Abstract: Background:

Maternal pertussis immunisation was introduced during the pertussis resurgence in England in 2012 as a temporary measure to protect infants too young to be vaccinated. The programme was shown to be safe and highly effective. However, continuation of maternal vaccination as a routine programme requires a cost effectiveness analysis.

Method:

The estimated prevented disease burden among mothers and their infants was obtained assuming 89% (95% CI: 19%-99%) vaccine efficacy for mothers and 91% (95% CI: 84%-95%) for infants. Future incidence was projected based on the disease rates in 2010-2012, including the four-year cycle of low and high incidence years. Full probabilistic sensitivity analysis was performed for different scenarios.

Results:

Assuming a vaccine coverage of 60%, there were 1650 prevented hospitalisations in infants (3.5% discounting, the first 10 years), including 55-60 deaths and ~20,500 cases among mothers, of which around 1800 would be severe. The annual costs of the programme are £7.3 million assuming a price of £10 per dose and £9.4 million assuming £15 per dose. Using discounting of 3.5%, a 200 year time horizon and a price of £10 per dose (+ £7.5 administration costs) only 25% of the iterations were below £30,000 per QALY. Using a 35% higher incidence resulted in 88% of the scenarios below this threshold. Assuming that the incidence remains at the level at the height of 2012, then the programme would be highly cost effective, with an ICER of £16,865 (£12,209-£25,976; price of £10 and 3.5%/3.5% discounting).

Conclusion:

Maternal vaccination is effective in preventing severe illness and deaths in infants but the cost-effectiveness of the programme is highly dependent on future incidence which is necessarily uncertain. However, the duration and magnitude of protection against transmission afforded by the current acellular vaccines is also uncertain as are the associated effects on future herd immunity. The direct protection offered by the maternal dose provides the only certain way of protecting vulnerable infants from birth.

Dear Editor,

The manuscript we present is on maternal pertussis vaccination; maternal vaccination was introduced in England to mitigate the observed increase in pertussis in 2012. The programme was initially introduced without much direct evidence, but was very effective.

We present a cost-effectiveness study based on the observed incidence and vaccine-efficacy in England. The future incidence of pertussis is projected including cyclical patterns and both the impact on mother and child. This approach enabled to investigate relevant implications of different discount and time horizon scenarios, as well as the relevant uncertainty.

However most importantly, as you will see in the discussion, the continuation of the programme, whose dramatic success in terms of infant cases and deaths prevented has galvanised global interest [see for example:

<http://www.fda.gov/downloads/AdvisoryCommittees/CommitteesMeetingMaterials/BloodVaccinesandOtherBiologics/VaccinesandRelatedBiologicalProductsAdvisoryCommittee/UCM474285.pdf>) is threatened by being considered not cost effective. While the decision body in the UK (Joint Committee for Vaccination and Immunisation) has deferred the decision about discontinuing the programme for 5 years, as there was natural concern about letting infants die from a vaccine preventable disease based on cost effectiveness criteria alone. In our discussion we challenge the application of conventional incremental cost effectiveness analyses to this programme and highlight other very tangible benefits that accrue from its implementation. Moreover, the programme is cost effective in epidemic years which raises interesting questions about whether it is feasible to turn it on and off depending on incidence as is currently done with antivirals for influenza.

As other countries are now actively promoting maternal pertussis immunisation but like the UK will need to consider cost effectiveness – even WHO through its Strategic Advisory Group of Experts requires cost effectiveness analyses to support its global recommendations. Ours is the first such analysis of an implemented programme and the methodological, practical, and ethical issues we identify are applicable for other countries and are likely to engender debate (and could be a suitable topic for a commentary).

We therefore hope that you consider this manuscript for review in your journal. The manuscript is not submitted elsewhere.

Yours sincerely,

Albert Jan van Hoek (on behalf of the co-authors)

Dear Editor,

To comply with the requirements to start the production process we have uploaded a set of “highlights” linked to the manuscript.

Regarding the publication. Could you please inform me regarding the “open access” option your journal offers, including the price and process? And within my institute it is common practice to have a press-release accompanying a publication and I planning to do so. Could you therefore please update me regarding publication dates.

