ABSTRACT

Clock Distribution Network Optimization by Sequential Quadratic Programming.

(May 2010)

Venkata Rajesh Mekala, B.E., Birla Institute of Technology and Science - Pilani,
India

Chair of Advisory Committee: Dr. Jiang Hu

Clock mesh is widely used in microprocessor designs for achieving low clock skew and high process variation tolerance. Clock mesh optimization is a very difficult problem to solve because it has a highly connected structure and requires accurate delay models which are computationally expensive.

Existing methods on clock network optimization are either restricted to clock trees, which are easy to be separated into smaller problems, or naive heuristics based on crude delay models.

A clock mesh sizing algorithm, which is aimed to minimize total mesh wire area with consideration of clock skew constraints, has been proposed in this research work.

This algorithm is a systematic solution search through rigorous Sequential Quadratic Programming (SQP). The SQP is guided by an efficient adjoint sensitivity analysis which has near-SPICE(Simulation Program for Integrated Circuits Emphasis)-level accuracy and faster-than-SPICE speed.

Experimental results on various benchmark circuits indicate that this algorithm leads to substantial wire area reduction while maintaining low clock skew in the clock mesh. The reduction in mesh area achieved is about 33%.

To GOD and my family

ACKNOWLEDGMENTS

I would like to thank all the people who have helped and inspired me during my graduate studies at Texas A&M University.

I especially would like to thank my advisor, Dr. Jiang Hu, who guided me throughout the course of two years of study at Texas A&M University. His ceaseless support always encouraged and motivated me to complete the project. I sincerely thank him for helping me out and for being my role model.

I thank Dr. Peng Li for his suggestions and valuable discussions. They were very helpful for my research work.

I thank Yifang Liu for his assistance and great support in the completion of this project. I would also like to thank Xiaoji for his help throughout the course of the project.

My deepest gratitude goes to my family and friends for their unflagging love and support throughout my life; this thesis was simply impossible without them.

I also like to thank Dr. Donald K. Friesen for agreeing to be a part of my committee and for teaching an excellent course on algorithms which formed the basis of my understanding on algorithms.

I extend my gratitude to the professors and staff in the Computer Engineering group of the ECE department at Texas A&M University and for guiding and helping me in one form or the other.

Last but not least, thanks to GOD for making me overcome all the hurdles of life.

CHAPTER I

INTRODUCTION

The clock signal is one of the critical interconnect signals on a chip. A Clock Distribution Network (CDN) delivers the clock signal from the source to the target flip-flops. There exist several topologies/architectures for the clock distribution networks [1]. A clock distribution network is shown in Fig. 1. which consists of multiple stages of clock buffering and an interconnect network.

Fig. 1. A clock network with several levels of buffering and interconnect wire segments.

To distinguish the quality between the clock networks, the clock designers weigh them based on the metrics like skew, slew and the power of a CDN. Designing a clock network is always a compromise between accomplishable skew, slew, power and

routing resources. In this research work, we focus on formulating the problem with the clock skew as a constraint.

The clock skew arises from a difference in latency from the clock source to the target flip-flops on the chip. Various factors such as Process variations, Voltage, Temperature (PVT) and cross coupling noise affect the clock skew [2–4]. If the clock skew is not properly controlled, timing violations and system failures are possible. Ideally, we wish to have “zero” skew which allows the accurate synchronization of functionalities across the chip with an improvement in performance. Fig. 2. shows a simple case where there is a delay difference between the clocks of the source and the target flip-flops.

Fig. 2. Clock skew arising due to delay mismatch between the clock source and target flip-flops. The skew till CLK1 is t_1 , till CLK2 is t_2 and till CLK3 is t_3 .

The power is also a serious bottleneck for chips operating at a higher frequencies. There is always a compromise between the achievable performance measured in terms of frequency of the clock and the power dissipation inside the chip. Thus, the power dissipated inside the chip is also emerging as an important consideration during the design of a clock network. The clock distribution network dissipates up to 40% of the chip power [5]. This includes only the dynamic power dissipated in the clock

network due to the charging and discharging of the clock node capacitances¹. The total capacitance to be driven by the clock buffers includes the capacitance of the interconnect and the sink capacitance associated with the flip-flops.

The CDNs could be broadly categorized into trees and non-tree networks. In many of the Application Specific Integrated Circuit (ASIC) designs, the clock is distributed across the chip using a clock tree. A clock tree network is a routing tree where the clock driver is the root node and the clock sinks are the leaf nodes. The clock tree synthesis is pretty much automated and it dissipates lesser power compared to other CDNs. However, a clock tree has low tolerance to process variations.

When it comes to high-performance microprocessors there are stringent constraints on the maximum allowed clock skew. In such cases, the clock mesh offers uniform, low skew clock distribution and offers better tolerance to On-Chip Variations (OCV) than a conventional clock tree. A clock mesh network is a grid of interconnects driven by buffers at various points and the clock sinks are connected to the nearest wire segment of the mesh. To cope with the process variations, an attractive option is to design a clock mesh which is robust and has higher tolerance towards process variations [4]. The clock mesh uses the redundancy created by loops to even out the delays across sink nodes distributed on the chip [4].

Many hybrid clock mesh topologies were analyzed in the past [1]. Among them we use the topology with a uniform clock mesh that is driven by a global buffered tree (as seen in Fig. 3.). The local interconnect referred as stubs, connects the clock ports of flip-flops to the nearest point on the mesh. The clock mesh on the flipside consumes a large area (metal resources) and dissipates higher power [6] compared

¹The flip-flops are quantified using the gate capacitance of the clock port. The flip-flops are often called as the sinks. The capacitance associated with the clock port in a flip-flop is called sink capacitance.

to the other CDNs. So, the clock mesh designs aim for a lower skew coupled with targeting for lesser power.

Fig. 3. A clock mesh network comprising of a clock driver, a H-tree driving the mesh buffers, a clock mesh and the sink capacitances.

A. Previous Works

Many of the research works like [2, 3, 7] centered on coping with the process variation effects on the clock skew. This was anticipated as the process variations impact the interconnects to a large extent and the clock signal is one of the most important on-chip interconnect signal.

