ABSTRACT – Background and Objectives: Previous studies reported a high prevalence of nightmares and dream anxiety in Borderline Personality Disorder (BPD) and the severity of dream disturbances correlated with daytime symptoms of psychopathology. However, the majority of these results are based on retrospective questionnaire-based study designs, and hence the effect of recall biases (characteristic for BPD), could not be controlled. Therefore our aim was to replicate these findings using dream logs. Moreover, we aimed to examine the level of dream disturbances in connection with measures of emotional instability, and to explore the protective factors against dream disturbances.

Methods: 23 subjects diagnosed with BPD, and 23 age and gender matched healthy controls were assessed using the Dream Quality Questionnaire, the Van Dream Anxiety Scale, as well as the Neuroticism, Assertiveness and Fantasy scales of the *NEO-PI-R* questionnaire. Additionally, subjects were asked to collect 5 dreams in the three-week study period and to rate the emotional and phenomenological qualities of the reported dreams using the categories of the *Dream Quality Questionnaire*.

Results: Dream disturbances (nightmares, bad dreams, night terror-like symptoms, and dream anxiety) were more frequent in patients with BPD than in controls. Dream disturbances correlated positively with Neuroticism, while Fantasy proved to be a negative correlate of dream disturbances.

Conclusions: Our study provides further support for the association between dream disturbances and BPD, links the presence of dream disturbances to the levels of emotional instability, and suggests that fantasy is a potential protective factor against dysfunctional dreaming.

Introduction

Sleep disorders are frequent, but relatively less emphasized in the diagnosis of Borderline Personality Disorder (BPD). However, patients diagnosed with BPD spend more time in REM sleep than healthy controls¹, their sleep is characterized by shorter REM latency, and increased REM density especially in the first REM cycle², they report worse sleep quality than controls, and show depression-like sleep disturbances³. Frequent nightmares and dream anxiety disrupting sleep and waking functioning are also reported in BPD, and disturbed sleep quality reflects the severity of psychopathological symptoms, dissociative experiences and childhood trauma found in patients with BPD^{4,5}. Moreover, dissociative symptoms and suicidal behaviour (characteristic for BPD) are associated with recurrent nightmares in different populations⁶⁻⁹. Nightmares disrupting sleep may deepen dissociative symptoms, since sleep loss elicits dissociative symptoms even in healthy volunteers according to a prospective study¹⁰. Except this study, the majority of the investigations were based on retrospective study designs, using sleep-questionnaires. As patients with BPD are highly susceptible to recall biases, it should be clarified if dream disturbances can be observed in a study de-

sign that examines the emotional characteristics of specific dream reports. Therefore our aim was to replicate the findings showing disturbed dreaming in BPD, and to clarify if the negative emotional aspects of dreaming are present in the specific dream reports as well. Collecting dream reports can also be viewed as a retrospective method, since it is based on memory processes, however specific dream reports in form of dream diaries are less susceptible to recall biases. Cippoli and Poli¹¹ demonstrated that the story-like organization of dreams does not differ between laboratory awakenings and morning reports. This suggests that dream logs are valuable and authentic tools to examine the dream quality of the individuals¹¹. Since nightmares are linked to a personality disposition characterized by emotional reactivity and vulnerability¹² we wanted to examine the level of dream disturbances in connection with the severity of emotional instability. Finally, we aimed to explore the protective factors against dream disturbances. Waking Fantasy and Assertiveness were focuses of our study, because the former had been related to the phenomenological qualities of dreaming¹³, and to an ability to integrate the random dream images into a coherent plot¹⁴, while the latter is thought to be an important coping skill in stress-full life situations, and its development is crucial in the therapy of BPD patients¹⁵.

Methods

Participants

23 patients (19 female and 4 male) meeting the DSM-IV diagnostic criteria of BPD and 23 age- and gender-matched healthy volunteers participated in the study. The diagnosis of BPD was confirmed by experienced clinicians, using the Hungarian version of the SCID-II¹⁶. Previous findings indicated that the Hungarian version of the SCID-II is characterized by excellent inter-rater reliability, and construct validity¹⁶. Subjects with other Axis II co-diagnoses were not included and patients with PTSD and Substance Abuse could not enter the study. The former because of the confounding factor of post-traumatic nightmares, the latter because of the influence that drugs and alcohol exert on sleep architecture¹⁷. 6 of the 23 BPD subjects were on their regular antidepressant (SSRI) medication during the study. The BPD patients were recruited from Hungarian psychiatric institutes and outpatient clinics. Written informed consent was obtained from the subjects, and the Local Ethics Committee approved the study protocol.

