

INSTRUCTIONS ON THE ANNOTATION OF PDF FILES

To view, print and annotate your article you will need Adobe Reader version 9 (or higher). This program is freely available for a whole series of platforms that include PC, Mac, and UNIX and can be downloaded from <http://get.adobe.com/reader/>. The exact system requirements are given at the Adobe site: <http://www.adobe.com/products/reader/tech-specs.html>.

Note: if you opt to annotate the file with software other than Adobe Reader then please also highlight the appropriate place in the PDF file.

PDF ANNOTATIONS

Adobe Reader version 9

When you open the PDF file using Adobe Reader, the Commenting tool bar should be displayed automatically; if not, click on 'Tools', select 'Comment & Markup', then click on 'Show Comment & Markup tool bar' (or 'Show Commenting bar' on the Mac). If these options are not available in your Adobe Reader menus then it is possible that your Adobe Acrobat version is lower than 9 or the PDF has not been prepared properly.

(Mac)

PDF ANNOTATIONS (Adobe Reader version 9)

The default for the Commenting tool bar is set to 'off' in version 9. To change this setting select 'Edit | Preferences', then 'Documents' (at left under 'Categories'), then select the option 'Never' for 'PDF/A View Mode'.

(Changing the default setting, Adobe version 9)

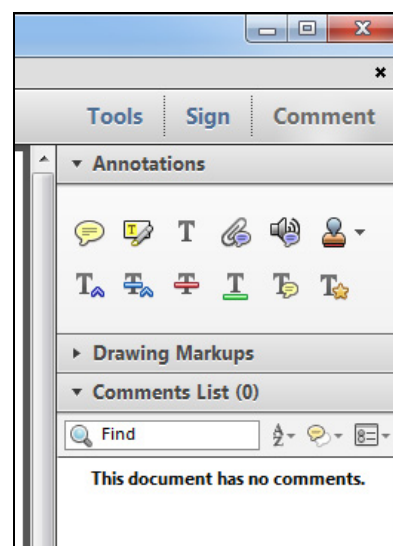

Adobe Reader version X and XI

To make annotations in the PDF file, open the PDF file using Adobe Reader XI, click on 'Comment'.

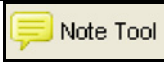

If this option is not available in your Adobe Reader menus then it is possible that your Adobe Acrobat version is lower than XI or the PDF has not been prepared properly.

This opens a task pane and, below that, a list of all Comments in the text. These comments initially show all the changes made by our copyeditor to your file.

Objective: Aortic computed tomography angiography (CTA) examination with electrocardiography gating is becoming the clinical routine image acquisition protocol for diagnosis and intervention planning. To minimize motion artifact, the images are reconstructed in the diastolic phase of the cardiac cycle. The aim of our study was to quantify aortic strain in an elderly nonaneurysmatic patient cohort and to identify the phases of the R-R cycle that correspond to the minimal and maximal aortic diameters. The quantification of aortic strain may enable the improvement of intervention planning and the introduction of more effective dose-saving protocols for CTA scans.

Methods: We assessed CTA images of 28 patients (14 men; mean age, 74 years). Aortic calcium score was calculated on native images. Angiography images were reconstructed in equally spaced 10 phases of the R-R cycle. After semiautomatic centerline analysis, we measured the cross-sectional areas in each of the 10 phases at 9 specific segments between the ascending aorta and the common iliac bifurcation representing the attachment sites of thoracic and abdominal stent grafts. Area-derived effective diameter, pulsatility ($A_{\max} - A_{\min}$), and strain $[(A_{\max} - A_{\min})/A_{\min}]$ were calculated. Repeated measurements were taken to evaluate inter-reader and intrareader reproducibility (10-10 patients each).

Results: A total of 4320 measurements were performed. We found significant difference between diastolic and systolic diameters ($D_{D,Z0} = 33.2$, $D_{S,Z0} = 34.4$; $P < .001$). Pulsatility values of the vessel diameters were 1.0 to 1.1 mm in the thoracic aorta, 0.7 to 0.9 mm in the abdominal aorta, and 0.5 to 0.6 mm in the common iliac arteries. Negative, moderate correlations were found between aortic strain and age ($r = -0.586$; $P = .001$), aortic strain and plaque area ($r = -0.429$; $P = .026$), and age and body mass index ($r = -0.412$; $P = .029$). We found positive, moderate correlation between age and plaque area ($r = 0.594$; $P = .001$). The aortic pulsatility curve has a positive extreme at 30% and a negative extreme at 90% of the R-R cycle throughout the aorta. Lin concordance coefficients were 0.987 for inter-reader and 0.994 for intrareader correlations.