The research on CDNs could be categorized into problems focused on solving clock tree and non-clock tree networks. The clock tree structures are well understood and the algorithms were targeted to size the interconnect network and buffers driving the clock tree in a divide-and-conquer fashion. However, this kind of approach is difficult to straightaway apply to a clock mesh.

In the next section, we summarize the research done on clock networks, the related optimization techniques and the approaches used to solve the problems formulated.

1. Clock Tree Networks

The research work described in [8] uses a moment-based sensitivity analysis to reduce the clock skew in a clock tree network. This is better than Elmore delay² computation as it matches several moments in the delay calculations instead of the Elmore delay. To improve the run-time of sensitivity-based methods they we also present heuristics. This technique is restricted to a clock tree. It is difficult to extend the technique to a clock mesh.

The objective of minimizing the skew under a power budget was proposed in [6]. They utilized Sequential Quadratic Programming (SQP) for solving the problem.

²Elmore delay is a simple first order approximation to the delay through an RC network.

However, the SQP they used is not rigorous but is based on breaking down the problem into quadratic programming sub-problems using heuristics. They used a simple extraction model for interconnect wire resistance and capacitance in a clock tree. Even though their objective function was quadratic, the delay versus size function is a linear approximation. Hence, its delay computation is inaccurate.

The clock tree sizing problem subject to skew constraints has been formulated in [9]. The sensitivities of delays with respect to buffer and wire sizes were computed and the power dissipated in the clock tree was minimized. Sequential Linear Programming (SLP) was used as the optimization technique. Their methodology was to modify the non-linear programming problem into a sequence of linear problems. The simulations were performed using SPICE³ model for clock buffers. They used a divide-and-conquer approach to compute the sensitivities so that the SPICE run-time can be reduced. The divide-and-conquer approach applies only to clock trees.

The clock tree's relatively separable topology allows them to use sophisticated algorithms and delay computations in a divide-and-conquer manner. However, it is unclear how to extend them to a clock mesh.

2. Non-clock Tree Networks

The redundancy existing in a non-clock tree network offers resistance to PVT variations. However, the redundancy is often compromised to minimize the power. Non-clock tree networks can be categorized into crosslinks and clock mesh.

³Simulation Program with Integrated Circuit Emphasis (SPICE) is a general-purpose circuit simulation program

a. Crosslinks

An algorithm based on inserting crosslinks in a clock tree network was proposed in [10]. The link insertion scheme converts a clock tree into a non-clock tree network to meet the skew constraint trading off wire length to achieve it.

The work in [11] investigates the buffer and wire sizing problem in a link based non-tree clock network. The algorithms for crosslinks are mostly based on using heuristics and are difficult to extend them to a clock mesh.

b. Clock Mesh

The timing uncertainty in clock-mesh based architectures has been analyzed in the presence of parameter variations in [4]. They modeled the sources of uncertainties assuming a distribution for parameter variations and obtained the delay distribution curve at each flip-flop. It states that the clock mesh is efficient in reducing the timing uncertainties. A Sliding Window Scheme (SWS) was proposed here to compute the clock latencies in mesh-based architectures.

The problem of removing the non-critical wire segments in a clock mesh to minimize the power dissipated was formulated using network survivability theory [12]. Combinatorial algorithms were proposed to solve this problem.

The recent paper on Meshworks [13] proposed work on obtaining good quality initial solution for a clock mesh. The problem of trading off skew and power has also been addressed. The methodology deals with automated planning, synthesis and optimization for a clock mesh. The problem uses Elmore model for the clock mesh and the algorithm is a greedy heuristic.

In [14], network algorithms were proposed to solve the linear programs derived for the sizing of interconnect elements of the clock mesh topology. The sizing algorithm

and the delay calculations were based on Elmore model of the interconnects. Due to relative inaccuracy of Elmore model, this research is applicable only at early stages of the design.

The design of a clock mesh is challenging as we need to use sophisticated delay model for accurately measuring the delay values. The components in a clock mesh are highly coupled with each other which makes it difficult to separate the original problem into smaller problems and solve. Some difficulties arise while trying to analyze the clock mesh. They are: a large number of metal loops exist in a mesh structure complicating the analysis [4], a large amount of memory and run-time is required for the simulations, the clock mesh is difficult to model accurately [7] and the process variations add difficulty in formulating the delay from clock root to flip-flop nodes.

The following section discusses about how this research work presented in the thesis is dissimilar from the existing and previous works on clock networks.

B. Motivation and Our Contributions

As discussed previously, one of the significant challenges in clock mesh optimization is the complexity of the network. The difficulty motivated the use of simple Elmore models or partial SPICE solutions in earlier works and lead to various observed limitations.

Various factors distinguish our work with many of the previous or existing works on a clock mesh network. In this work, we first adopt a current-source based gate modeling approach to speedup the accurate analysis of large mesh networks with near SPICE accuracy. Further, we develop efficient adjoint sensitivity analysis capability to provide desirable design sensitivity information, which allows a much more rigorous application of SQP formulation, leading to improved solution quality and generality.

A rigorous Sequential Quadratic Programming (SQP) approach is used contrary to many of the previous works which simply solve a nonlinear programming problem through a sequence of quadratic approximations. We use the Karush-Kuhn-Tucker (KKT) conditions to improve the computational efficiency. A quadratic delay formula used in our problem improves the accuracy compared to a linear delay approximation used in [6]. So, we use the quasi-newton approximation formula for obtaining the second-order derivatives of variables considered in the problem.

To the best of our knowledge, our work is the first clock mesh sizing method that does systematic solution search and is based on accurate delay model. Several benchmarks from ISPD [15] and ISCAS [16] are evaluated using the algorithm. The average improvement obtained in clock mesh area over the benchmarks is around 33%.

In the further sections we describe the efficacy of using a rigorous Sequential Quadratic Programming (SQP) approach to solve the problem of minimizing the power dissipation in a clock mesh satisfying the skew constraints. The variables we sought to vary are the widths of the wire segments of a clock mesh.

CHAPTER II

CLOCK NETWORK OPTIMIZATION

A. Problem Formulation

Given a clock distribution network consisting of a clock mesh driven by a clock tree, our objective is to minimize the power dissipation of the clock network while meeting skew constraints by means of sizing the interconnects in the clock mesh. Independent variables in this continuous optimization problem include the sizes of all the interconnects in the mesh. Power dissipation is approximately measured by the total wire area. The skew is presented in a delay variance form. To restrict the skew among all sinks of the network, the maximum value of delay variance is set by the problem.