Procedure

Participants were told that the purpose of the study was to investigate their sleeping and dreaming habits, and the relationship between dreaming and personality. Subjects were asked to fill in the *Van Dream Anxiety Scale*¹⁸, the *Dream Quality Questionnaire*¹⁹, as well as the Neuroticism, the Assertiveness and the Fantasy scales of the Hungarian version of the *NEO-PI-R*²⁰. After completing the questionnaires subjects were asked to keep a dream diary, recording 5 "home dreams" within the three-week period of the study. The subjects had to write

down the collected dreams in the morning after awakening, on a sheet of paper, and - on the basis of the shortened version of the *Dream Quality Questionnaire* - they had to rate the emotional load, the bizarreness, the vividness and the effect on waking mood of each reported dream.

Instruments

The Van Dream Anxiety Scale (VDAS) provides the assessment of nightmare frequency and dream anxiety caused by frightening dreams. The items of the self-rating scale are concerned with nightmare frequency and the maleficent effects of nightmares on daytime functioning. Items are weighted on a 0-4 scale and summed to yield a global VDAS score of 0-42. According to our results based on a sample of 70 patients diagnosed with adaptation disorder and 70 matched controls, the VDAS has been shown to be a valid and reliable instrument to measure nightmare frequency and dream anxiety (Cronbach's $\alpha = 0.96$). All items are loading on one factor explaining 73% of the intersubject variance.

The Dream Quality Questionnaire (DQQ) containing 11 dream-specific items, measures the clinically relevant aspects of dreaming, like the emotional load, the bizarreness, and the vividness of dreams, the tendency of experiencing frequent non-recurrent and recurrent nightmares and night-terror-like symptoms, and the effects of dreams on daytime mood. The *DQQ* contains three main factors, the positive, the negative and the neutral emotional aspects of habitual dreaming. According to our results based on the data of a large national sample consisting of 5009 individuals, the negative emotional aspects of dreaming was inversely related to the levels of well-being, while the

positive emotional aspects of dreaming was positively associated with well-being. To sum up DQQ proved to be a valid and reliable psychometric instrument assessing the emotional quality of dreaming¹⁹.

The shortened version of the DQQ was used to measure the quality of the reported dreams. The 4 items measured the emotional load, the bizarreness, the vividness and the effect on waking mood of each reported dream. The emotional load of the reported dream was asked to be rated by a 5-point scale (0 - expressly oppressive, 1 - bad, 2 - neutral, 3 - happy, 4 - expressly gratifying). The average of the ratings generated the DE (Dream Emotion) score. The effect of the reported dream on daytime mood was also measured by a 5-point scale. The average of the ratings generated the DI (Dream Influence) score.

The NEO-PIR-H1 was used to measure the emotional instability of the subjects. The Neuroticism factor contains the following subscales: Anxiety, Anger and Hostility, Depression, Self-Consciousness, Impulsivity and Vulnerability. The internal consistency of the Neuroticism Factor as measured by the Cronbach's α was 0.92. The Cronbach's α coefficients for the Assertiveness and Fantasy scales were 0.77 and 0.81 respectively. The validity of the NEO-PIR-H1 was tested with the FFPI-H, the Five Factor Personality Inventory (Hungarian version)²⁰. The correlation of the Neuroticism factor with the Emotional Stability factor of the FFPI-H was -0.54 ($p < 0.05$).

Results

One subject from the BPD group failed to report any dream in the study period, therefore his results were excluded from the analysis of prospective, but not retrospec-

tive dream data. This way we examined the results of the completed questionnaires, and the ratings of a total of 209 dream reports. Some of the subjects (3 from the BPD and 4 from the control groups) provided less than 5 dreams. The mean frequency of reported dreams was 4.64 per subject ($SD = 1.09$). Groups did not differ in their reported dream frequency ($t = -0.04$; $p = 0.96$).

Habitual dream behaviour: retrospective results

The two groups differed significantly in several variables of the Dream Quality Questionnaire. 50% ($SD = 0.51$) of the BPD group reported frequent nightmares that caused sudden awakenings, but only 9% ($SD = 0.29$) of the control group reported the same experience. This difference was significant according to the Fisher exact probe ($p = 0.0027$). Similarly 68.1% ($SD = 0.46$) of the BPD group reported night terror-like symptoms as compared to the 22% ($SD = 0.42$) of the controls that according to the Fisher exact probe proved to be significant ($p = 0.002$). Furthermore, the BPD group suffers more frequently from recurrent nightmares than the healthy control group [(Mean: 2.55 ($SD = 1.05$) vs. 1 ($SD = 1$)); $t = 5.03$; $p < 0.001$]. BPD and control subjects differed significantly on the three DQQ factors. BPD patients achieved significantly higher scores on the *negative emotional aspects of dreaming* factor [Mean (BPD): 8.12 ($SD = 3.28$); Mean (control): 3.63 ($SD = 1.99$)]; ($F = 23.45$; $df = 1, 44$; $p = 0.000019$), while the control group achieved higher scores in the factors of *positive* [Mean (BPD): 1.70 ($SD = 0.94$); Mean (control): 2.36 ($SD = 0.78$)] and *neutral aspects of dreaming* [Mean (BPD): 1.44 ($SD = 0.79$); Mean (control): 2.05 ($SD = 0.83$)]; ($F = 6.81$; $df = 1, 44$; $p = 0.0124$ and $F = 5.52$; $df = 1, 44$; $p = 0.0235$ respectively).