Please don't hesitate to contact me,

Yours faithfully,

Albert Jan van Hoek

Cost-effectiveness and programmatic benefits of maternal vaccination against pertussis in England.

Abstract

Background:

Maternal pertussis immunisation was introduced during the pertussis resurgence in England in 2012 as a temporary measure to protect infants too young to be vaccinated. The programme was shown to be safe and highly effective. However, continuation of maternal vaccination as a routine programme requires a cost effectiveness analysis.

Method:

The estimated prevented disease burden among mothers and their infants was obtained assuming 89% (95% CI: 19%-99%) vaccine efficacy for mothers and 91% (95% CI: 84%-95%) for infants. Future incidence was projected based on the disease rates in 2010-2012, including the four-year cycle of low and high incidence years. Full probabilistic sensitivity analysis was performed for different scenarios.

Results:

Assuming a vaccine coverage of 60%, there were 1650 prevented hospitalisations in infants (3.5% discounting, the first 10 years), including 55-60 deaths and ~20,500 cases among mothers, of which around 1800 would be severe. The annual costs of the programme are £7.3 million assuming a price of £10 per dose and £9.4 million assuming £15 per dose. Using discounting of 3.5%, a 200 year time horizon and a price of £10 per dose (+ £7.5 administration costs) only 25% of the iterations were below £30,000 per QALY. Using a 35% higher incidence resulted in 88% of the scenarios below this threshold. Assuming that the incidence remains at the level at the height of 2012, then the programme would be highly cost effective, with an ICER of £16,865 (£12,209-£25,976; price of £10 and 3.5%/3.5% discounting).

Conclusion:

Maternal vaccination is effective in preventing severe illness and deaths in infants but the cost-effectiveness of the programme is highly dependent on future incidence which is necessarily uncertain. However, the duration and magnitude of protection against transmission afforded by the current acellular vaccines is also uncertain as are the associated effects on future herd immunity. The direct protection offered by the maternal dose provides the only certain way of protecting vulnerable infants from birth.

Words: 319

Highlights (for review)

- Maternal pertussis vaccination is highly effective at preventing infant deaths
- Its cost-effectiveness as an adjunct to paediatric vaccination needs evaluation
- Future pertussis incidence is the major determinant of cost-effectiveness
- The ability of acellular vaccines to control transmission is questionable
- Given this uncertainty continuation of maternal immunisation is advisable

1 **Introduction**

2 In October 2012 a maternal pertussis vaccination programme was introduced in England [1] as an
3 outbreak measure in response to the highest number of infant cases and deaths from pertussis in
4 more than a decade in 2012. All of the infants who died developed disease before they were eligible
5 to receive the primary course of vaccine. The maternal programme has been well received in
6 England, with uptake peaking at 60% and evidence of a direct impact in infants under 3 months of
7 age [1].

8 Maternal vaccination is offered in every pregnancy, ideally between 28 and 32 weeks, but up to 38
9 weeks [1] and works in two ways: by passive immunisation of the infant through the transport of
10 antibodies across the placenta and by directly protecting the mother which lowers the probability of
11 her being a source of infection to her infant. The programme effectiveness against infant disease has
12 been estimated to be 91% (84%-95%) in England [1] Maternal vaccination thus offers a safe [2] and
13 effective way of directly protecting those too young to be vaccinated.

14 Although this programme was introduced as a temporary outbreak response measure, the question
15 now is whether, based on the evidence of effectiveness, maternal vaccination should be added to
16 the routine programme in England. In the England, policy recommendations by the Joint Committee
17 and Vaccination and Immunisation require evidence of cost effectiveness.

18 In this paper we investigate the cost-effectiveness of introducing maternal vaccination programme
19 into the national immunisation schedule, offering a dose to women in every pregnancy.

20

1 **Methods**

2 *Programme under consideration*

3 The programme under study in this analysis is vaccinating pregnant woman in the 3rd trimester with
4 one dose of a pertussis-containing vaccine designed for adult boosting. In practice, women will be
5 offered vaccine at the first appointment in the 3rd trimester (week 28-32, where possible and up to
6 38 weeks).

