
277 than breeding farms, however, insufficient data were available to include stratification  
278 by farm type in the model. The opinion elicited is provided in Table 3. The probability  
279 of farmers purchasing through a voluntary scheme was associated with significant  
280 unquantified uncertainty which was further investigated in the sensitivity analysis.  
281 Over one year it was assumed that each batch purchaser elected either to participate in  
282 the scheme or not for all batches destined for that farm represented by a Bernoulli  
283 random variable.

284

285 Probability of purchase given risk score,  $P_{buy}(P_{score}, S_{score})$

286

287 For those farmers participating in the scheme, the probability that farmers will buy  
288 certain animals will depend on their own farm status, their risk appetite, and also on

289 the information provided by the score regarding the animals for sale. As with the  
290 percentage of farmers using the scheme, there will be considerable variability between  
291 farmer needs (breeding farmer purchasing versus farmer restocking large numbers),  
292 other factors, such as the price of the animal, and on the overall ‘trust’ a farmer places  
293 in the risk scores and on the local implementation of the RBT scheme including the  
294 amount of educational activities rolled out with schemes. Stakeholders were asked to  
295 consider a hypothetical farmer that was interested in using risk scores. For each risk  
296 score pairing (seller score – purchaser score), respondents were asked to select a  
297 probability ranging from “Will” to “Will not” divided into six increments. Each of the  
298 boxes was associated with a probability, with a maximum of 100% representing  
299 “Will” and minimum of 0% for “Will not” with 1%-25%, 26%-50%, 51%-75%, and  
300 76%-99% for the middle four boxes. There were 12 quantitative responses provided  
301 with 5 unknowns (5 stakeholders did not answer this question in the questionnaire). A  
302 discrete distribution was then simulated until convergence for each pairing to estimate  
303 the combined expert opinion mean, maximum and standard deviation of the  
304 associated uncertainty. The uncertain probability of purchase for each pairing of risk  
305 score between purchaser and seller was applied in the risk assessment using a fitted  
306 lognormal distribution using the key statistics of the distribution shown in Table 4. A  
307 Bernoulli random variable with the given probability was sampled for the variability  
308 associated with the decision to purchase given the risk score.

### 309 **Estimating the number of infected movements within a statutory scheme**

310

311 The statutory scheme was based on the compulsory provision of the risk score to  
312 auctioneers and purchasers prior to purchase. In a perfect system this would imply  
313 that all purchasers would be involved in the scheme with  $P_{Scheme(P_{score}, P_{region})}=1$ .

314 However, the potential for purchase of animals from farmers not using the system was  
315 discussed with stakeholders and a minimum of 5% and maximum 15% thought to be  
316 plausible bounds for the uncertain probability of not complying with the scheme, with  
317 a mean value of 10%. For those farmers participating in the statutory scheme, the  
318 probability of the purchase being made ( $P_{buy(P_{score}, S_{score})}$ ), given that the risk score  
319 was made available was assumed to be the same as that estimated within the voluntary  
320 scheme.

321

### 322 **Estimating the impact of changes to calculating the risk score**

323 The baseline risk score for each farm, as described in the accompanying paper, was  
324 based on selected risk factors from a full model identified by a logistic regression. The  
325 impact of including some of the removed risk factors (region risk West England and  
326 Wales, and breakdowns > 10 years previously) on the performance of the score was  
327 investigated together with a more simplified scheme (only 0-2 years since breakdown  
328 and breakdown information without high risk movements), and finally the impact of  
329 implementing a rule whereby farmers are not permitted to purchase animals of higher  
330 risk status than their own herd.

331

### 332 **Parameter uncertainty and sensitivity analysis**

333 During development of the risk assessment several key parameters were identified as  
334 being uncertain with little available information to describe that uncertainty.