Independent sample t-tests were used to compare the means of the VDAS scores of the BPD and the control group. The mean value of the BPD group was 23.55 (SD = 15.46) while for the control group it was 5.04 (SD = 5.44). The difference was significant ($t = 5.31$; $p < 0.001$), assuming the Levene's test for the equality of variances (26.28; $p < 0.001$). Analysis of variance of the results of the VDAS scores showed that the main grouping variable (BPD vs. control) explained 41.2% of the Variance ($p < 0.01$) (Adjusted R Squared = 0.37). Gender and the interaction of group and gender failed to show any significant effect.

Dream log data: prospective results

Each participant had an average score of emotional load, bizarreness, vividness, and effect on daytime mood for his/her reported dreams. These were submitted to independent sample t-test. The self-rated emotional load of dreams differed significantly: more negative dreams were assessed in the BPD group ($t = -4.02$; $p < 0.001$). Neither the vividness nor the bizarreness of these specific dreams did differ significantly, but dreams of the BPD patients showed a tendency to have longer effect on waking mood compared to the dreams of the control group ($t = 2.37$; $p = 0.023$) (see Table 1).

Correlations of dream features with daytime behaviour

Table 2 presents the Pearson's correlation coefficients, depicting the relationship between dream variables and other psychometric measures (Neuroticism, Fantasy, Asser-

tiveness) in the whole sample. Neuroticism proved to be a strong and positive correlate of the questionnaire based dream disturbances and a negative correlate of the DE score (the emotional load of the reported dreams; 0 - expressly oppressing, 5 - expressly gratifying), showed a moderate correlation with the DI (the effect on daytime mood of the reported dreams) score and a moderate negative correlation with the neutral-DQQ score. The Fantasy score showed a negative and moderate correlation with dream disturbances and a positive correlation with positive dream emotions. The level of Assertiveness did not correlate with any of the dream variables.

In order to control the effect of age and group membership, and to detect the predictive power of our variables of interest (Neuroticism, Fantasy, Assertiveness) on dream disturbances, we conducted a series of Linear Regression Analyses. First we aimed to determine the predictive power of Neuroticism, Fantasy, Assertiveness on the VDAS score, controlling for age and group membership. At the final step of the analysis only the effect of Neuroticism ($\beta = 0.50$; $t = 2.67$; $p < 0.01$) and Fantasy ($\beta = -0.28$; $t = -1.99$; $p < 0.05$) proved to be significant, explaining 45% of the Variance. We obtained similar results using the emotional load of the reported dreams (DE) as the dependent factor. The effect of group membership lost its level of significance after entering Neuroticism and Fantasy. Furthermore in this analysis Assertiveness showed also a tendency-like correlation (see Table 3).

The Path Analysis determining the possible interaction between Fantasy and Neuroticism showed that Fantasy and Neuroticism are two independent factors predicting the VDAS score (Estimate = 0.004.; $p = 0.901$).

Table 1
Differences between the dream log data of BPD and control subjects: prospective results

Dream characteristics	BPD (n = 22) Mean (SD)	Control (n = 23) Mean (SD)	Test statistic (t-value, two tailed)
Emotional load of the reported dreams ¹	1.87 (0.66)	2.66 (0.63)	-4.016*
Vividness of the reported dreams	1.25 (1.25)	1.36 (1.36)	-0.885
Bizarreness of the reported dreams	1.94 (1.95)	2.06 (2.06)	-0.867
Effect on waking mood of the reported dreams ²	2.47 (1.14)	1.68 (1.04)	2.366**

¹ 0 – most negative, 5 – most positive.

² 1 – uncharacteristic, 5 – even across several days.

* p < 0.0001; ** p = 0.023.

The effect of medication on Dream data

We investigated on an exploratory level the possible effect of SSRI on dream disturbances. Levels of significance for the comparison of mean scores with independent sample t-test between the medicated and the non-medicated BPD subgroups for the VDAS, negative-DQQ and emotional load of the reported dreams were $p = 0.84$; $p = 0.95$ and $p = 0.99$ respectively. However, these results should be interpreted carefully because of the small sample size.