Conclusions: Aortic strain can be reliably quantified on electrocardiography-gated CTA images. Pulsatility of the aorta can be substantial in the thoracic aortic segments of young patients; therefore, the routine use of systolic images is not recommended. In addition, we demonstrated that images at 30% of the heart cycle correspond to the largest diameter of the aorta. (J Vasc Surg 2015;■:1-6.)

There is growing evidence that endovascular aortic repair (EVAR) can be safely and effectively performed in thoracic and abdominal aortic diseases, such as aortic aneurysm and acute aortic syndrome.¹⁻⁵ Simultaneously, a shift in the last 15 years can be observed from open repair to EVAR; however, there is an ongoing debate as to whether we should push the boundaries too far in favor of EVAR.⁶ Thoracic and abdominal EVAR is associated with lower mortality rates compared with open repair, but there is a non-negligible number of EVAR patients who suffer late

complications of the stent grafts caused by migration and endoleaks.⁷⁻⁹ As both undersizing and excessive oversizing are known to be associated with complications in the short and long term, precise sizing of the stent graft is crucial.^{8,10,11}

Previous generations of computed tomography (CT) scanners with a lower number of detector rows and slower gantry rotation without electrocardiography (ECG) synchronization produced images with a blurred aortic contour and a somewhat averaged aortic diameter because of aortic wall motion. Nowadays, technologic advances allow rapid ECG-gated CT angiography (CTA) of the whole aorta during a single breath-hold, confronting us with new problems: which phase of the cardiac cycle should be used for image acquisition or reconstruction?¹² Conventionally, diastolic images are preferred as systolic images are often compromised by motion artifacts. However, aortic diameter changes during the R-R cycle can be substantial, especially in the young; wavy aortic contour on pediatric CT images is a usual finding. If the systolic-diastolic difference of the aortic diameter is considerable, this can result in an undersized stent graft.¹²

In this study, our primary objective was to measure the strain of the whole aorta on ECG-gated CTA images in an

elderly patient cohort with atherosclerotic but otherwise normal aorta. Our secondary objective was to identify the phases of the R-R cycle that correspond to the maximal (systolic) and minimal (diastolic) diameters, enabling us to introduce dose-saving options for CTA scans of future patients.

METHODS

CT imaging. Imaging of the aorta was performed in 28 patients (14 men; mean age, 72.9 ± 12.0 years) with a 256-slice multidetector CT scanner (Philips Brilliance iCT; Koninklijke Philips N.V., Best, The Netherlands) using an ECG-gated protocol tailored for imaging of the aorta. The study was performed on images readily available from patients being evaluated for transcatheter aortic valve repair (TAVR) or from patients with suspected acute aortic syndrome.

Hemodynamic parameters were measured with an electronic sphygmomanometer before administration of contrast material. A low-dose (tube voltage, 100 kV) native scan was followed by retrospective ECG-gated CTA of the whole aorta (100 kV) with a reduced field of view to maximize spatial resolution. Nonionic contrast agent was

injected into an antecubital vein at a flow rate of 4 to 5 mL/s using a power injector. Images were reconstructed using a sharp convolution kernel and iterative reconstruction algorithm (iDose,⁴ Koninklijke Philips N.V.) with a slice thickness of 1 mm and an increment of 1 mm. Multi-phase images were reconstructed corresponding to every 10% of the R-R cycle, resulting in 10 series of images for each patient. Data sets were transferred to stand-alone workstations for further analysis.

Image analysis. Image analysis, vessel segmentation, and cross-sectional measurements were performed by two independent radiologists experienced in cardiovascular imaging. Aortic calcifications were calculated using the dedicated coronary calcium scoring software of an Extended Brilliance Workspace (HeartBeat CS, Koninklijke Philips N.V.).