7 *Impact of the vaccine*

8 The duration and type of protection induced in the mother and infant differs. The infant is passively
9 protected by maternal antibodies until development of active immunity following receipt of the first
10 dose of pertussis-containing vaccine at 2 months of age. In this analysis disease up to three months
11 of age was considered preventable by maternal vaccination assuming that those hospitalised
12 between two and three months are either still unvaccinated, or were exposed before they could
13 develop protective antibodies after the first dose of the primary course. Vaccinating the mother, will
14 boost her pre-existing immunity which will afford protection for a longer time. This was assumed to
15 be 5 years, based on estimates of the duration of protection after a 5th dose of acellular vaccine
16 given around five years of age and antibody persistence after an adolescent acellular booster [3].
17 However, pertussis antibody titres rapidly decline within a year of boosting [4] and therefore vaccine
18 is recommended in each pregnancy, regardless of vaccine history in order to passively protect the
19 infant. This means that some women will get pregnant again and receive the vaccine for a second
20 time while still protected against disease. Therefore, to take this into account, the effective duration
21 of maternal protection was reduced. Where vaccine recipients do not become pregnant again they
22 enjoy five years of protection; when they do have a subsequent pregnancy an average interval
23 between pregnancies was assumed of 3 years based on national maternity data [5]. For the analysis
24 a weighted average duration was calculated based on the observed distribution of first, second, third

1 and fourth pregnancies (see the online material for more detail). The average duration of protection
2 was estimated as 3.89 years or 47 months.

3 Therefore, for example, if a mother was vaccinated in the 5th month of the programme two months
4 before delivery, disease in the mother would be on average prevented from month 5 until month 52
5 and in the infant from month 7 until the end of month 9 of the programme.

6

7 *The preventable disease burden*

8 The transmission of pertussis is cyclical, with a 3-4 year interval between high transmission years.
9 Due to the fluctuating disease burden the cost effectiveness of a dose will change over time within
10 the cycle. Therefore the programme was evaluated over a longer period, using a fluctuating monthly
11 incidence. The fluctuation was simulated by a sine-function with a peak every 4 years, oscillating
12 between the maximum and minimum incidence.

13 As the vaccine prevents both disease in the infant and the mother, separate estimates of the
14 preventable disease burden were made. For infants under 3 months, the burden of disease was
15 estimated from hospital admission data as pertussis at this age is severe and over 90% of cases
16 require in-patient care [6]; it is also the most complete data source as admissions in infants under 3
17 months are nearly double the number of notified cases in this age group [6]. In contrast, pertussis in
18 adults is often a mild, unrecognised illness so notifications and laboratory confirmed cases will
19 substantially underestimate the true burden of clinical illness; it is conservatively assumed that
20 laboratory confirmed cases comprise only a third of all clinically significant pertussis illness in adults
21 [7]. Evidence suggests that the source of infection for most infant pertussis cases is other family
22 members [8] so it can be assumed that the exposure in mothers and infants is similar resulting in a
23 synchronised cyclical pattern of infection in both groups.

1 The future incidence of pertussis is uncertain given the recent resurgence in the UK and some other
2 countries, possibly associated with more rapid waning of immunity after immunisation with acellular
3 than whole cell vaccine [3,9]. Several future incidence scenarios are therefore presented – a low,
4 base case and a high incidence scenario. A low incidence scenario based on 75% of the cases
5 observed in 2012, a base case scenario assuming outbreak sizes as observed in 2011-2012 and three
6 high incidence scenarios, one with 35% more disease than in 2012 in the peak years, a second with
7 35% higher incidence in the low years, and a third with both a higher incidence in the peaks and
8 troughs. These incidence scenarios were used in combination with different scenarios on the time-
9 horizon and discounting.

10 *Disease outcomes*

11 *Infants:*

12 The sine function was fitted using the overall incidence of hospitalised disease in infants under 3
13 months between September 2010-September 2012. The incidence in the trough year was based on
14 the observed number of hospitalised infant cases in 2010.

15 *Hospitalisation*

16 Infants were admitted to hospital and could have 1 day of admission, multiple days of admission
17 without intensive care, multiple days with intensive care, and multiple days with intensive care and
18 extracorporeal membrane oxygenation (ECMO), for a proportion of intensive care patients special
19 transport was needed.

