

Daily report 21-05-2021

**Analysis and prediction of COVID-19 for  
EU-EFTA-UK and other countries**

**Full version**

## Foreword

The present report aims to provide a comprehensive picture of the **pandemic situation of COVID-19** in the EU countries, and to be able to foresee the situation in the next coming days. We provide some figures and tables with several **indexes and indicators** as well as an **Analysis** section that discusses a specific topic related with the pandemic.

As for the predictions, we employ an **empirical model**, verified with the evolution of the number of confirmed cases in previous countries where the epidemic is close to conclude, including all provinces of China. The model does not pretend to interpret the causes of the evolution of the cases but to permit the **evaluation of the quality of control measures made in each state** and a **short-term prediction of trends**. Note, however, that the effects of the measures' control that start on a given day are not observed until approximately 7-14 days later.

We show an individual report with several graphs and a summary table with the main indicators for different countries and regions. We are adjusting the model to **countries and regions** with at least 4 days with more than 100 confirmed cases and a current load over 200 cases.

# Situation and highlights

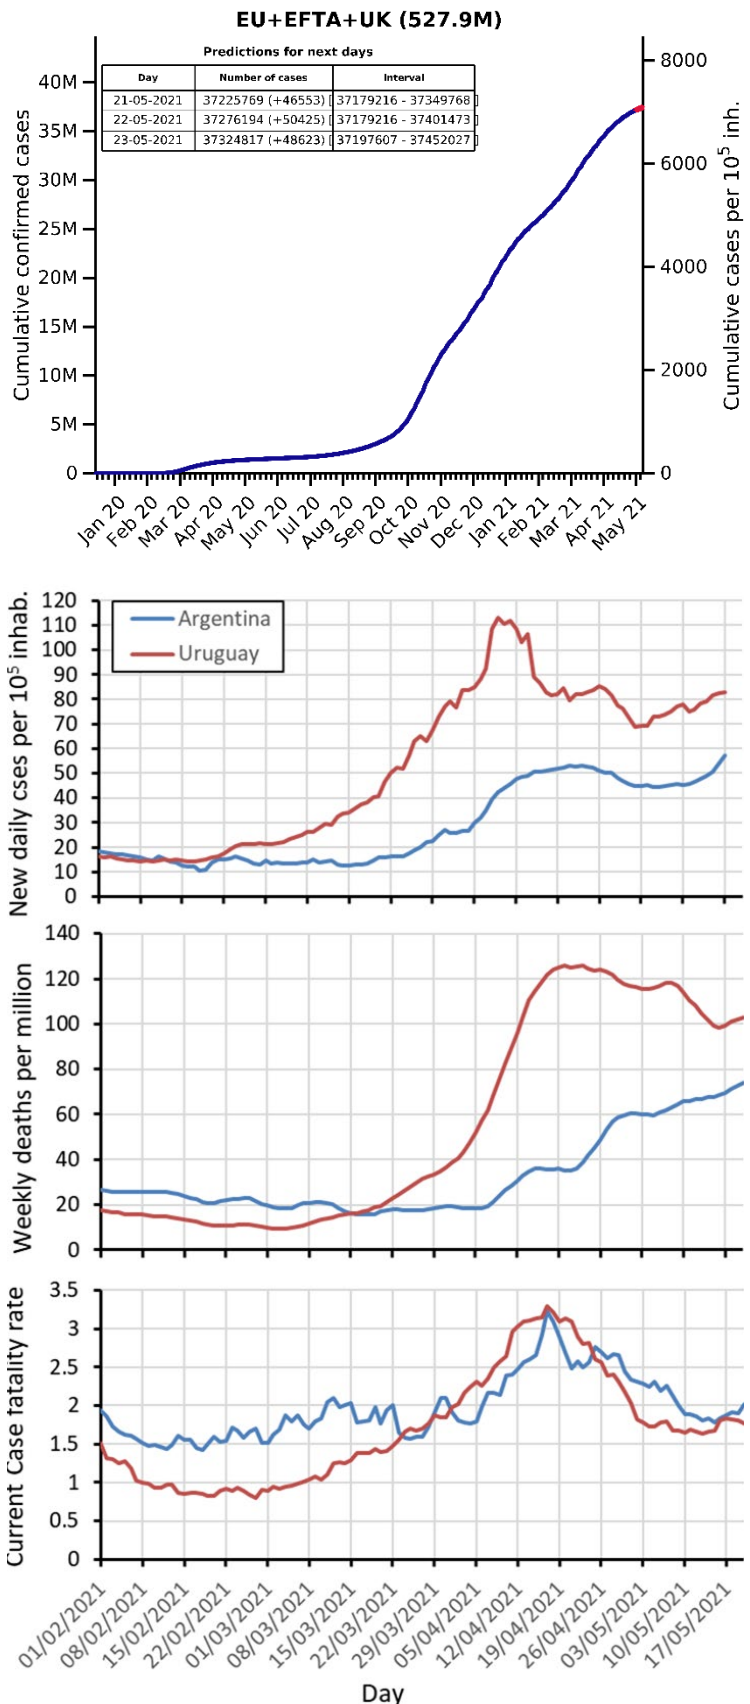

## Global situation

South America epidemiological situation is not clearly improving yet. Overall, they are in a complex situation with a tendency to stabilize the number of cases. We focus here on two countries, Uruguay and Argentina. The graphs highlight three important issues:

- Since the beginning of May, the number of daily new cases is increasing significantly. The value is especially high in Uruguay.
- The number of weekly deaths per million inhabitants in Argentina has been increasing since the beginning of April. Uruguay tends to improve slowly but is at a really high level.
- Despite the high mortality rate, the current Case Fatality Rate has improved since the end of April, the value is not excessively high.

In Uruguay, more than 70 doses have been distributed per 100 inhabitants, and it is surprising that there is not still a clear improvement in the situation. The difference in efficiency of the first dose could explain the situation. Other countries such as Bolivia are also deteriorating rapidly, however, the number of cases diagnosed daily is still low. The ability to make diagnoses must be much lower than in countries with higher HDI, so it is difficult to compare situations. If we look at the current Case Fatality Rate in all countries (See next page), we see how Uruguay and Chile, the ones with the highest vaccination rate, have a rather low CFR within the set. Venezuela's very good values raise questions about its real situation.

The situation in Brazil does not seem as complicated as in Uruguay or Argentina, but since April 25, the number of new daily cases has been gradually increasing.

### Highlights

- The situation has improved in almost all countries, including Denmark, which is still growing but seems to be slowing down this trend ( $\rho_i \approx 1.05$ ).
- Portugal is the only country with a growth rate above 1.1. Nevertheless, its low incidence keeps the country far from the risk zone ( $EPG=57$ ).

### Situation and trends per country

Maps of current situation in EU countries. Colour scale is indicated in each legend.

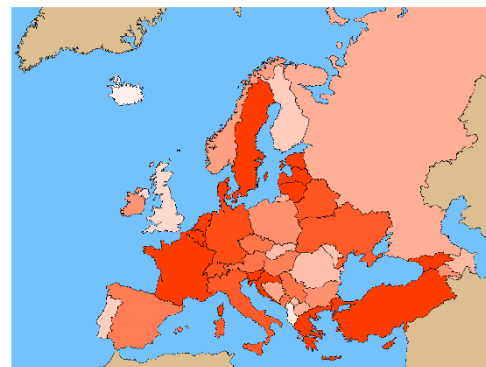

- Cumulative incidence: total number of reported cases per 100,000 inhabitants
- $A_{14}$ : Cumulative incidence last 14 days per 100,000 inhabitants (active cases)
- $\rho_7$ : Empiric reproduction number
- EPG: Effective Potential Growth ( $EPG = A_{14} \cdot \rho_7$ )

<sup>(1)</sup>  $\rho_7$  is the empiric reproduction number. <sup>(2)</sup> EPG stands for Effective Growth Potential, which is the product of reported cumulative incidence of last 14 days per 10<sup>5</sup> inhabitants by  $\rho_7$  (empiric reproduction number). Biocom-Cov degree is an epidemiological situation scale based on the level of last week's mean daily new cases (<https://upcommons.upc.edu/handle/2117/189661>, <https://upcommons.upc.edu/handle/2117/189808>).

**Situation of hospitalisations and ICUs in some EU countries.** The analysis is done for those countries that report a historical series with current (active) number of patients in hospitals and ICUs<sup>1</sup>. We provide:

- Current active hospitalisations and patients in ICU per 100,000 inhabitants.
- Current absolute number of active hospitalisations and patients in ICU.
- Rate of occupation of curative care hospital beds by Covid-19 patients (data from Eurostat 2018<sup>2</sup>), only for hospitalisations.
- Current rate of occupation with regards to the maximum Covid-19 occupation reached in this pandemic.
- Weekly increase in Covid-19 patients in hospitals and ICUs.

Country	Hospitalisations					Intensive Care Units				Last available datapoint

<sup>(1)</sup>  $\rho_7$  is the empiric reproduction number. <sup>(2)</sup> EPG stands for Effective Growth Potential, which is the product of reported cumulative incidence of last 14 days per 10<sup>5</sup> inhabitants by  $\rho_7$  (empiric reproduction number). Biocom-Cov degree is an epidemiological situation scale based on the level of last week's mean daily new cases (<https://upcommons.upc.edu/handle/2117/189661>, <https://upcommons.upc.edu/handle/2117/189808>).

## Analysis: On the B.1.1.7 variant substitution dynamics of SARS-CoV-2 in Catalonia (Spain).

Viruses are constantly changing through mutations that bring on small genetic differences. The great expansion of the coronavirus causes coexistence of different genetic variants of the same virus. Mutations in this virus can have a major impact if they increase its transmissibility, virulence, mortality, or escape the effect of antibodies acquired through a natural infection or vaccination<sup>1</sup>. On December 2020 – March 2021 period, Catalonia (7.6 million inhabitants) has suffered the pandemic third wave (Figure 1).