335 Therefore, upper and/or lower limits of parameters were identified and implemented  
336 in separate simulations of the risk assessment:

337

338 (1) The between herd prevalence of bTB  $p(inf)$ , calculation uses a value from the  
339 literature that herds cannot achieve a probability of freedom greater than 62%  
340 for 24 months post breakdown (detailed in the accompanying paper). The  
341 uncertainty associated with this value is not known. To estimate the impact of  
342 this uncertainty, the probability of infection for each farm was increased and  
343 decreased by 5% and separately simulated.

344 (2) The level of participation of farmers in a voluntary RBT scheme,  
345  $P_{scheme}(P_{score}, P_{region})$  was acknowledged in discussions as being highly  
346 uncertain - relating to farmer trust in that RBT scheme and ease of use and  
347 accessibility. Model scenarios were run at levels of 20%, 40%, 60%, 80% and  
348 100% farmer participation to evaluate the relationship between participation  
349 and performance of the scheme.

350 (3) The probability farmers would still purchase high risk animals once bTB  
351 information was provided,  $P_{buy}(P_{score}, S_{score})$ , was associated with the  
352 purchasers status and the amount of education and explanation that  
353 accompanied the roll out of any scheme, which at present is uncertain. To  
354 investigate the impact of RBT schemes that change the baseline probability of  
355 buying higher risk animals, a scenario was simulated where all purchasing  
356 farmers were 10% more likely and 10% less likely to purchase higher risk  
357 animals than the values elicited for the baseline model.

358

359 A sensitivity analysis based on Analysis of Variance (ANOVA) was undertaken. An  
360 ANOVA was selected as it has previously provided robust insights regarding  
361 identification of key inputs in probabilistic risk assessments, for example, Mokhtari  
362 and Frey, 2005. The reduction in infected movements comparing no RBT scheme and

363 a statutory RBT scheme at 90% compliance per farm was used as the response  
364 variable. Predictor variables were values of each input parameter for that farm  
365 represented by a range. The ANOVA was populated with half a million randomly  
366 selected farms.

367

## 368 RESULTS

369

370 The trade in cattle between farms without a RBT scheme, with a voluntary RBT  
371 scheme, and with a statutory RBT scheme, were simulated over one year for each  
372 farm. The number of infected movements that, if pre-movement tested, batch tested  
373 clear was summed and stratified by country and area. It was assumed in the baseline  
374 and each scenario that all movements from herds in the high risk area were pre-  
375 movement tested. Uncertainty and variability considered in the model was represented  
376 by 5<sup>th</sup> and 95<sup>th</sup> percentiles (within parentheses), which indicate the range within which  
377 90% of the results lie. Uncertainty was also considered in separate scenario runs of the  
378 risk assessment. It should be emphasised that not all variability and uncertainty has  
379 been estimated in the calculations and scenarios, as not all can be quantified.  
380 Therefore results describe the amount of quantified variability and uncertainty  
381 included in the assessment. Results stratified by region and by farm risk score, are  
382 presented in the supplementary materials.

383

### 384 **Results with no RBT scheme**

385 For trade in cattle with no RBT scheme there were 379,951 batches of animals moved  
386 off farm in England and Wales to another farm in England and Wales where the risk  
387 score and region of the seller and purchaser was determined. As shown in Table 5,

388 this represented a total of 1.2 million animals with 18.4%, 43.3%, 5.6%, 10.8%, and  
389 22.0% of animals sold by farms scoring 1, 2, 3, 4, and 5 respectively, where a score of  
390 1 is the lowest risk and a score of 5 is the highest risk score. An estimated mean of  
391 35,588 infected animals were on farms from which off movements occurred (farms  
392 not under restriction or those restricted but with a specific licence to move to another  
393 restricted facility) with 5<sup>th</sup> and 95<sup>th</sup> percentiles that this varied between 32,881 and  
394 38,369. Of these infected animals, approximately 11% or 3,981 (5<sup>th</sup> 2,775, 95<sup>th</sup> 5,288)  
395 were sold to purchasers in England and Wales with the majority remaining on farm.  
396 Of those 3,981 infected animals per year, an estimated mean of 41.8% infected  
397 animals were sold by farms scoring 5, rising to an average 60.2% for farms scoring 4  
398 or 5, whilst 6.1% were estimated to be sold from the lowest risk farms scoring 1.