20 The duration of admission and whether there was an admission to the paediatric intensive care unit
21 (PICU) was based on the Hospital Episode Statistics (HES) for the period January 2007-February 2012,
22 HES is a database that includes all hospital admissions in England [10] The admission rate to PICU is
23 assumed to be the proportion of patients who needed ventilation (procedure codes OPCS4 E85,
24 E89, X58 and X52). The duration of admission to the PICU and whether ECMO or special transport

1 was needed was based on the Paediatric Intensive Care Audit Network (PICAnet) database (2006-
2 2012) which contains detailed information on PICU admissions.

3 The costs were based on the NHS reference costs 2012-2013 [11], using PA65A (Non-elective Upper
4 respiratory Tract Disorder £422 (£282-£523) for those admitted without an overnight stay and
5 PA65B (Non-elective Long stay Upper respiratory Tract Disorder with complications; £758 (£552 –
6 £885) per day) for non-ICU days in case of overnight stay and XB04Z (Pediatric Critical Care Intensive
7 Basic Enhanced; £2,110 (£2,004-£2,130) per day) or XB01Z (Pediatric Critical Care Intensive –
8 ECMO/ECLS; £4,391 (£3,966-£4,763) per day in case of PICU admission without or with ECMO
9 respectively.

10 *Mortality*

11 Although previously it was suggested that the number of pertussis deaths were substantially
12 underestimated [12], a more recent analysis showed that the reporting of deaths was consistent
13 between various sources and that therefore the under reporting of recognised pertussis deaths in
14 England is small [13]. There were 16 reported deaths due to pertussis in infants under 3 months of
15 age born between 1 October 2011- 30 September 2012 (before the maternal programme was
16 introduced) and a total of 513 reported hospitalisations in infants under 3 months in the same
17 period giving a case fatality rate of 3.1% (95% CI: 1.75%-4.7%).

18 The total utility loss for a fatal case was calculated based on the estimated life expectancy with a
19 correction for the population norms of the quality of life by age. The life expectancy was based on
20 the 2008-2010 mortality [14] and the population norms were obtained from a 2010 survey among
21 22,166 adults age 16 and over using the SF-6D; for those younger than 16 a population norm of 0.9
22 was assumed [15].

23 *Adults*

1 For adults, estimations were made for reported and non-reported disease burden which followed
2 the same sine function as in the infants. In the peak month of 2012 the incidence in infants under 3
3 months was 43.3 per 100,000. Hence assuming a similar incidence in adults the estimated number
4 of infections among the 9,569,461 women aged 20-44 in the population in the peak month was
5 95.69×43.3 per 100,000 = 4,144. In the peak month there were 365 laboratory confirmed cases
6 among women aged 20-44, therefore 8.8% (365/4,114) of the infections among women are believed
7 to be laboratory confirmed.

8 Public Health England performed a patient survey to estimate the loss in quality of life due to
9 pertussis as well as the related health care costs [16]. Two groups of patients were recruited;
10 laboratory confirmed cases, and coughing household contacts. The latter group is a proxy for
11 pertussis which is not laboratory confirmed.

12 There was a marked difference in the overall QALY loss between the two groups with 0.1 QALY for
13 the confirmed cases and 0.04 QALY for the non-confirmed cases [16]. The health care costs were
14 £55.55 for those confirmed and £25 for the coughing house hold contacts.

15 *Vaccine efficacy*

16 There are two licensed acellular pertussis-containing vaccines that can be used for maternal
17 immunisation, Repevax™ and Boostrix/IPV™. Both contain low-dose diphtheria toxoid plus tetanus
18 toxoid in combination with acellular pertussis and inactivated polio antigens but differ with respect
19 to the number and amount of pertussis antigens each contains. Repevax™ was used for the maternal
20 immunisation programme until July 2014 and its effectiveness estimated as 91% [1] but its efficacy
21 as a booster dose in adults has not been evaluated. Boostrix/IPV has not been evaluated in a
22 maternal programme but has demonstrated efficacy against laboratory-confirmed pertussis in a
23 randomised controlled trial in adolescents (89%, 95% CI: 19%-99%) [17]. For the purposes of this

1 evaluation it was therefore assumed that both booster vaccines are suitable candidates for use in a
2 maternal programme and that the protection afforded to mother and infant by each is similar.