Let I be the set of interconnects in the mesh. Denote by $x_i, i \in I$ the width/size of element i in the interconnect set. The area of the i^{th} element is represented by w_i . Apparently, the area occupied by a wire segment is linear to the its size. Let S be the set of all the sinks of the network. Denote by $d_j, j \in S$ the propagation delay of the signal from the root of the clock tree to sink j . Now, we formulate our problem as follows:

$$\text{Minimize:} \quad w = \sum_{i \in I} w_i = \mathbf{x}^T D, \quad (2.1)$$

$$\text{s. t.} \quad \sigma^2 = \sum_{j \in S} (d_j - \mu)^2 \leq \delta, \quad (2.2)$$

$$L_{\mathbf{x}} \leq \mathbf{x} \leq U_{\mathbf{x}},$$

where D is the coefficient vector reflecting the linear size-area relation, $\mu = \frac{\sum_{j \in S} d_j}{|S|}$ is the average value of the sink delays, and δ is the given maximum variance. L_x and

U_x represent the lower bound, upper bound vectors of the wire widths respectively.

The skew constraint in the variance form has many advantages compared to maximum skew formula. The quadratic form is a differentiable function whereas maximum skew ($\forall(i, j \in S) \text{Max}|d_i - d_j|$) form is non-differentiable.

As an analogy, the quadratic cost can be thought of as connecting each pair of sinks with a spring in the time domain and then trying to minimize the total energy in the system of springs [6].

B. Algorithm Overview

The flow-chart shown in Fig. 4. summarizes the important steps of the Clock Mesh Sizing using Sequential Quadratic Programming (CMSSQP) algorithm. The SPICE netlist is generated with an initial topology of clock mesh for the specified benchmark. The sensitivity analysis program generates the sensitivities of each wire segment in the clock mesh with respect to its resistance and capacitance. Details of the sensitivity calculations are provided in Chapter III. The sensitivities with respect to wire widths are calculated with the help of chain rule in Eqn. 2.3.

$$\frac{\partial \sigma^2}{\partial X} = \left(\frac{\partial \sigma^2}{\partial R} \cdot \frac{\partial R}{\partial X} \right) + \left(\frac{\partial \sigma^2}{\partial C} \cdot \frac{\partial C}{\partial X} \right) \quad (2.3)$$

A transient simulation of the clock mesh gives the delay values with respect to the input waveform at all sink nodes. We compute the delays from the transient simulation waveform contrary to many of the previous works focused on calculating the Elmore delays. We use compact delay models for the buffers driving the clock mesh [17]. The quasi-newton approximation of the Hessian matrix is computed and then the quadratic programming sub-problem is formulated and solved.

After completion of one iteration of the Clock Mesh Sizing using Sequential

Quadratic Programming (CMSSQP), we get the size change vector for all wire segments of the clock mesh. The wire segment widths vector is updated and the steps described above are repeated in the same fashion until a convergence criterion is satisfied.

The convergence criterion can be taken as a constant number of iterations or until there is no significant reduction in clock mesh area in successive iterations.

We use strict sequential quadratic programming approach to solve the clock mesh optimization problem. SQP is driven by gradient and Hessian of objective and constraint functions. This information is needed to formulate the quadratic programming sub-problems. Therefore, the sensitivity analysis is essential to provide accurate gradient computation (information in Chapter III.). The sensitivity analysis we used gives us the values of the sensitivities of skew variance constraint function with respect to wire segment's resistance and capacitance i.e. $\frac{\partial \sigma^2}{\partial R}$ and $\frac{\partial \sigma^2}{\partial C}$. These values are used to compute the sensitivities of skew variance constraint function with respect to wire segment's width i.e. $\frac{\partial \sigma^2}{\partial X}$ using a simple chain rule as given in Eqn. 2.3.

These values are used to solve the quadratic programming sub-problems. Fig. 5. shows the π -model of a clock mesh. The resistance, capacitance values are calculated for each wire segment of the clock mesh using the formulae displayed in the figure. The Hessian value is obtained in each iteration of CMSSQP using quasi-newton method. The power dissipation is indirectly measured by the total interconnect area. Reducing the clock mesh area reduces the interconnect load capacitance seen by the buffers driving the clock mesh. Thus, reducing the clock mesh area reduces the total dynamic power dissipation.