CTA images were analyzed using an Advantage Workstation (GE Healthcare Europe GmbH, Freiburg, Germany). After automatic vessel segmentation and centerline detection, cross-sectional area of the lumen was measured in a semiautomatic fashion at the following nine locations: ascending aorta proximal to the brachiocephalic trunk (Ishimaru Z0), between left common carotid

artery and left subclavian artery (Ishimaru Z2), immediately distal to the left subclavian artery (Ishimaru Z3), 5 cm distal to the left subclavian artery (Ishimaru Z4), 5 cm above celiac trunk ostium, below renal ostia, middle infrarenal aorta, and right and left common iliac artery (Fig 1, a).^{13,14} Position was matched in three dimensions between series of different phases by recording the slice number that involved the segment of the centerline at the exact point of the measurements taken. Cross-sectional areas were recorded in square millimeters. Diameter was calculated as the diameter of a virtual circle with the same cross-sectional area (area-derived effective diameter; Fig 1, b-e). To minimize measurement errors and to increase inter-reader agreement, direct diameter measurements were avoided.¹² Pulsatility was defined as the largest difference between systolic maximum and diastolic minimum diameter or area. Vessel strain was calculated as a ratio of pulsatility and minimum area $[(A_{\max} - A_{\min})/A_{\min}]$. Patients gave written informed consent before CT examination was performed. The experimental protocol and informed consent were approved by the Regional Ethical Committee of Semmelweis University (133/2011).

Statistical analysis. Data processing and analysis were performed using IBM SPSS Statistics 22.0 (IBM Corporation, Armonk, NY) and R (R Foundation for Statistical Computing, Vienna, Austria) software. Shapiro-Wilk test was used to assess the normality of the data. Wilcoxon signed rank test was used to compare diastolic and systolic measurements. Correlations were analyzed with Spearman ρ test. Lin correlation was used to evaluate inter-reader and intrareader agreement.¹⁵ Statistically significant difference was established at $P < .05$. Continuous variables are presented as median (interquartile range).

RESULTS

A total of 4320 measurements on 28 patients were performed, involving 1800 repeated measurements on 20

patients to evaluate inter-reader and intrareader reproducibility. Patient demographics are shown in Table.

Wilcoxon signed rank test showed significant difference between the cross-sectional areas of the diastolic and systolic phases ($P < .001$) at every anatomic location measured.

Area pulsatility is reduced along the course of the aorta; the highest level was measured at the Z0 position (42.9 mm² [28.8-74.0 mm²]) with a continuous decrease along the aorta to an almost negligible value at the level of the iliac arteries (8.5 mm² [6-12 mm²]). This equals a diameter pulsatility of 1.0 mm (0.6-1.6 mm) at the thoracic aorta (Z0), 0.7 mm (0.6-1.0 mm) at the abdominal aorta (below renal ostia), and 0.5 mm (0.4-0.8 mm) at the common iliac arteries (Fig 2, a). As vessel diameter is decreasing more rapidly than pulsatility (Fig 2, b), vessel strain is somewhat higher in the infradiaphragmatic segments but does not reach the level of significance; 3% to 5% was found throughout the aorta with wide interquartile ranges (Fig 2, c).

To identify the positive and negative extremes in the R-R cycle of aortic pulsatility, we derived a parameter representing the precession of the actual diameter relative to the mean diameter $[(d_{\text{actual}} - d_{\text{mean}})/d_{\text{mean}}]$. This resulted in a graph resembling an arterial pressure curve, with a systolic extreme at 30% and a diastolic extreme at 90% of the R-R cycle (Fig 2, d).

Lin concordance coefficients were 0.987 for inter-reader (range, 0.985-0.991; strength of agreement: substantial) and 0.994 for intrareader (range, 0.993-0.995; strength of agreement: almost perfect) correlations.¹⁵ A higher inter-reader variability was found between iliac artery measurements (concordance coefficients were 0.831 for right common iliac artery and 0.267 for left common iliac artery; strength of agreement: poor). Therefore, iliac artery measurements were excluded from correlation analysis.

Negative correlations were found between aortic strain and age ($r = -0.498$, $P = .007$ at Z3; $r = -0.586$, $P = .001$ at Z4; $r = -0.539$, $P = .003$ at 5 cm above celiac trunk ostium), aortic strain and plaque area ($r = -0.429$, $P = .026$ at Z4; $r = -0.436$, $P = .023$ at 5 cm above celiac trunk ostium), and age and body mass index ($r = -0.412$; $P = .029$). Positive correlation between age and plaque area ($r = 0.594$; $P = .001$) was found. Pulse pressure did not show any significant correlation with the other parameters.