399

#### 400 **Voluntary RBT scheme**

401 Uptake by farmers for a voluntary RBT scheme was estimated to vary between 40%  
402 to 81%, as shown in Table 3, dependent on location and purchaser bTB status. Table 5  
403 presents the estimated results from implementation of a voluntary RBT scheme with  
404 approximately 17% of animals that were traded with no RBT scheme being rejected  
405 by the initial buyer. It can be seen that the estimated trade from lower risk sellers was  
406 found to be less affected, with trade from higher risk sellers being most affected to  
407 low risk purchasers. The estimated trade was most affected in the high risk areas in  
408 England and Wales (regional differences shown in supplementary materials). There  
409 was an estimated mean rejection of 23% (5<sup>th</sup> 22%, 95<sup>th</sup> 25%) of infected animals by  
410 purchasers based on sellers providing the risk score voluntarily.

411

412 **Statutory RBT scheme**

413 Under a statutory RBT scheme with an estimated mean compliance of 90% of  
414 purchasers having access to the risk score of the seller an estimated mean of 26% of  
415 animals were rejected once the risk scores were made available. The majority of  
416 estimated trade to low risk purchasers (score 1) from high risk sellers (score 4 or 5)  
417 was affected by the implementation of a statutory scheme. Of the estimated number of  
418 infected animals on farm a mean of 37% (5<sup>th</sup> 35%, 95<sup>th</sup> 39%) of infected animals were  
419 rejected by purchasers. Of those infected animals rejected from sellers, the majority  
420 are estimated to be those sold by high risk farms (score 4 or 5), with on average a 53%  
421 reduction in infected movements from those farms.

422

423 **Alternative schemes**

424 Figure 3 displays the boxplot of different RBT schemes according to the estimated  
425 mean percentage reduction of infected movements. Results using the baseline risk  
426 score are presented in dark green and highlights the linear relationship between the  
427 percentage uptake by farmers and the percentage reduction achieved by that scheme.  
428 The dark green dashed line through the simulation results represents the uncertainty  
429 regarding the level of uptake for each scheme. The dashed black vertical lines through  
430 each box plot represent the between year variability and uncertainty about the mean  
431 simulation result and terminate at the estimated minimum and maximum value.

432 Variations on the baseline risk score used in an RBT scheme, adding or subtracting  
433 certain risk factors from the scoring system (as described in the accompanying paper)  
434 at 90% compliance has been provided together with an extrapolation of how those  
435 schemes would perform. From the results it can be seen that there are only marginal

436 increases in the performance of the scheme given the addition of risk factors selected  
437 from the logistic regression (region risk West England and Wales, and breakdowns >  
438 10 years previously). The impact of a ban on farmers purchasing below their farm risk  
439 score, assumed to be implemented with 100% compliance yields a 49% reduction the  
440 initial purchase of infected animals (5<sup>th</sup> 47%, 95<sup>th</sup> 51%).

441

#### 442 **Parameter uncertainty and sensitivity analysis**

443

444 There were three important parameters identified by the ANOVA: (1) the uncertain  
445 probability of the purchaser buying the animal once the sellers score was shown  
446 (derived from expert opinion)  $P_{buy(P_{score}, S_{score})}$ , (2) the variable risk score of the  
447 seller,  $S_{score}$ , and (3) the variable risk score of the purchaser,  $P_{score}$ . It should be  
448 noted that the uncertain level of compliance for the statutory scheme,  
449  $P_{scheme(P_{score}, P_{region})}$  was significant but less significant than the top three. For the  
450 voluntary scheme, the uncertainty associated with the probability of participating in  
451 the scheme was also highly important.