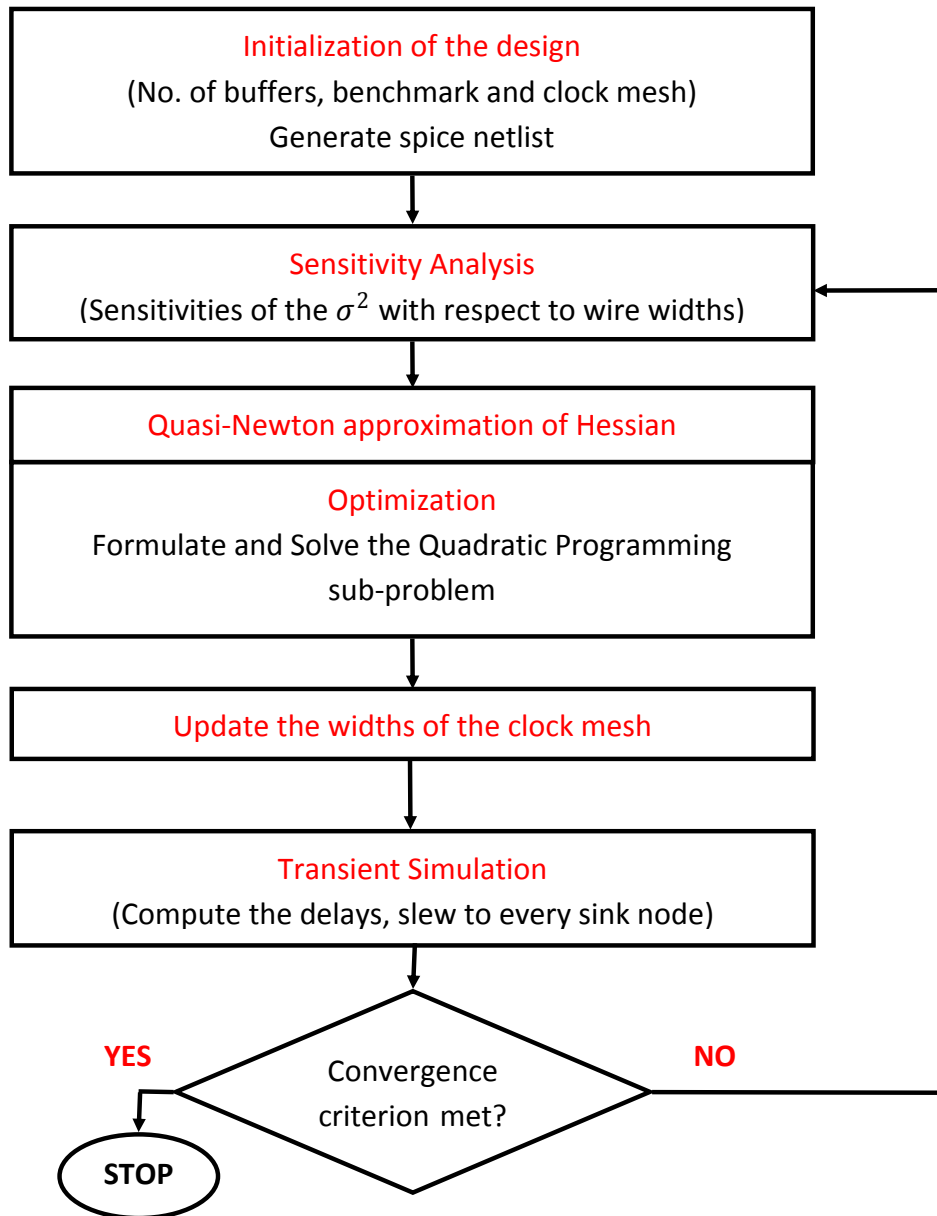

Fig. 4. CMSSQP framework, flowchart depicting the different steps of CMSSQP algorithm.

Fig. 5. π model of a clock mesh.

The following sections describe the SQP, sensitivity analysis and the results we obtained.

C. Sequential Quadratic Programming (SQP) for Clock Network Sizing

1. Sequential Quadratic Programming

The delay (\mathbf{d}) of signal to sinks is in complex relation to element sizes (\mathbf{x}), which make the constraint of clock network optimization problem very difficult to handle in optimization. Our approach is to capture the sensitivity of skew variation with respect to the size of all the elements in the network and improve the skew and power consumption in a local region one step at a time. Intuitively, repeating this improvement in multiple iterations makes the element size vector move towards the best solution for the whole problem. This kind of strategy is backed up by a well-founded optimization method called Sequential Quadratic Programming (SQP) [18].

Basically, SQP breaks the original problem into a sequence of sub-problems.

Each of these sub-problems is a Quadratic Programming problem (QP), which can be solved efficiently. That is, the original highly complex problem is turned into a sequence of quadratic programming problems. One set of critical values in this transform are the gradient of the Lagrangian. Denote by $\mathcal{L}(\mathbf{x}, \lambda)$ the Lagrangian of the original problem in Eqn. 2.1. and Eqn. 2.2., i.e.,

$$\mathcal{L}(\mathbf{x}, \lambda) = \mathbf{x}^T D - \lambda(\delta - \sigma^2). \quad (2.4)$$

Denote by $\nabla_{\mathbf{x}}\mathcal{L}(\mathbf{x}, \lambda)$ the gradient vector of the Lagrangian function, i.e.,

$$\nabla_{\mathbf{x}}\mathcal{L}(\mathbf{x}, \lambda) = D + \lambda\nabla_{\mathbf{x}}\sigma^2. \quad (2.5)$$

For a specific setup of all mesh wire widths in the clock network, the gradient of sink delay variance, $\nabla_{\mathbf{x}}\sigma^2$, can be obtained by circuit simulation and advanced sensitivity analysis, details of which is explained later in chapter III. In this section, we use $\nabla_{\mathbf{x}}\sigma^2$ in our derivation as it is given by the sensitivity analysis.

To see how to solve the original problem given in Eqn. 2.1. and Eqn. 2.2., we start with the Karush-Kuhn-Tucker (KKT) conditions of the problem, which are the necessary conditions for any optimal point of the problem. The KKT conditions imply that the gradient of the Lagrangian is zero and the constraints are satisfied at the optimal point, i.e., for our problem,

$$D + \lambda\nabla_{\mathbf{x}}\sigma^2 = 0, \quad (2.6)$$

$$\delta - \sigma^2 \geq 0. \quad (2.7)$$

One common way to solve an equation as Eqn. 2.6. is Newton's method. Basically, Newton's method searches for the root of an equation $f(x) = 0$ in an iterative matter. Starting from an initial point x_0 , the method finds the next approximation,

x_1 , by first order derivative. This operation continues in iterations until it converges to the root. In the n^{th} Newton iteration, the new approximation is calculated as $(J_n * (x_{n+1} - x_n)) = -f(x_n)$, where J_n is the Jacobian matrix evaluated at x_n ,

$(x_{n+1} - x_n)$ is a Newton step. In our case, the solution of Eqn. 2.6. is approached by utilizing the same scheme.

Let the Newton step in iteration k of solving Eqn. 2.6. be

$$\begin{bmatrix} \mathbf{p}_{\mathbf{x},k} \\ \mathbf{p}_{\lambda,k} \end{bmatrix} = \begin{bmatrix} \mathbf{x}_{k+1} \\ \lambda_{k+1} \end{bmatrix} - \begin{bmatrix} \mathbf{x}_k \\ \lambda_k \end{bmatrix},$$

where \mathbf{x} and λ are all variables in the equation, $\mathbf{p}_{\mathbf{x},k}$, $\mathbf{p}_{\lambda,k}$ are the vectors representing change in width of wires and Lagrangian multiplier.