DISCUSSION

This study was undertaken to evaluate the strain of the vessel segments commonly used as landing zones of aortic stent grafts on CTA images. A previous work conducted by Parodi et al¹² examined the proximal segment of the descending aorta of 27 patients. They found significant difference between systolic and diastolic diameters at 1, 4, and 8 cm distal to the left subclavian artery, thus concluding that the use of diastolic images for stent graft planning can result in undersizing and possible complications.

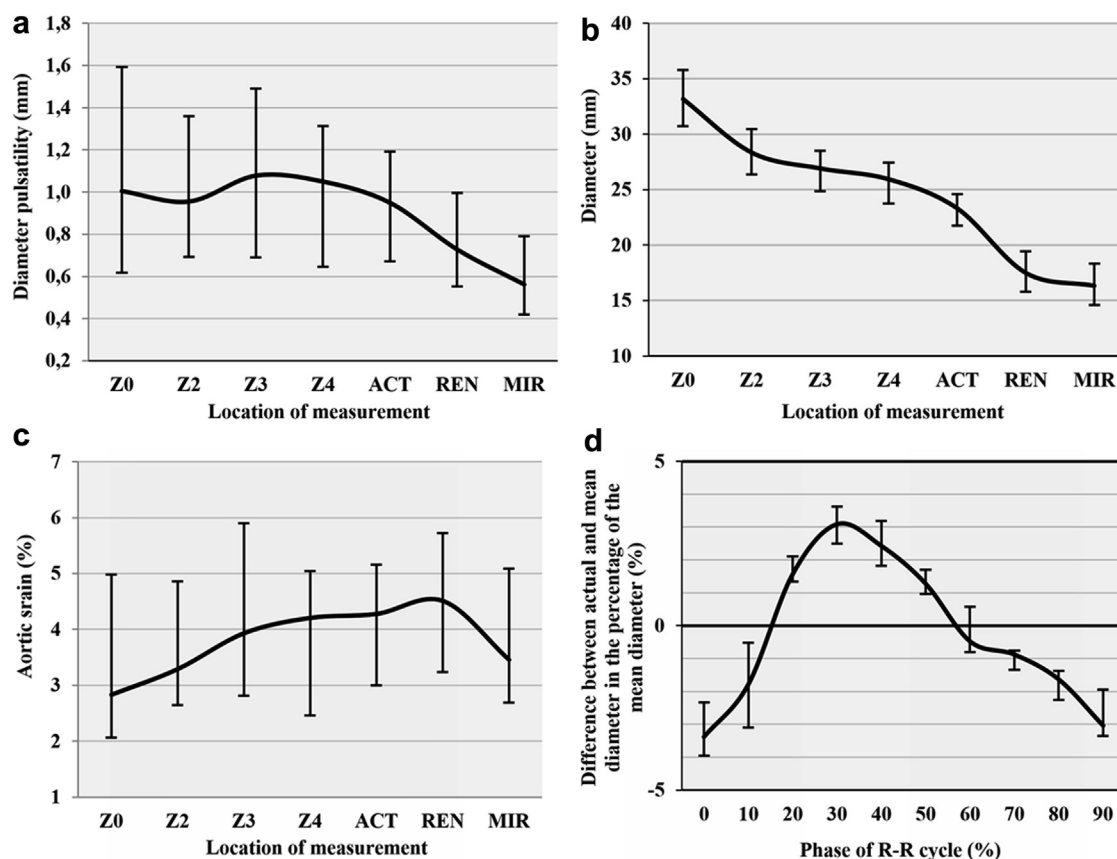

Fig 2. Geometric parameters of the aorta: (a) diameter pulsatility; (b) diameter; (c) strain; (d) difference between actual and mean diameter in the percentage of the mean diameter. Data are presented as medians with interquartile ranges. ACT, At 5 cm above celiac trunk origin; MIR, middle infrarenal aorta; REN, below renal ostia; Z0, Z2, Z3, Z4, Ishimaru zones of the thoracic aorta.

Our results refine these findings, as 75% of the patients had a diameter pulsatility of <1.5 mm in the thoracic aorta. This questions the need for systolic images in thoracic stent graft planning.

The magnitude of pulsatility is reduced with the distal tapering and branching of the aorta, being <1 mm in the abdominal aorta and iliac vessels in the majority of the patients, which questions its relevance regarding the sizing of infradiaphragmatic prostheses. On the basis of our findings, neither three-dimensional motion nor pulsatility of these vessels is notable; thus, the routine use of ECG gating for abdominal CTA examinations is not recommended unless it does not increase radiation dose and contrast agent volume (prospective ECG-triggered, high-pitch helical acquisition is available on some of the latest scanners only).