3 *Cost effectiveness analysis*

4 It is common practice in cost-effectiveness analysis to evaluate a supplementary strategy relative to
5 the existing practice as baseline. Therefore the existing vaccination programme against pertussis was
6 not re-evaluated. The analysis was performed from a health care payer's perspective, in line with the
7 recommendations of the National Institute of Clinical Excellence (NICE). The impact of the discount
8 rate was investigated in 2 scenarios; discounting both QALYs and costs with 3.5%, and discounting
9 both with 1.5%. To reflect the incorporated disease burden within the cost effectiveness analysis the
10 discounting was applied to the estimated number of future cases. The programme was evaluated
11 with 4 different time horizons: 5 years, 10 years, 30 years, 200 years. The assumed vaccine price was
12 £10 or £15 plus £7.50 administration costs per dose. The uncertainty in the cost-effectiveness results
13 were based on 1000 samples using Latin hyper cube sampling from the assigned distributions. All
14 analysis was performed in R 2.14.1 [18] and an overview of all the used assumptions are given in
15 table 1.

16 For the probabilistic sensitivity analysis, distributions were assigned. To derive an average value a
17 normal distribution was used defined by the mean and standard deviation (SD) of 1000 bootstrap
18 samples of the original data (so to obtain an average of the mean); to derive a percentage a beta
19 distributions was assigned so to constrain the values between 0 and 1, again based on the mean and
20 SD of 1000 bootstrap samples of the mean. For costs inputs triangular distributions were used, with
21 the published maximum and minimum [11] as the upper and lower quartile

22

1 **Results**

2 In figure 1 the incidence in infants and women aged 20-44 is shown. As can be seen the disease
3 between the two age groups follows a similar time course, underpinning the assumption that
4 disease acquisition among mothers and infants is closely related, but with a time lag likely due to the
5 later recognition and confirmation of adult compared with infant cases.

6 The sine wave used in the model is based on the outbreak in 2012 (figure 2). In table 2 the disease
7 burden using this model and the observed number of cases in 2012 are compared and shown to be
8 similar, with 590 observed and 554 modelled infant cases and 15 vs 17 deaths. It should be noted
9 that in October 2012 maternal vaccination was introduced, reducing the number of infant deaths.
10 After introduction of the maternal programme, the peak months had an incidence of 28 per 100,000
11 population months in infants under 3 months, and troughs of 3.5 per 100,000 population months.

12 In the base case incidence scenario, among a vaccinated birth cohort (60% coverage), there would
13 be an expected 1800-2000 hospitalisations (3.5% and 1.5% discounting respectively) over the first 10
14 years after introduction, which would include 55-60 deaths. Around 20,500 cases (3.5% discounting)
15 would be prevented among mothers, of which around 1800 would be severe. However, the 95%
16 confidence interval around the 20,500 cases is 4,500 to 24,500, reflecting the wide CIs around the
17 vaccine efficacy estimate in adults (Table 3). The annual costs of the programme are £7.3 million
18 assuming a price of £10 per dose and £9.4 million assuming £15 per dose. See table 3 for a detailed
19 breakdown of the gained costs and QALYs due to the maternal vaccination programme and the
20 related incremental cost effectiveness ratio (ICER). The cost-effectiveness of the programme is
21 driven by the prevented mortality among infants, as vaccinating only for the benefit of adults is not
22 cost-effective.

23 Projecting the 2010-2012 incidence into the future, with a peak every 4 years, the costs per QALY
24 gained vary considerably depending on the discount rate, time horizon and vaccine price. Figure 3

1 shows the fluctuation in the price per dose in which 50% of the iterations are cost-effective (under
2 the £20,000 threshold) over time in the base-case model. Table 4 shows the percentage of iterations
3 in which the ICER is below a £20,000 or £30,000 cost per QALY threshold for different scenarios.
4 When using discounting as recommended by NICE (3.5% for both costs and disease burden) in only
5 one scenario are more than 50% of the iterations below the £30,000 threshold (5 year time horizon).
6 Using discounting of 1.5% for costs and 1.5% for disease burden, all investigated scenarios have
7 around 90% of the iteration below £30,000 (in case of a price of £15 this is at least 50%).