The Jacobian of Eqn. 2.6. is given by:

$$\begin{bmatrix} \nabla_{\mathbf{xx}}^2 \mathcal{L}(\mathbf{x}, \lambda) & \nabla_{\mathbf{x}} \sigma^2 \end{bmatrix}.$$

Denote by $H = \nabla_{\mathbf{xx}}^2 \mathcal{L}(\mathbf{x}, \lambda)$ the Hessian of the Lagrangian function. Then, the Newton step calculation implies that $\mathbf{p}_{\mathbf{x},k}$ and $\mathbf{p}_{\lambda,k}$ satisfy the following system:

$$\begin{bmatrix} H_k & \nabla_{\mathbf{x}} \sigma_k^2 \end{bmatrix} \begin{bmatrix} \mathbf{p}_{\mathbf{x},k} \\ \mathbf{p}_{\lambda,k} \end{bmatrix} = \begin{bmatrix} -D - \lambda_k \nabla_{\mathbf{x}} \sigma_k^2 \end{bmatrix}. \quad (2.8)$$

Simple manipulation to Eqn. 2.8. gives us:

$$H_k \mathbf{p}_{\mathbf{x},k} + D + \lambda_{k+1} \nabla_{\mathbf{x}} \sigma_k^2 = 0 \quad (2.9)$$

Eqn. 2.9. can be solved by:

Minimize:

$$\frac{1}{2} \mathbf{p}_{\mathbf{x}}^T H \mathbf{p}_{\mathbf{x}} + D^T \mathbf{p}_{\mathbf{x}}, \quad (2.10)$$

s. t.

$$\delta - \sigma^2 \geq 0,$$

which is the constraint given in Eqn. 2.7. Note that Eqn. 2.9. is actually a KKT condition (zero gradient of Lagrangian function) of the optimization problem above.

Therefore, by transforming a Newton iteration, which solves the KKT conditions given in Eqn. 2.6., into a Quadratic Programming (QP) problem, one iteration of solving the original problem given in Eqn. 2.1. and Eqn. 2.2. is turned into a QP sub-problem as following:

$$\text{Minimize:} \quad \frac{1}{2} \mathbf{p}_x^T H \mathbf{p}_x + D^T \mathbf{p}_x, \quad (2.11)$$

$$\text{s. t.} \quad \delta - (\sigma^2 + (\nabla_x \sigma^2)^T \mathbf{p}_x) \geq 0, \quad (2.12)$$

$$L_x \leq \mathbf{x} \leq U_x,$$

where size step \mathbf{p}_x consisting of size change for all elements in \mathbf{x} is the solution of the system. The multiplier step \mathbf{p}_λ is obtained from Newton's step 2.8. given \mathbf{p}_x .

After solving the QP sub-problem in Eqn. 2.11. and Eqn. 2.12. in an SQP iteration, we get the step values \mathbf{p}_x of the wire width variables. Then, the Lagrangian multiplier's step value \mathbf{p}_λ can be obtained from Eqn. 2.9. with known \mathbf{p}_x . Thereafter, the values of \mathbf{x} and λ are updated accordingly.

There are various methods to solve the quadratic programming sub-problem in 2.11. and 2.12 efficiently. In order to formulate the QP sub-problem and give it to a QP solver engine, we need to have both the gradient and the Hessian of the Lagrangian function. As we have mentioned previously, through sensitivity analysis we obtain the gradient. However, computing Hessian using techniques like sensitivity analysis is too expensive. The runtime is prohibitive in this way. Therefore, in practice we approximate the Hessian given the gradient. Here, we use quasi-newton

method to approximate the Hessian $H = \nabla_{\mathbf{x}\mathbf{x}}^2 \mathcal{L}(\mathbf{x}, \lambda)$.

To sum up the sequential quadratic programming (SQP) method above, we list the major steps in each iteration of SQP in Algorithm 1. Line 3 in the outline of the algorithm represents the operation of circuit simulation and sensitivity analysis. Line 4 is dedicated to formulate the QP sub-problem with calculated Hessian and gradient and solve the sub-problem.

2. Quasi-Newton Approximation of Hessian

In this section, we describe the Hessian approximation method we utilize in this work. Since the BFGS method [19] we use is a well-adopted quasi-newton algorithm, only the major steps of the procedure are outlined here. Denote by \tilde{H} the approximation to the real Hessian. In iteration $k + 1$, the approximation \tilde{H}_{k+1} is calculated based on \tilde{H}_k from previous iteration.

To simplify the presentation, we define the changes on the wire width variables and the gradient as follows.

$$s_k = \mathbf{x}_{k+1} - \mathbf{x}_k, \tag{2.13}$$

$$y_k = \nabla_{\mathbf{x}} \mathcal{L}(\mathbf{x}_{k+1}, \lambda_{k+1}) - \nabla_{\mathbf{x}} \mathcal{L}(\mathbf{x}_k, \lambda_{k+1}). \quad (2.14)$$

An effective modification of y_k is defined as

$$r_k = \theta_k y_k + (1 - \theta_k) \tilde{H}_k s_k, \quad (2.15)$$

where

$$\theta_k = \begin{cases} \frac{0.8 s_k^T \tilde{H}_k s_k}{s_k^T \tilde{H}_k s_k - s_k^T y_k}, & \text{if } s_k^T y_k < 0.2 s_k^T \tilde{H}_k s_k \\ 1, & \text{otherwise} \end{cases}$$

The definition of θ_k above guarantees the approximation of the Hessian is always positive definite when it is updated with the following formula.

$$\tilde{H}_{k+1} = \tilde{H}_k - \frac{\tilde{H}_k s_k s_k^T \tilde{H}_k}{s_k^T \tilde{H}_k s_k} + \frac{r_k r_k^T}{s_k^T r_k}. \quad (2.16)$$

CHAPTER III

SENSITIVITY ANALYSIS

The sensitivities in Eqn. 2.5. are obtained using adjoint sensitivity analysis. The adjoint sensitivity analysis [17] has been developed by Dr. Peng Li and Xiaoji Ye. The idea of adjoint sensitivity analysis is to construct an adjoint circuit whose topology is identical to the original circuit, by properly setting up the branch constitutive relations and input stimulus of the adjoint circuit, the desired sensitivity information of the original circuit can be obtained by doing a convolution-like computation between transient waveforms of the original and the adjoint circuit.