The wide distribution of the samples of aortic strain measurements can most likely be addressed by the heterogeneity of our patient cohort. There are data that aortic strain reduces with advancing age. Previous studies show that thoracic aortic strain in a young adult can be as high as 33%, with a nonlinear decrease with advancing age; 80% of the total decline of aortic strain occurs before the fifth decade.^{16,17} The significant

negative correlation in our elderly and small patient cohort between aortic strain and age emphasizes the importance of using systolic images in young patients. Young patients are at the highest risk of suffering an involuntary undersizing of an aortic stent graft due to the use of diastolic images. This risk is further increased by the progressive dilation of the aorta with age, which is in the range of 1.5 mm per 10 years according to literature data.¹⁶

The higher inter-reader variability found between iliac artery measurements can be addressed by the following three causes: (1) possible anatomic mismatch between the different phases due to vessel tortuosity; (2) smaller diameter of the vessels; and (3) extensive blooming artifacts caused by the calcification of the common iliac arteries, making edge detection more difficult.

We found significant negative correlation between aortic strain and plaque area; however, it is not clear whether calcification itself has a role in the increase of wall stiffness. Previous research suggests that alterations in cellular and extracellular components of the vessel wall appear in young adulthood, causing alterations in mechanical properties of the vessel wall preceding calcification.¹⁶

To reduce the effective dose of future patients needing aortic imaging, identification of positive (systolic) and negative (diastolic) extremes of the aortic diameter during the R-R cycle was necessary. Dose-saving methods such as prospective ECG triggering or ECG-dependent tube current modulation must be used to maximize image quality at 30%. With the limited temporal resolution of today's CT technology, accurate assessment of temporal shifts of the curves between different vessel segments is barely possible and most likely irrelevant regarding stent graft planning.

A possible role of ECG-gated CTA imaging in the evaluation of aneurysmatic disease progression, rupture risk estimation, and prediction of proximal neck dilation has been raised by several authors.^{18,19} Local vessel parameters can be derived from aortic strain: pressure strain elastic modulus and vessel distensibility. A major drawback of these parameters is the need of blood pressure values, as continuous invasive blood pressure recording is usually not possible during image acquisition. Measuring blood pressure levels before or after injection of contrast material causes an unpredictable error, as inspirational breath-hold and Valsalva maneuver can have major effects on the short-term regulation of hemodynamic parameters. Novel mechanical parameters derived by others show a promising result in the understanding and quantification of the local properties of the healthy and diseased aorta.^{18,19} Finding a new parameter that can be derived from widely available CTA images and that could estimate disease progression would be a game changer for patients with aortic disease.

Study limitations. Inclusion of TAVR candidates raises questions, as these patients may have abnormal pulse pressures due to aortic valve stenosis or insufficiency. There were no significant correlations between pulsatility or strain and aortic pulse pressure, nor significant difference in aortic strain between TAVR and not TAVR patients.

The three-dimensional motion of the aorta can result in a mismatch between the phases of the R-R cycle in the same cross sections of the measured segments. Measurement locations were anchored to the table position and slice number, as a reliable anatomic landmark of the aortic wall was not present in every location. However, aortic motion is usually <1 mm. Heterogeneity of aortic strain resulting in significant difference between the phases is not likely.

All of our patients were nonaneurysmatic patients, whereas the majority of aortic interventions are planned to treat aortic aneurysms. We believe that our recommendations based on our nonaneurysmatic cohort can be beneficial for aneurysmatic patients also. However, further investigations are needed to evaluate the interindividual and intraindividual differences in aortic pulsatility and strain in aneurysmatic disease.

CONCLUSIONS

Aortic strain can be measured on ECG-gated CTA images with high reliability and reproducibility. The aortic pulsatility was <1 mm in the abdominal aorta

and <1.5 mm in the thoracic aorta in the majority of the patients; therefore, the routine use of systolic images cannot be justified. In most cases, nongated CTA is appropriate for device selection if descending thoracic or abdominal aortic disease is present. However, a subgroup of younger patients might exist in whom aortic strain can reach the level of significance.

Novel mechanical parameters derived from dynamic cross-sectional images may have a future role in estimating disease progression as they can be accurately measured on routine CTA scans.