**Figure 1.** Daily new cases in Catalonia (Spain) during the period December 2020 – March 2021 (third wave). Data from DadesCovid<sup>2</sup>.

During this wave, a substitution process of the multiple variants by a new variant began, the so-called British variant (B.1.1.7 or 20I/501 Y.V1). This process of replacement almost caused the disappearance of not only the majority variant that existed (20E (EU1)), but of all the others.

In order to better understand the dynamics of the epidemic from the period mentioned below, **we present a model that describes this substitution process.** The data used in this report comes from Can Ruti Sequencing Hub, where a protocol to track the existence of new variants in the North Metropolitan Area of Barcelona (2 million inhabitants, around 25 % of Catalan population) was established by January 2021. Each week, around 100 (January) or 200 (March) PCR positive samples are processed in order to obtain their sequence and determine the variant. These samples are randomly chosen between those positive cases diagnosed in the health area. Given that the objective is to track the spreading of the B.1.1.7 variant, in this report we are going to distinguish those that belong to the B.1.1.7 variant from those that belong to other variants.

The B.1.1.7 variant of the virus started being systematically detected in Catalonia in mid-December 2020, during the rising phase of the third wave. Since then, the analysis of the infections origins by sequencing has increased. At first it was noticed that the B.1.1.7 variant was replacing, not only the previous majority variant,

<sup>1</sup> <https://upcommons.upc.edu/handle/2117/335882>

<sup>2</sup> <https://dadescovid.cat/descarregues?lang=eng>

but all the other variants that already existed then. The period which has been observed a clearer replacement by the B.1.1.7 variant lasted approximately from mid-February to mid-March.

### *Theoretical framework of the substitution process*

The theoretical analysis was described previously in a previous report<sup>1</sup> and consists of an exponential growth model based on some previous considerations. It assumes that changes in the effective reproductive coefficient due to higher transmission are reproduced in a way that specific increase in secondary attack rates measured in the UK will lead to the same increase in the reproductive coefficient of this variant anywhere. This presupposition says that non-pharmaceutical interventions (NPIs) do not affect the relative increase in the reproductive coefficient  $R_t$ . Also, another assumption is that both variants have the same incubation time.

Briefly, the theoretical framework assumes the evolution of two independent epidemic: one caused by the B.1.1.7 variant, and the other one caused by older variants. This assumption results on a sigmoid model that correctly reproduces the substitution process provided by observations. The basic parameters and variables of the model are:

- $N_{B.1.1.7}$  and  $N_{other}$ : daily new cases corresponding to each variant.
- $R_{B.1.1.7}$  and  $R_{other}$ : effective reproduction numbers corresponding to both epidemic curves.
- $\xi = N_{B.1.1.7}/N_{other}$ : ratio between number of cases of each variant – when  $\xi \ll 1$ , the B.1.1.7 variant is residual; when  $\xi = 1$ , both variants are equally present among new cases; when  $\xi \gg 1$ , the variant B.1.1.7 represents the majority of the cases.
- $\chi_{B.1.1.7}$  and  $\chi_{other}$ : percentage of new cases that correspond to each variant – this percentages can vary from 0 % to 100 %, depending on the prevalence of each variant.
- $\eta$ : increase in transmissibility of the B.1.1.7 variant with regards to the previous ones – if  $\eta = 1.5$  it means that the new variant is 50% more transmissible than the original one.

### *Analysis of the substitution using the fraction of cases between variants*

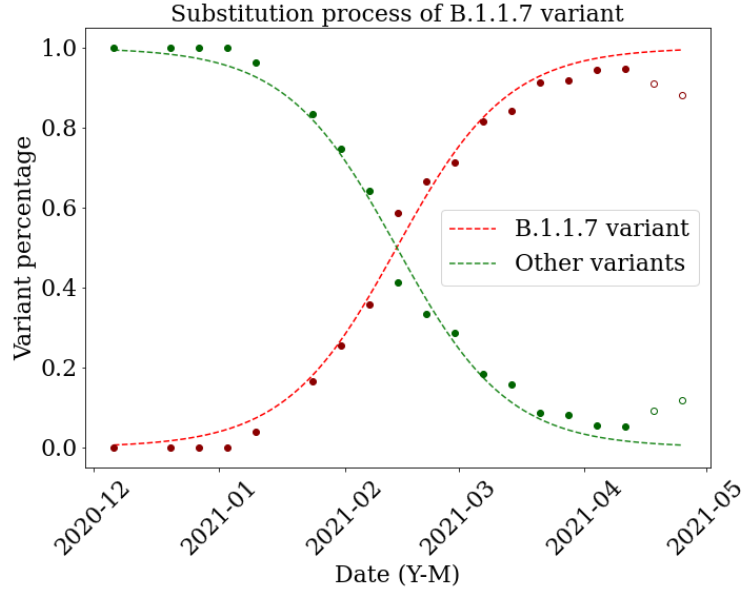

First we analyse the evolution of the variant percentage respect to the B.1.1.7 variant and all other variants existing during the studied period. The definition of the B.1.1.7 variant percentage is the following:

$$\chi_{B.1.1.7} = \frac{N_{B.1.1.7}}{N_{other} + N_{B.1.1.7}} = \frac{\xi_0 e^{\delta t}}{1 + \xi_0 e^{\delta t}} \quad (1)$$

$$\chi_{other} = \frac{N_{other}}{N_{other} + N_{B.1.1.7}} = \frac{\xi_0 e^{-\delta t}}{1 + \xi_0 e^{-\delta t}}; \quad (2)$$

For the details of the calculation of the sigmoid function, see the previous report<sup>1</sup>.

In Figure 2 we have plotted the evolution of the percentage of cases for each variant obtained from random sequencing ( $\chi_{other}$  and  $\chi_{B.1.1.7}$ ) together with the fitted substitution model. We can see in Figure 2 that the substitution process started by mid-December, and ended in mid-April, when almost all SARS-CoV-2 infections come from the B.1.1.7 variant.

**Figure 2:** Evolution of the percentage of B.1.1.7 variant and the other variants obtained from Sequencing measurements with a sigmoid fit only for the colour-filled markers. The quality parameters of the fitting are Reduced  $\chi^2 = 0.00134112$ , AIC = -110,570018, and BIC = -108,903592).

In the previous figure, we have adjusted a sigmoid function<sup>1</sup> that describes the evolution of the fraction of cases originated for each variant, see eqs. (1-2). The model consists of two parameters: the initial ratio,  $\xi_0 = \frac{N_{0,B.1.1.7}}{N_{0,others}}$ , and the increase in contagiousness of the new variant with respect to the original variants,  $\delta$ , which relates the increase in transmissibility ( $\eta$ ) with the incubation time ( $\tau$ ) ( $\delta = \ln \eta / \tau$ ). The parameters resulting from the fittings are  $\xi_0 = 0.006 \pm 0.003$  and  $\delta = 0.073 \pm 0.006 \text{ d}^{-1}$ , collected from Figure 2. The former is the initial fraction.

The time when both variants have the same number of cases is when  $\xi_t = N_2(t)/N_1(t) = 1$ . This corresponds to the intersection points of the two curves in Figures 1, when the percentage of the B.1.1.7 variant and the other variants is 50 %. Also, we can use the previous equations (1) and (2) to find the intersection time with the parameters  $\xi_0$  and  $\delta$  found with the fitting.

$$\frac{N_2(t)}{N_1(t)} = \frac{\xi_0 e^{\beta_1 t} e^{\delta t}}{e^{\beta_1 t}} = \xi_0 e^{\delta t} = 1 \quad (3)$$

Then, the intersection time  $t$ , in days, when both percentages are 50% is:

$$t = \frac{-\ln(\xi_0)}{\delta} \quad (4)$$

We have collected the intersection time for Sequencing data. According to these results, the intersection point (50 % each variant) would have been achieved around the 14<sup>th</sup> February 2021. On the other hand, with the parameter  $\delta$  we can compute the **increase in transmissibility,  $\eta$** . Assuming an incubation time ( $\tau$ ) of 5 days, the increase in transmissibility  $\eta$  that given by the next relation:

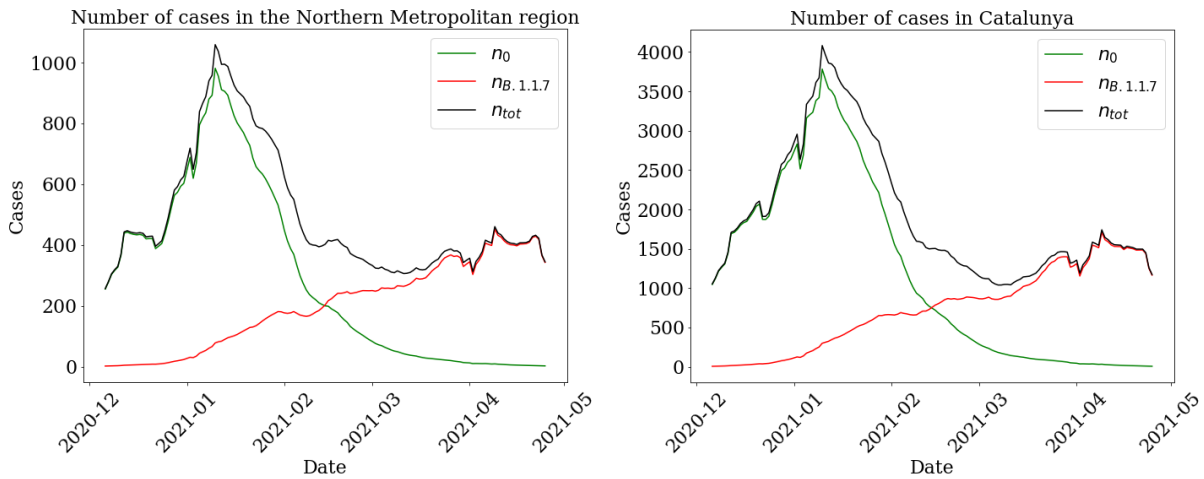

$$\delta = \frac{\ln(\eta)}{\tau} \rightarrow \eta = e^{\delta \tau} \quad (5)$$

giving rise to the value  $\eta = 1,44 \pm 0.04$ . This last result tells us that once the substitution process will have taken place completely, with 100% of infections coming from the B.1.1.7 variant, **the reproduction number will be around 44% higher than on the previous months**, when almost all cases came from other variants.

### Analysis of the number of cases

We now present an analysis of the absolute number of cases which came from B.1.1.7 variant or of the old variants. To do so, we have used the sigmoid fit introduced before to estimate, at every point of time, what the fraction of the total cases that were originated by the B.1.1.7 variant or by the old variants was. The data of the total number of detected cases in Northern Metropolitan region and in Catalunya were obtained from open data from Catalonia Government<sup>3</sup>. These data series were first smoothed by applying a 7-day running average, using data from three days before to three days after each point. Then, using the fitted sigmoid, we split the cases of each day between those that correspond to B.1.1.7 variant and those that correspond to other variants.

The plot of the number of estimated cases that correspond to each variant over time during the studied period is given by Figure 3. We can see in the figure that, before the intersection points of the substitution (mid-February), the evolution curve of the total cases (black curve) followed the dynamics of the old variants (green). Then, after the substitution, the curve of the total number of cases (in black) resembles the dynamics of the B.1.1.7 variant (in red). Also, we can see a decrease in cases corresponding to the end of the third wave (Figure 3), when the percentage of B.1.1.7 variant with respect to all cases was below 30%, i.e., the European variant 20E (EU1) was majority with respect to the B.1.1.7.

**Figure 3.** Evolution of the number of cases in Northern Metropolitan region (left) and in Catalunya (right). Total number of cases are obtained from official databases, while green (old variants) and red (B.1.1.7) curves are estimations using the model fitted to the Sequencing data.

### Analysis of the effective reproduction numbers

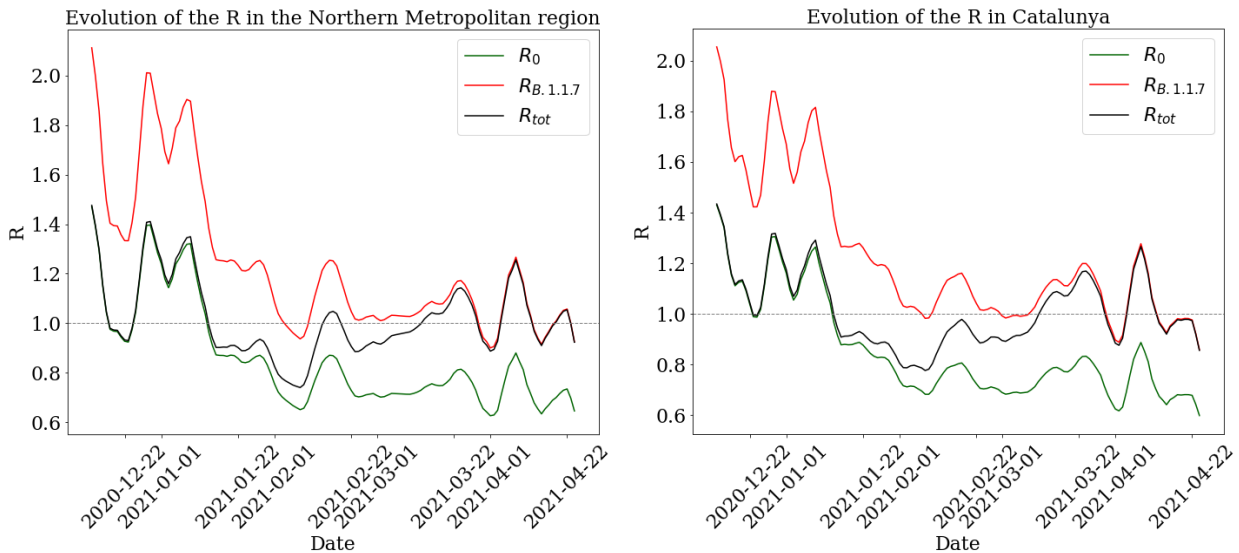

Effective reproduction number is used to measure the rate at which an epidemic spread. It is a measure of the average number of people infected by an infectious person. It is often referred to as  $R_0$  (basic reproductive number), which is the value of before propagation begins, while  $R_t$  denotes the effective value of the reproduction number with time. Mathematical models such as SIR or SEIR are usually used to calculate this reproductive rate. An empirical alternative to assess an equivalent indicator ( $\rho$ ) was defined previously<sup>4</sup>. The  $\rho_t$  is defined as the quotient between the average of those infected in the last three days and those infected five days ago, also as an average of three days:

$$R_t \approx \rho_t = \frac{N(t-1)+N(t)+N(t-1)}{N(t-6)+N(t-5)+N(t-4)} \quad (6)$$