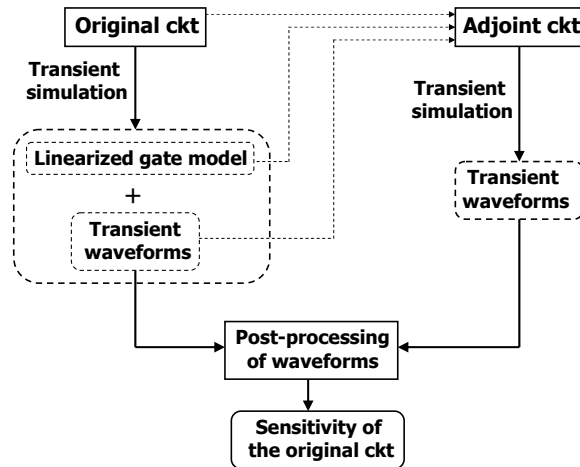

Fig. 6. Analysis flow of the adjoint sensitivity analysis framework.

The analysis flow of the proposed adjoint sensitivity analysis framework is shown in Fig. 6. First of all, we simulate the clock mesh to generate its transient waveforms. Since we use compact gate model [17] instead of transistor level model for nonlinear clock drivers, linearized compact gate model at every time point is saved for the

purpose of constructing the adjoint circuit later. Once the simulation of the original circuit is finished, an adjoint circuit is constructed based on the original circuit, transient waveforms of the original circuit and linearized gate models. The adjoint circuit is essentially a time-varying linear circuit. We then simulate the adjoint circuit to obtain its transient waveforms. After the simulation of the adjoint circuit is finished, we post-process the original transient waveforms and adjoint transient waveforms to get the sensitivity information of the clock mesh. The original circuit/clock mesh and its corresponding adjoint circuit are shown in Fig. 7. The detailed derivation and formulas of the adjoint analysis can be found in [20].

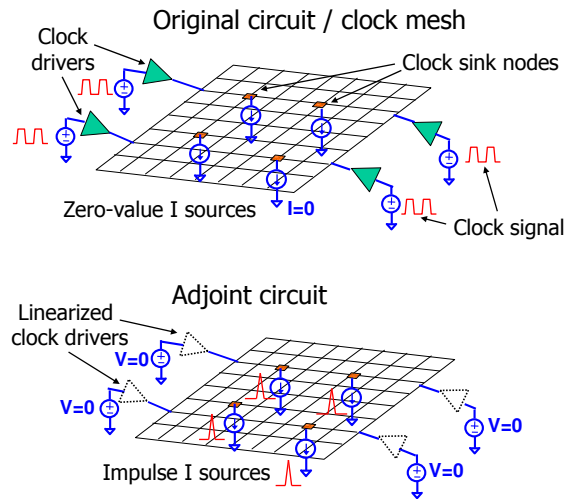

Fig. 7. Original and adjoint circuits in the adjoint sensitivity analysis for clock mesh.

Notice that clock mesh has nonlinear clock drivers which need special treatment. In this work, we adopt the waveform independent gate model [17] to model nonlinear clock drivers. The compact gate model provides up to two orders of magnitude speedup over SPICE simulation while maintaining the same level of accuracy. The

detailed structure of the two-stage gate model is shown in Fig. 8. The first stage is a second-order RC stage which models the internal gate delay. The output node of the first stage is a fictitious node whose voltage response V_c is the controlling voltage for the second stage. The second stage consists of a voltage-controlled current source $I_n(V_c, V_o)$ and a nonlinear capacitor $Q_{nc}(V_c, V_o)$, both of which are controlled by V_c and the output voltage V_o of the gate.

Fig. 8. Detailed structure of the two-stage waveform independent gate model.

The general principle of adjoint circuit analysis still holds for nonlinear circuits since adjoint circuit analysis is derived from Tellegen's theorem which only depends on the Krichhoff's Current and Voltage Laws. During the simulation of the original circuit, at each timepoint, the nonlinear current source I_n and nonlinear capacitor Q_{nc} are linearized into linear elements,

$$\begin{aligned} I_n(V_c, V_o) &= \frac{\partial I_n}{\partial V_c} \cdot V_c + \frac{\partial I_n}{\partial V_o} \cdot V_o \\ &= g_c \cdot V_c + g_o \cdot V_o \end{aligned} \quad (3.1)$$

$$\begin{aligned} Q_{nc}(V_c, V_o) &= \frac{\partial Q_{nc}}{\partial V_c} \cdot V_c + \frac{\partial Q_{nc}}{\partial V_o} \cdot V_o \\ &= C_c \cdot V_c + C_o \cdot V_o \end{aligned} \quad (3.2)$$

where $g_c \cdot V_c$ represents a voltage-controlled current source, g_o is a regular conductance, C_c represents a transcapacitance whose charge is controlled by V_c , C_o is a regular

capacitor. In the adjoint circuit, g_o and C_o remain the same; for controlled elements, the controlling and controlled branches are swapped. The linearized gate model in the original circuit and its corresponding form in the adjoint circuit are shown in Fig. 9. Notice here the first stage of the gate model in the adjoint circuit is essentially isolated from the entire circuit since it does not control the second stage or other part of the circuit now. During the simulation of the original circuit, g_o , g_c , C_c and C_o are varying, therefore, the adjoint circuit is a time-varying linear circuit. If different gate model or transistor-level gate model is used to simulate the clock drivers in the original circuit, we can still linearize each nonlinear element into linear elements and apply the procedure for linear elements to handle them.

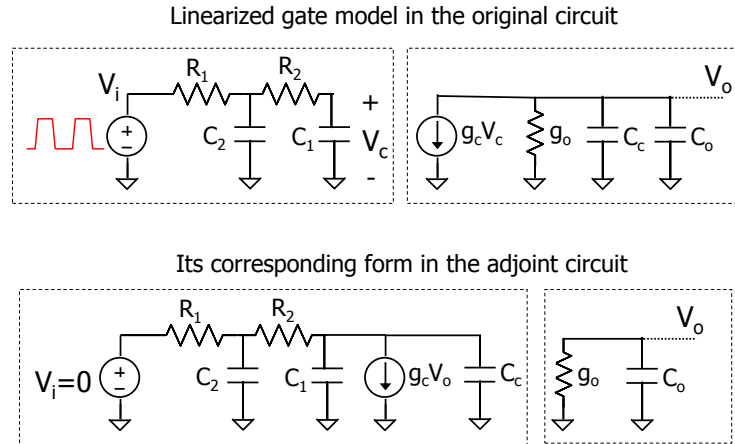

Fig. 9. Linearized gate model and its corresponding form in the adjoint circuit.