8 The findings above are very sensitive to the modelled incidence. When the incidence in both the
9 peak and troughs is increased by 35%, at least 88% of the iterations achieve ICERs below £30,000
10 (3.5%/3.5% discounting and a vaccine price of £10) in all investigated time horizons, see table 5.
11 Assuming that the incidence remains at peak level in 2012, then the programme would be highly
12 cost effective, with an ICER of £16,865 (£12,209-£25,976; price of £10 and 3.5%/3.5% discounting).

13 The timing of introduction of the programme influences the overall cost-effectiveness, especially for
14 short time horizons with a higher discounting scenario, as is shown in figure 4.

15

1 **Discussion**

2 Our cost effectiveness analysis shows that maternal pertussis immunisation would be highly cost
3 effective if the peak incidence of infant disease at the time the programme was introduced,
4 continues. However, our estimates were highly dependent on the future incidence of pertussis in
5 infants under 3 months of age. This is necessarily difficult to predict given the uncertainties around
6 the reasons for the resurgence and the transmission dynamics of pertussis. Although there has been
7 a cyclical pattern in the past, it is not as steady and clear as simulated in our model. Moreover there
8 may be more variation in the peaks and troughs in the future, as well as in the inter-epidemic period,
9 which up to now in the UK has remained unchanged at 3 to 4 years since the start of vaccination in
10 the 1950s. Although the sine wave fitted the 2012 outbreak well, when using it for projecting
11 temporal patterns in future incidence, there is necessarily considerable uncertainty about the
12 magnitude of future peaks and troughs especially for time horizons extending many decades into the
13 future. For shorter time horizons, the timing of the peaks in relation to the start of the programme
14 has a major influence on cost effectiveness due to the effect of discounting.

15 During periods of low incidence there is less direct benefit for the infant, but during periods
16 with high incidence the benefit is considerably greater. The assumptions about future incidence in
17 our model are therefore critical in determining cost-effectiveness. In the decade before the 2012
18 resurgence pertussis incidence was at an all-time low in England. However there are reasons to
19 believe that there will be a sustained elevated incidence in infants and other age groups in the
20 future, with peaks similar to, or larger than, observed in 2012. If the resurgence seen in the UK and
21 some other countries is associated with the shorter duration of protection of acellular vaccines then
22 there will be more susceptible individuals in the population than in the period when whole cell
23 vaccine was used which is likely to result in an elevated endemic incidence. There is evidence for this
24 from the US which introduced acellular vaccines in 1997; a resurgence was first seen around 2005
25 and an elevated endemic incidence has continued since then [19]. In England in 2014, which was a

1 trough year, there was a higher than expected number of laboratory confirmed cases and deaths
2 among infants under 3 months of age compared with the pre-resurgence trough year of 2010,
3 having taken into account the impact of a continuing effective maternal immunisation programme
4 (PHE). This suggests that the elevated incidence first observed in 2012 is likely to continue and be
5 reflected in both trough and peak years.

6 The vaccine prevents a greater number of infections in the mother than the infant. This is
7 because the infant is only protected for 3 months compared to almost 4 years of the mother.
8 However the disease burden is significantly greater in young infants who are at risk of death and
9 may require invasive procedures such as ventilatory support. Therefore the prevention of pertussis
10 in infants contributes more to the overall cost-effectiveness than prevention in the mothers.
11 Another limiting factor related to this, the number of death due to pertussis in infants is likely to be
12 higher due to under ascertainment leading to an even greater relative burden among infants. In
13 adults the impact of pertussis is on the quality of life which is adversely affected by the prolonged,
14 severe cough as it disrupts sleep and interferes with normal daily activities. The QALY loss in adults
15 with confirmed pertussis and in their coughing household contacts was estimated during the 2012
16 resurgence [16]. However, estimating the overall burden of pertussis in the population remains
17 difficult. The confirmed cases for whom we have information probably represent the most severe
18 end of the illness spectrum and therefore the distribution of patients with severe and less severe
19 symptoms remains speculative.