<sup>3</sup> <https://dadescovid.cat/descarregues?lang=eng>

<sup>4</sup> <https://biocomsc.upc.edu/en/shared/methods.pdf>

We present an analysis of the evolution of the empiric reproductive number during the substitution period, computed as detailed above (Eq. (3)). From the sigmoid fit that was made with smoothed data, we obtained a curve that estimates the number of cases that corresponded weather to the B.1.1.7 variant or to the other old variants. Then, using the total number of daily infections in Catalunya and in the Northern Metropolitan region, we have computed the empiric reproduction number that corresponded to the old variants, to the B.1.1.7 variant o to the whole series. The result is shown in Figure 4, using data from *Sequencing*. These results show that **the decreasing phase of the third wave would have been a combination of the old variants decreasing with an  $R_t$  around 0.7 with the B.1.1.7 variant increasing with an  $R_t$  around 1.1.**

**Figure 4.** Evolution of the  $R_t$  for sequencing data of Northern Metropolitan region (left) and Catalunya (right).

In Figure 5 we show the ratio between both reproduction numbers, one for the original variant and the other for the new variant, as a function of time ( $R_{t,B.1.1.7}/R_{t,other}$ ). We see that the **ratio between both reproduction numbers is almost constant over time**, as expected from the theoretical model. In addition, we obtained very similar results between the Northern Metropolitan region and Catalonia. In both cases we see that the new variant is approximately a 44% more transmissible, as we found in previous calculations (i.e.,  $R_{t,B.1.1.7}/R_{t,other} \approx 1.44$ ). This constant behaviour of the reproductive coefficient quotients determines that the infections follow the sigmoid dynamics described before independently on the conditions, or in other words, it indicates that **the process of substitution took place independently on the NPIs.**

**Figure 5.** Evolution of the ratio between the reproductive number of the B.1.1.7 estimated series and that of the other variants series,  $R_{t,B.1.1.7}/R_{t,other}$ . Cases estimated from the model fitted to Sequencing data of Northern Metropolitan region (left) and Catalunya (right).