CHAPTER IV

RESULTS AND CONCLUSIONS

A. Experimental Setup

The benchmarks are taken from International Symposium on Physical Design (ISPD [15]) and International Symposium on Circuits and Systems (ISCAS [16]). Sample formats of these benchmarks are shown in appendix A. The Berkeley Predictive Technology Model (BPTM [21]) 65nm technology transistor models are used for designing the buffers driving the clock mesh. The clock mesh designed is a uniform grid of wires spanning the entire area. A mesh of size $(m \times n)$ has m rows and n columns of wires. The total area of the clock mesh is calculated with the formula given in Eqn. 4.1.

$$\text{Total area of the clock mesh} = \sum_{i \in I} w_i l_i \quad (4.1)$$

where w_i is the width and l_i is the length of a wire segment within the clock mesh. The mesh is driven by buffers placed uniformly on the clock mesh. The number of buffers are adjusted such that the slew numbers are reasonable for the initial design. The initial slew numbers are reported in Table I. The π model (refer to Fig. 5.) is used for the interconnect wire segments of the clock mesh. The supply voltage is 1.2V. The skew among all the sinks in the clock mesh benchmark is calculated using the formula: $(\forall(i, j \in S) \text{Max}|d_i - d_j|)$ where d_i is the delay to the i^{th} sink point.

All the different components of the Clock Mesh Sizing using Sequential Quadratic Programming (CMSSQP) as can be seen in Fig. 4. are integrated on a top-level using PERL [22] programming language. The sensitivity analysis has been implemented in C++. The quadratic programming sub-problem in Eqn. 2.11. and Eqn. 2.12. is solved using MOSEK [23] optimization engine.

The simulations are run on a Linux platform machine. It has two Intel Xeon E5410 quad-core processors.

The benchmarks are profiled for the distribution of the sink capacitances. A sample distribution of sinks for the benchmark r1 is shown in Fig. 10.

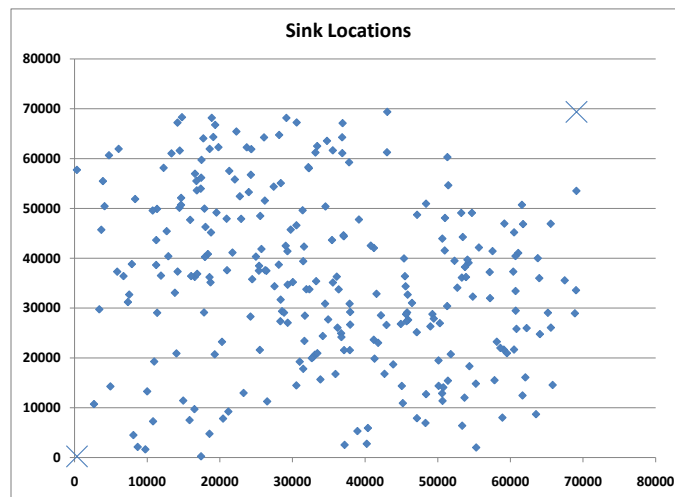

Fig. 10. Sink distribution in r1 benchmark. A point on the graph gives the (x, y) location of a sink capacitance.

This gives an estimate of the initial clock mesh size to be used. Some benchmarks have sparse distribution of the capacitive loads and some have a dense distribution. With reference to Table I., the number of sinks varies from a 91 to 3101 sinks considering all the benchmarks. The clock mesh designed varies in size from a (6×6) to (40×40) dense mesh over all the benchmarks. The subsequent section summarizes the main results obtained using CMSSQP, solution quality, dependence of solution with different design parameters and runtime of CMSSQP.

Table I. Summary of initial clock mesh design results

H-Spice Results

B. Main Results

Tables I., II. and III. summarize the results obtained by executing CMSSQP program on different benchmarks. Columns (1-3) in Tables I., II. and III. represent the characteristics of the benchmarks. The benchmark name, number of sinks in that particular benchmark and the clock mesh size designed are mentioned here. Columns (4-6) in Tables I. and II. show the maximum skew, maximum slew and total clock mesh area before and after executing the CMSSQP algorithm respectively. Columns (4-5) in Table III. show the runtime and percentage reduction in clock mesh area by running CMSSQP program on the corresponding benchmarks. The average reduction in clock mesh area achieved by running CMSSQP on all the benchmarks is about 33%. As seen, the CMSSQP achieves a significant reduction in clock mesh area.

Table II. Summary of results on different benchmarks after executing CMSSQP

H-Spice Results					
Benchmark	No. of sinks	Size of mesh	Final (after CMSSQP)		
			Max Skew (ps)	Max Slew (ps)	Area (μm^2)

As interpreted from the Eqn. 2.2., we have two cases:

1. Case when the skew constraint is relaxed. i.e. if ($\sigma^2 < \delta$), we have the freedom to increase the σ^2 close to δ , decreasing the total area of the clock mesh.
2. Case when the skew constraint is tight. i.e. if ($\sigma^2 > \delta$), CMSSQP drives the solution towards satisfying the skew constraint by either increasing or decreasing the total clock mesh area by **non-uniform sizing** of interconnect wire segment elements.

Fig. 11. shows the trend between the total area of clock mesh and the allowed maximum skew (considering all the sink pairs) for a benchmark ispd09f11. The skew constraint is varied to obtain the values in the figure. As can be ascertained from the figure, the amount of reduction in total area of clock mesh due to non-uniform sizing of mesh elements is proportional to the skew constraint.

Table III. Summary of results demonstrating the runtime and reduction in area obtained by running CMSSQP program on corresponding benchmarks

H-Spice Results				
Benchmark	No. of sinks	Size of mesh	Runtime (s)	Area reduction (%)

r5	3101	32X32	15440	25.9
Average			3110	33

Since, the Hessian matrix estimate starts with a unity matrix, it takes a few iterations to get an accurate value. The minimum area satisfying the skew constraint of ($\sigma^2 < \delta$) as in Eqn. 2.2. is obtained in a few iterations.