20 Due to the high efficacy of the maternal vaccination programme and the relatively high
21 uptake of the vaccine, other approaches to prevent the disease burden in infants (in the first two
22 months of life) have not been considered in this cost-effectiveness analysis. These include neonatal
23 vaccination, where the new born receives a dose just after birth, and a cocooning strategy where the
24 mother (and other household members) receives the vaccine after birth. A neonatal dose will not
25 confer the 91% protection estimated for maternal immunisation as efficacy of single dose at around

1 2 months of age is only about 50% [6]. Moreover there is an expected delay in vaccine response
2 leaving the infant unprotected in the first two weeks of life. Therefore such a programme will be
3 considerably less effective and therefore less cost-effective compared to a maternal programme.
4 The cocooning strategy aims to protect the infant from exposure by proactively vaccinating likely
5 contacts of the neonate. However, this requires the vaccination of more individuals than just the
6 mother, and is reliant on the efficacy of the acellular pertussis vaccine against transmission of
7 infection.

8 Due to the periods of low incidence, the cost effectiveness of the maternal programme
9 could be improved by switching it off at times of low incidence and on again when incidence
10 increases. However this approach would be programmatically challenging as it would require a clear
11 and timely trigger for the “on switch”. While this is done with the use of antivirals for influenza,
12 which are recommended when consultations for influenza-like-illness achieve a pre-defined rate,
13 this would be more difficult for pertussis because of the delay between onset, disease recognition,
14 laboratory confirmation and reporting. Furthermore for the infant to achieve the maximum benefit
15 the optimal timing of vaccination is before the period when antibodies are actively transferred
16 across the placenta, which is believed to commence around week 32 [20]. Therefore to make sure
17 infants are protected at the high incidence period the programme needs to be initiated at least two
18 months before the peak, to allow enough time for seroconversion in the mother and transfer of the
19 antibodies. This would require a sensitive and reliable incidence-based trigger – one that preferably
20 does not rely on an increase in infant deaths which was the trigger for the 2012 maternal
21 immunisation programme. Also, by switching the programme off because of cost-effectiveness
22 reasons society will have to accept that potentially preventable infant deaths will occur in the low
23 incidence period.

24 The cost effectiveness of the maternal programme was assessed as a supplement to the
25 existing 4 dose paediatric programme. With the high coverage of the existing programme in England

1 the incidence of disease in infants too young to be vaccinated has already been substantially
2 reduced from the pre-vaccine era. As a result, the cost effectiveness of the maternal programme
3 under the baseline incidence scenario was not favourable. This is despite the residual high morbidity
4 and mortality in infants even before the recent resurgence when the annual admission rate in
5 infants under 3 months was still over 1 per 1000 with 7 pertussis deaths per million maternities (14,
6 18). The main objective of existing pertussis programmes is to reduce infant morbidity and mortality
7 [9]. Had maternal vaccination been an option when national vaccination was first introduced in the
8 1950s it may well have been the initial strategy chosen to achieve immediate infant protection with
9 mass child hood vaccination considered later. However when introduced as an adjunct to an existing
10 mature paediatric vaccination programme it may not appear cost effective. Our results are therefore
11 highly context dependent and reflect the historical evolution of the UK programme. In other
12 settings where vaccine coverage and disease control is poorer, the incremental benefit of maternal
13 pertussis vaccination will be greater. Its administration would be facilitated in those countries
14 already offering tetanus vaccine in pregnancy by the development of a low priced combined
15 acellular pertussis/tetanus vaccine.

16 In addition to cost-effectiveness other factors merit consideration. First, is the absolute
17 budget impact of the programme which will be relatively inexpensive as it will cost below £10 million
18 per year. Second, is the guaranteed protection the programme provides, compared with the
19 uncertainties of relying on herd immunity. It therefore provides reassurance that whatever happens
20 to the transmission of disease in the future we have an intervention in place that can protect
21 vulnerable infants. Third, are the wider benefits that will accrue from that programme that have not
22 been included in the current cost-effectiveness analysis. Under the NICE guidelines, any QALY loss to
23 care givers is not included in a cost-effectiveness analysis. Nevertheless prevention of death of a
24 young infant prevents grief in the parents and their direct social network. Fourth, the direct
25 protection of the mother, which will last for some years, might prevent transmission within the
26 household on later occasions. A recent household contact study in the Netherlands showed that

1 mothers played a key role in transmission of pertussis to other household members as well as her
2 infant [8].