## Conclusions

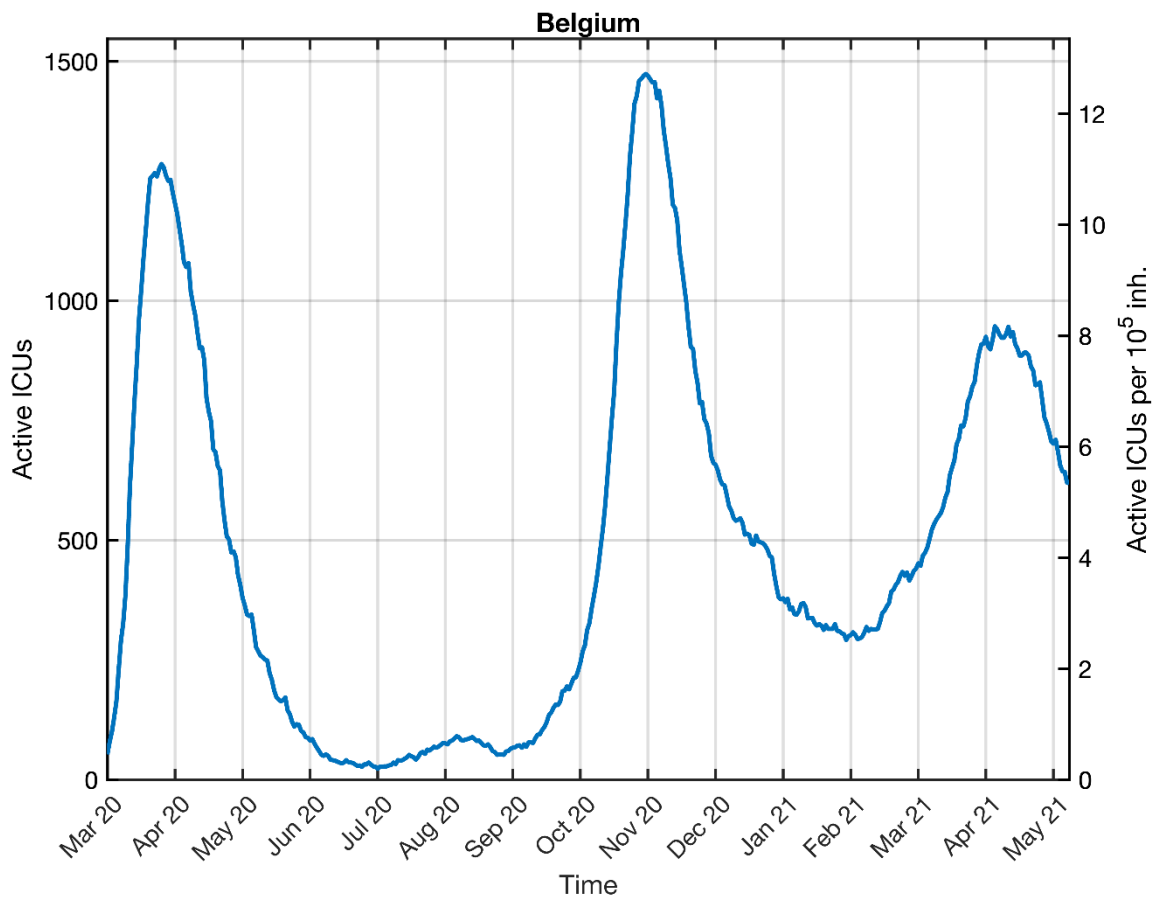

We have analysed the evolution of the B.1.1.7 variant with respect to the rest of the variants using the data from the *Sequencing* measurements. **The results are coherent with the substitution process described in the previous theoretical report<sup>1</sup> and gives rise to sigmoid dynamics for the rise of B.1.1.7 variant.** From the fitting we obtain an increase in transmissibility of around 44% with respect to the previous variants.