Discussion

The results of our study indicate that dream disturbances like frequent nightmares, bad dreams, night-terror-like symptoms and dream anxiety are common clinical features of patients diagnosed with BPD. These findings cohere with previous studies reporting a high rate of nightmares and high levels of dream anxiety in BPD^{4,5}. However, these studies used retrospective questionnaires that cannot exclude the possibility of recall biases. In order to diminish the effect of recall biases we examined the emotional quality of a total of 209 dream reports provided by patients with BPD and healthy controls. “Home dream” reports are considered to be a valid tool examining the “dream experience”²¹, and dream reports are not substantially influenced by the reconstructive effects of recall¹¹. We found that patients with BPD rated their dreams more distressing, and that their dreams had prolonged effect on waking mood. 68.1% of the BPD patients reported that they have experienced night terror like symptoms, compared to the 22% of the control group. This result

is worth further investigation, because to our knowledge no previous studies reported association between night terrors and BPD. However, a high frequency of night terrors was shown to be associated with PTSD²², while the latter is related in some aspects to BPD or it is often co-morbid with it²³. Dream disturbances were related to higher levels of Neuroticism. This finding coheres with the report of Schredl²⁴ revealing an association between neuroticism and nightmare frequency in a non-clinical sample. Recently, Levin and Nielsen¹² traced a comprehensive multilevel model of dream and nightmare formation interpreting the emotional-cognitive level of disturbed dreaming as reflecting the influence of *affect load* (a consequence of daily variations in emotional pressure) and *affect distress* (a disposition to experience events with highly reactive emotions) and the neural level of disturbed dreaming as reflecting the dysfunction of the fronto-limbic network, comprising the amygdala, the hippocampus, the medial prefrontal cortex, and the anterior cingulate cortex. Our findings fit into the model, since BPD is characterized by unstable relationships (generating affect load) and emotional reactivity (akin to the notion of affect distress), moreover emotional dysfunctions in BPD are linked to anatomical and functional discrepancies in the fronto-limbic network²⁵⁻²⁸.

Assertiveness is considered to be an important coping skill, but it showed only a tendency-like connection with the emotional aspects of dreaming. In contrast, higher levels of Fantasy were inversely related to dream disturbances. These findings indicate that while assertiveness can be key component in appropriate waking functioning, the less controlled cognitive process of dreaming may benefit more from the ability of imagination. Fantasy Proneness, measured by the Creative Experiences Questionnaire

(CEQ)²⁹ was found to be associated with dissociation and deviant nocturnal sleep experiences³⁰. This finding is in apparent contrast with our results showing the benign influence of fantasy. Nevertheless, while Fantasy Proneness is characterized by tendencies for absorption and suggestibility the Fantasy scale of the NEO-PIR measures the level of free-floating imagination and frequent daydreaming. Therefore we consider that CEQ and Fantasy measure two different phenomena, among which only the former is related to dissociation. This is in concordance with the considerations of Giesbrecht and colleagues³⁰ emphasizing the difference between Fantasy Proneness and the Openness Factor of the NEO-PIR (the factor where Fantasy scale “belongs”).

We suggest that fantasy can be a protective factor against nightmares and bad dreams, and that the free-floating imagination in dreaming can serve the role of emotion regulation by genuinely structuring and rewriting the dream scenario, and thus integrating the negative emotions into more complex cortical networks. One possible function of dreaming is the elaboration of stressful and traumatic events by creating new, adaptive contexts for the negative emotions determining the dreaming process^{12,31-33}. Imagery Rehearsal Therapy of Posttraumatic nightmare sufferers is based on the generation of new, alternative outcomes for the “dead end” of the recurrent traumatic nightmares³⁴. Our results indicate that therapeutic interventions focusing on the development of imaginative skills may be useful for the treatment of nightmare sufferers.

In sum, our study provides further support for the association between dream disturbances and BPD, links the presence of nightmares, bad dreams and dream anxiety to the severity of emotional instability, and suggests that fantasy is a potential protec-

tive factor against dysfunctional dreaming. Furthermore our results suggest that not the BPD diagnosis *per se* but the specific emotional dysfunctions contribute to the dream disturbances.

Finally, these results need further support, and may be considered as a preliminary study because of the small sample size. Dream collection by laboratory awakenings would be an even more valid method that could rule out the possible effects of selective recall tendencies in dream reports. Additionally, our results are only applicable to women because of the small number of male participants. Despite that we could not detect any effect of the medication on dream quality, the effects of SSRI's in the BPD group cannot be ruled out, because antidepressants may increase dream intensity³⁵. However, mainly bizarreness, but not anxiety dreams were enhanced by SSRI's. Moreover, the effect of SSRI on dreaming is still not unequivocal, since another study reports that post-medication dreams of a women suffering from anxiety were more similar to the female population means, than the pre-medication ones³⁶.