3 Other countries have used alternative strategies to control the transmission of pertussis
4 such as a booster dose in adolescence. However the direct contact between adolescents and young
5 infants is low [21], hence the impact of this programme relies on the vaccine having an impact on
6 disease transmission and the importance of adolescents in driving the infection among people who
7 do have contact with infants. Pertussis incidence in infants under one year of age has continued to
8 rise despite the introduction of the adolescent booster in the US, though coverage has not been high
9 [19]. Also vaccinating adolescents might increase the average age of infection resulting in more
10 susceptible young mothers.

11 In conclusion, while maternal vaccination is a highly effective intervention for preventing
12 deaths and severe pertussis illness among young infants, its ICER as judged by standard NICE criteria
13 may not be favourable if future incidence remains as observed in 2010-2012. However the maternal
14 programme has a major benefit compared with the existing paediatric programme as it offers the
15 opportunity to directly protect this highly vulnerable population, who previously could only be
16 indirectly protected by herd immunity which has proven to be unreliable. Given the uncertainty
17 about the ability of acellular vaccine to protect against transmission and maintain high levels of herd
18 immunity, provision of passive protection to infants until they can develop their own active
19 immunity through vaccination would seem prudent at least for the time being. Therefore it has been
20 decided to keep the maternal vaccination in place in the United Kingdom for at least another 5
21 years, and to re-evaluate its cost-effectiveness in the light of the future epidemiology of pertussis
22 [22].

4 Funding

5 AJVH was part funded by the National Institute for Health Research Health Protection Research Unit
6 (NIHR HPRU) in Immunisation at the London School of Hygiene and Tropical Medicine in partnership
7 with Public Health England. The views expressed are those of the authors and not necessarily those
8 of the NHS, the NIHR, the Department of Health or Public Health England. The NIHR had no role in
9 study design, data collection and analysis, decision to publish, or preparation of the manuscript.

10

11 Conflict of interest

12 The authors do not have any conflict of interest to declare. All authors have completed the ICMJE
13 uniform disclosure form at http://www.icmje.org/coi_disclosure.pdf and declare: no support from
14 any organisation for the submitted work; no financial relationships with any organisations that might
15 have an interest in the submitted work in the previous three years, no other relationships or
16 activities that could appear to have influenced the submitted work.

17

18 Contributions

19 AJVH, HC, GA, NA and EM conceptualised the study. AJVH, in assistance of HC and NC, collected and
20 structured all the input. AJVH performed all the modelling and programming. AJVH and EM drafted
21 the first manuscript. All authors read and commented on the final draft.

22

1 Transparency

2 AJVH affirms that the manuscript is an honest, accurate, and transparent account of the study being
3 reported; that no important aspects of the study have been omitted; and that any discrepancies
4 from the study as planned (and, if relevant, registered) have been explained.

2 Figures

3

4 Figure 1 Monthly incidence of hospitalised pertussis among infants (left axis) and laboratory
5 confirmed cases among women aged 20-44 years (right axis).

6 Figure 2 Comparison of the disease incidence model with peaks every 4 years as observed in 2012.

7 Figure 3. The fluctuation of the cost-effective price per dose in the base-case scenario. In high
8 incidence years the price is over £10 (3.5%/3.5% discounting), however in the low incidence years
9 the price per dose is below £0, which means that the maximum cost per dose goes below £7.5 (the
10 administration cost).

11

12 Figure 4 The effect of an expanding time horizon on the price. Shown is the price at which 50% of the
13 scenarios is deemed cost-effective under a threshold of £20,000 with an expanding time horizon
14 under the two discounting scenarios. The value of 2 months, uses a time horizon of 2 months, 3

- 1 month/ 3 month etc. The profile of the first few years is highly dependent on where you start in the
- 2 epidemic cycle.