452

453 In addition to the sensitivity analysis, scenarios were identified during model  
454 development and parameterisation where there was limited information on parameter  
455 uncertainty with results shown in Table 6 and displayed in the boxplot in Figure 3.  
456 The true between herd prevalence of bTB infection,  $P_{inf}$ , the proportion of herds that  
457 have at least one infected animal, is associated with considerable uncertainty from the  
458 freedom from infection model (AHVLA, 2011) which is heavily reliant on input  
459 assumptions. Using alternative parameterisations, the performance of RBT schemes  
460 was within the convergence values for the original parameterised simulations. This is

461 due to the fact that the percentage change in infected movements is not dependent on  
462 the scale of the true prevalence, only the pattern of the true prevalence across English  
463 and Welsh farms. However, the absolute number of infected movements per year was  
464 significantly affected. Decreasing the between herd prevalence by 5% decreased the  
465 number of infected movements by a mean of 22%, whilst increasing by 5% increased  
466 the average number of infected movements by 21%.

467

468 Simulations were carried out varying the percentage uptake by farmers and the  
469 percentage reduction achieved. For every 10% of farmers that participated in the  
470 baseline scheme there was an additional 3.8% reduction in the initial purchase of  
471 infected animals until the mean estimated maximum of 38% was reached at the  
472 maximum of 100% participation.

473

474 The greatest increase in performance of the score arose from a 10% decrease in the  
475 baseline estimates for risky farmer behaviour (purchasing cattle at higher risk than  
476 their own farms) with a 45% mean reduction in the initial purchase of infected  
477 animals (5<sup>th</sup> 43%, 95<sup>th</sup> 47%). This result concurs with the identification in the  
478 ANOVA of this parameter as having the highest impact on the RBT performance  
479 output considering the associated quantified uncertainty and variability.

480

481 DISCUSSION

482

483 Cattle trading patterns are complex and dynamic due to seasonal factors, economic  
484 factors and changes in Government controls. Nevertheless a quantitative approach to  
485 estimating the impact of a RBT scheme was possible for England and Wales. It was

486 possible to estimate with a reasonable amount of confidence the impact of a specific  
487 scheme over one year and show that a significant impact could be achieved with the  
488 reduction of movements from high risk areas or high risk farms.

489

490 One of the major reasons for adopting a quantitative approach was the need to account  
491 for the dynamic movement patterns between farm types and farm areas and regional  
492 differences in the application of control measures. Historic paired movements were  
493 used which linked direct farm to farm animal movements and those via markets to  
494 farms. This allowed a comparison between high and low risk areas and different  
495 trading schemes. The absolute results for the number of animals infected and traded  
496 was dependent on the scale of the between herd and within herd prevalence. The  
497 between herd prevalence was associated with uncertainty not quantified in the model.  
498 However, the comparison between cattle traded with no RBT and the different RBT  
499 schemes was not dependent on the magnitude of prevalence – only the regional or  
500 farm characteristic pattern. It was apparent that changes in the calculation of the  
501 between herd prevalence could have a significant effect on the absolute number of  
502 infected movements predicted. The provision of values for the number of infected  
503 animals with associated uncertainty is, however, provided as such values are  
504 important for economic analyses when considering the cost benefits of establishing  
505 and maintaining a RBT scheme. Before consideration could be made of a statutory  
506 scheme, a cost-benefit analysis would be required estimating the full costs of  
507 implementing a scheme, such as impacts on trade and adjustments of the market,  
508 together with the benefits of reduced disease spread.