The design parameters such as lower bound of the wires (L_x in Eqn. 2.2.) and upper bound of the wires (U_x in Eqn. 2.2.) can be changed to meet the desired skew constraint. The vector of wire widths is limited to values ranging from $0.5 \times$ initial width to $2 \times$ initial width. Fig. 12. represents the case (a), where the skew constraint is relaxed. It shows the variation of the maximum skew among all the sink pairs and the total area of the clock mesh collected for r1 benchmark in each iteration.

The maximum skew has only small increase of about 3ps. The increase of the maximum slew is also very small. Whereas, the reduction in clock mesh area is significant. Fig. 13. represents the case (b), where the skew constraint is tight.

As we can see CMSSQP drives the solution to satisfy the skew constraint at an expense of increasing the total clock mesh area. Other benchmarks exhibit similar

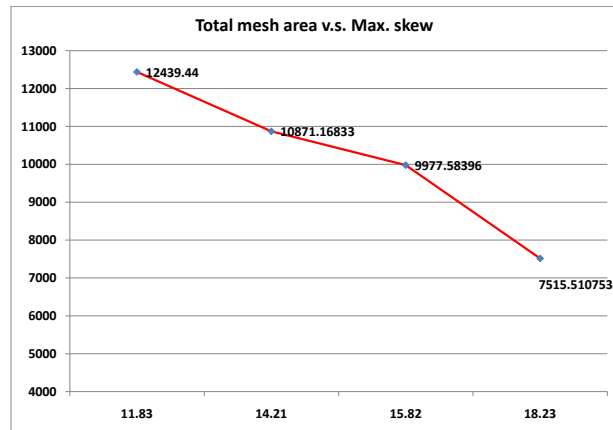

Fig. 11. Area-skew tradeoff by varying δ .

Fig. 12. Case (a): ($\sigma^2 < \delta$), σ^2 , total clock mesh area in each iteration.

Fig. 13. Case (b): ($\sigma^2 > \delta$), σ^2 , total clock mesh area in each iteration.

behavior for the cases (a) and (b). The summary of the improvement in area obtained for the various benchmarks is specified in Table I.

C. Runtime

It was previously pointed out that the runtime for clock mesh simulations is large. However, this difficulty is greatly subdued with CMSSQP. As discussed before, the minimum possible value for clock mesh area is achieved in a few iterations of CMSSQP. CMSSQP drives the solution monotonously towards satisfying the skew constraint.

This improves the overall runtime as it is a systematic search. With reference to Fig. 4., the total time of CMSSQP can be approximated as the sum of time taken by sensitivity analysis, transient simulation and optimization of quadratic programming sub-problem. Fig. 14. shows the dependency of overall runtime of CMSSQP with clock mesh density. We can easily observe that the number of wire segments increase

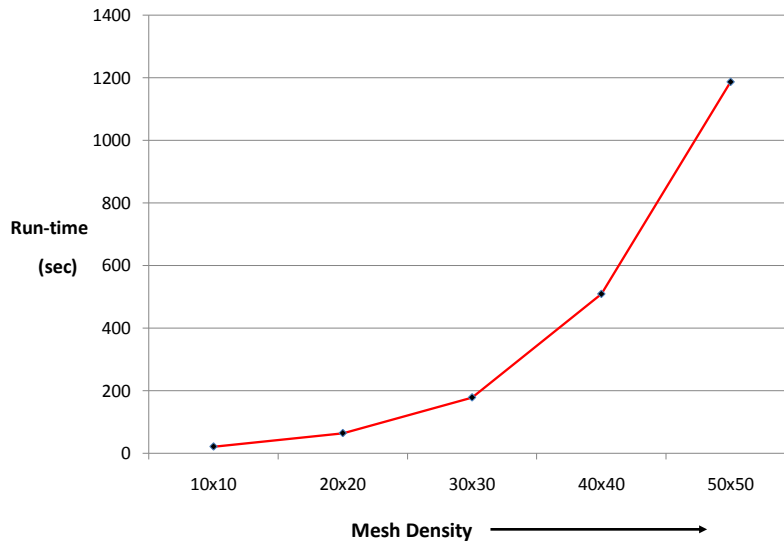

Fig. 14. Runtime of CMSSQP, runtime increases quadratically with mesh size.

quadratically with an increase in mesh density. Thus, the runtime for simulations increase quadratically. Hence, the runtime of the algorithm increases quadratically with the mesh density.

D. Conclusions and Future Work

The research work has been focused on sizing the interconnect elements within the clock mesh. We believe that sizing the interconnect wire segments of the clock mesh and the buffers driving the mesh simultaneously would yield more improvement in the power of a clock mesh area satisfying the constraints. The work presented here can be easily extended for sizing buffers and mesh elements simultaneously.

In this work, we have presented an algorithm for reduction of power satisfying specified skew constraints in a clock mesh. It is fully automated and efficient in terms of time and quality. The CMSSQP program is robust in dealing with any

complex clock mesh network. Also, the solution obtained is a systematic search converging towards satisfying the skew constraint. Experimental results suggest that the CMSSQP can achieve up to 33% reduction of total clock mesh area. This results in a significant reduction in power consumed by the buffers.

The methodology developed is quite generic. It could be applied to any problems which have the objective, constraint functions of the type specified in section 3. Thus, it has been demonstrated that the CMSSQP is an efficient technique in minimizing the the power while meeting the skew constraints in a clock mesh network.

Venkata Rajesh Mekala was born in Vetapalem, India. He completed his Bachelor of Engineering (Hons.) degree in electrical and electronics engineering from the Birla Institute of Technology and Science, Pilani, India in June 2006. He subsequently worked for one year as a design engineer before starting his graduate studies as a computer engineering major at Texas A&M University in the Fall of 2007. His research interests are in digital design and architecture, computer aided design for VLSI physical design. He can be reached at the following email address: mvrajesh1@gmail.com. His permanent address is SRT - 961, Flat # 202, Sanathnagar, Hyderabad, Andhra Pradesh - 500018 - India.

The typist for this thesis was Venkata Rajesh Mekala.