509

510 Analysis of the results from the risk assessment demonstrated the importance of  
511 encouraging maximal uptake of schemes. The sensitivity analysis and parameter  
512 uncertainty scenarios demonstrated the importance of farmer purchase  
513 behaviour,  $P_{buy}(P_{score}, S_{score})$  on the performance of any RBT scheme. The quantified  
514 uncertainty associated with this parameter could be reduced from gathering  
515 appropriate data from any pilots conducted. In addition, careful consideration should  
516 be given to any programme of education of farmers which could result in reducing  
517 risky purchase behaviour, thereby considerably improving the performance of RBT  
518 schemes. Importantly, we repeatedly heard at stakeholder meetings that many farmers  
519 believed that if an animal had been tested for bTB, then that animal was not infected,  
520 i.e. they considered that the bTB test applied was 100% sensitive. This may lead to  
521 the conclusion that further effective education of farmers may be warranted. The  
522 England TB RBT group also identified that a voluntary scheme will only succeed if a  
523 critical mass of farmers participate (Defra, 2013a). This will depend on how well any  
524 scheme is rolled out, ease of use, trust, the level of understanding achieved of the risk  
525 posed by purchasing cattle to herds and sufficient information being made available to  
526 farmers to make an informed choice.

527

528 In the absence of any RBT scheme being piloted in England and Wales during the  
529 lifetime of this research project, the values elicited by expert opinion represented a  
530 ‘best guess’, however, it is the only data currently available. Should any schemes be  
531 piloted, it would be advisable to monitor initial uptake and changes in farmer  
532 behaviour to update the risk assessment. For example, Gates and colleagues  
533 monitored the change brought about by cattle movement restrictions on Scottish farms  
534 (Gates et al., 2013). Such data would be invaluable to reduce the uncertainty

535 associated with model estimates. Given sufficient data, further work could investigate  
536 the most likely fate of those infected movements that initially fail from high scoring  
537 sellers. The England RBT group commented that a short research project be  
538 conducted after an introductory period to investigate engagement and behavioural  
539 change. This may include a survey of auctioneers as to whether any risk-based trading  
540 data has been included in catalogues or on screen/boards at point of sale and how  
541 many buyers are asking for the risk score prior to purchase. Statutory databases could  
542 also be queried as to whether any significant changes had occurred to paired  
543 movements (particularly those deemed the most risky) between/into/out of selected  
544 geographical/incidence based/score based categories. An alternative would be a check  
545 on the average distance travelled for movements from holdings of certain categories.

546

547 A RBT scheme would reduce infection transmission attributable to cattle movements  
548 which is one transmission pathway contributing to the bTB epidemic (Gopal et al.,  
549 2006). This would reduce the between herd prevalence (the proportion of farms with  
550 at least one infected animal). In the risk assessment, historical movements are either  
551 accepted or rejected; the model makes no attempt to reallocate the movement to  
552 another farm or area once the original trade is declined. However, at the market or  
553 sale, another farmer may purchase the rejected batch at a lower price. Alternatively  
554 farmers with high scores may seek out other purchasing farmers with the same risk  
555 status for trade, for example, with the development of 'orange' markets. The model  
556 indicates that, given the introduction of a RBT scheme, there would be significantly  
557 less infected animals purchased by low scoring farms, particularly for those low risk  
558 farm that are located in the high risk area (HRA). If those rejected movements were  
559 sold to high risk farms, which may already be harbouring undetected infection, this

560 may, in the long term, increase the bTB within herd prevalence of those herds  
561 engaging in this risky behaviour. Unfortunately, the risk assessment is simulated only  
562 over one year and therefore cannot quantify the long-term changes that may eventuate  
563 from implementation of risk-based schemes, however, if such farms resided in an area  
564 of higher testing frequency, such as the HRAs in England and Wales, detection of  
565 those infected animals may occur earlier due to a higher prevalence of infection on the  
566 test farm, and increased frequency of testing in the form of pre-movement tests and  
567 annual whole herd tests thus complementing and potentially improving the sensitivity  
568 of the current regional controls in place.

569

## 570 CONCLUSIONS

571

572 In conclusion, this paper details the design of the first risk assessment to measure the  
573 impact of theoretical risk-based animal trading schemes based on a given farm risk  
574 score for bTB. If a voluntary or statutory RBT scheme was in place, a significant  
575 impact could be achieved with the reduction of infected movements from high risk  
576 areas or high risk farms. Key to reducing infected movements through a risk-based  
577 trading scheme is promoting maximal uptake in schemes and on reducing risky farmer  
578 purchase behaviour.