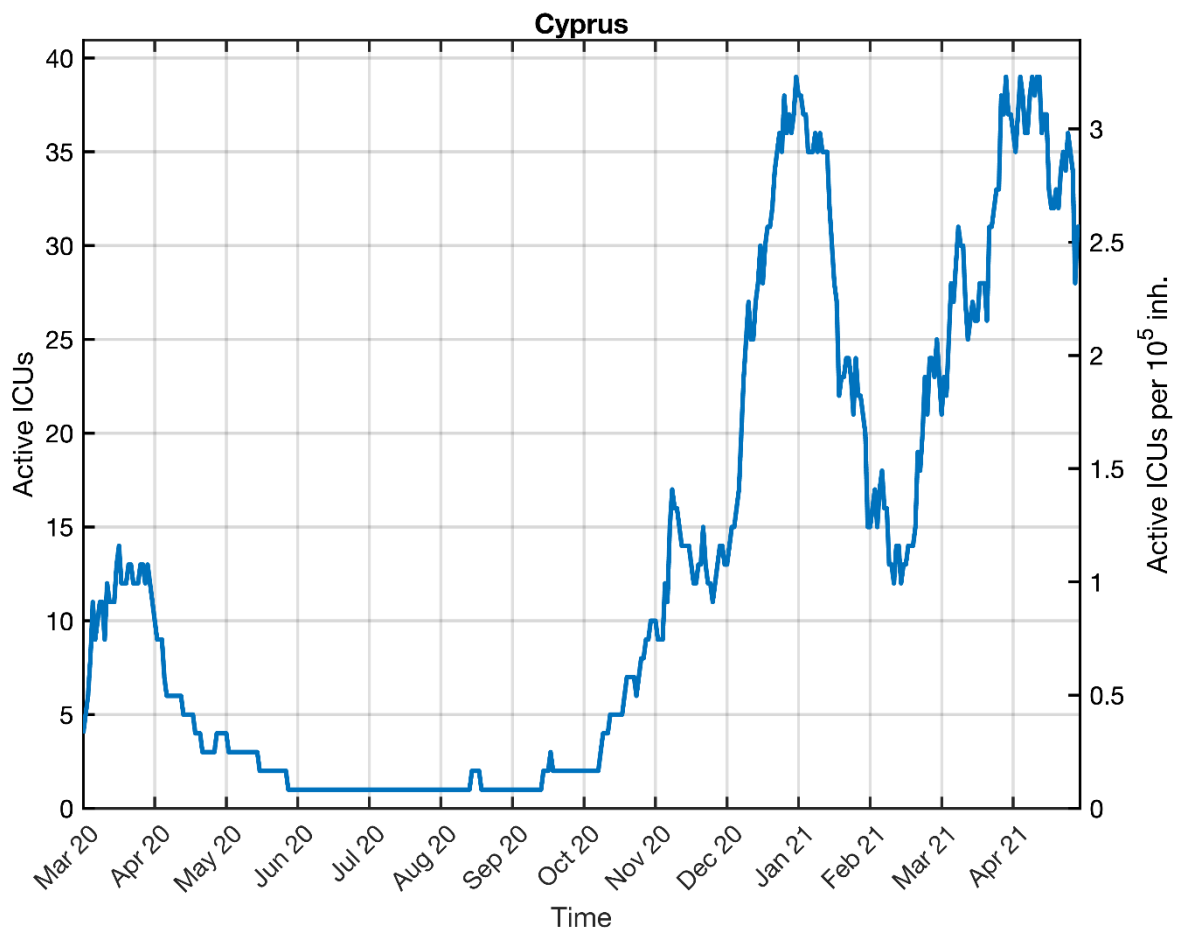

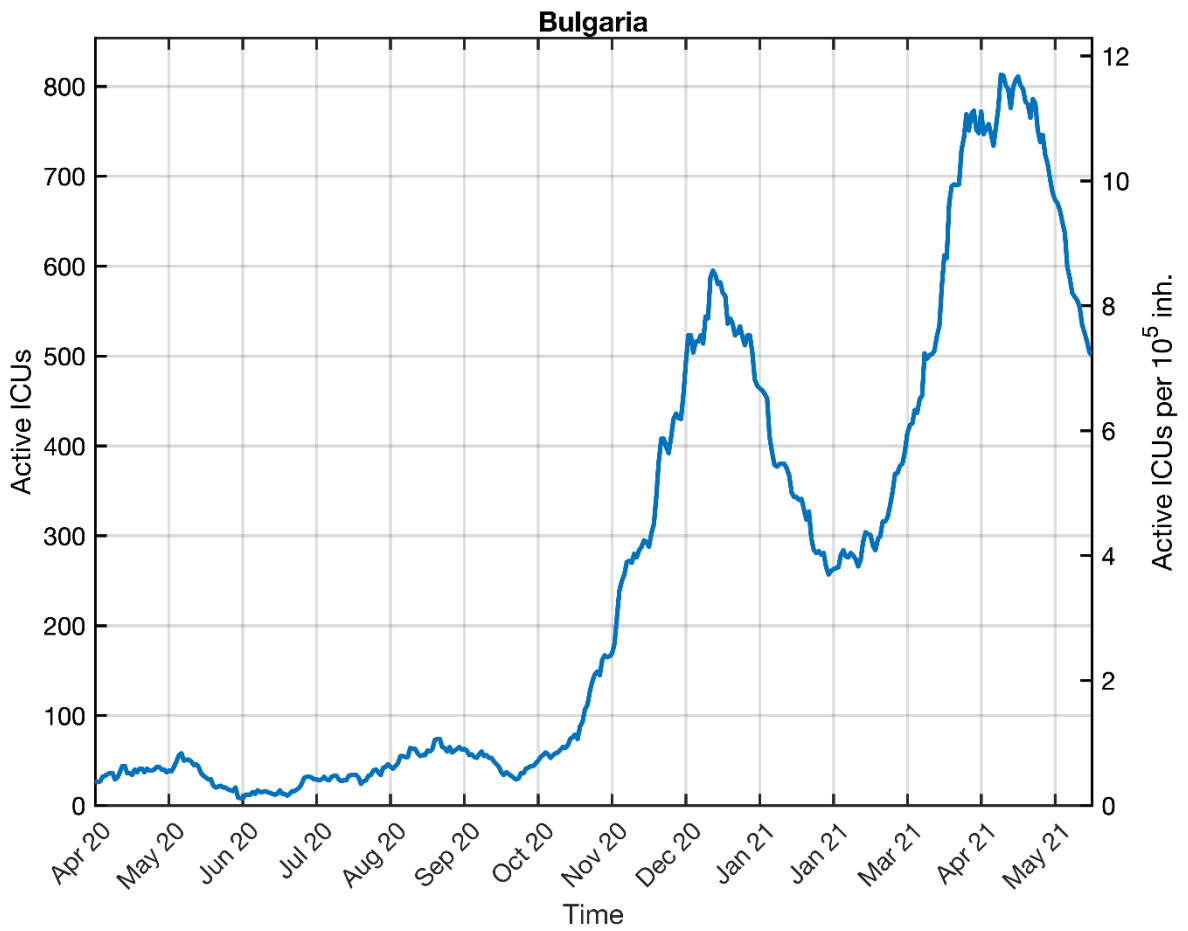

We have employed the resulting sigmoid substitution in combination to the data series of cases in Northern Metropolitan region and whole Catalunya in order to quantify the estimated cases associated to each variant and to calculate the evolution of the reproductive number of the B.1.1.7 variant and the other during the beginning of 2021.

Finally, we have evaluated the changes on the transmissibility observed in the data to evaluate the dependence of the increase in transmissibility on the particular situation of the pandemic, note that data is obtained during different states of the third wave in Catalonia. We have seen that the decreasing phase of the third wave, which occurred with an  $R_t$  around 0.9, would have been a combination of the old variants decreasing with an  $R_t$  around 0.7 and the B.1.1.7 increasing in a range of  $R_t$  between 1.0 and 1.1. **We conclude that the fitting is satisfactory, independently of the state of the pandemic, and, therefore, it indicates that the increase in transmissibility is independent on the non-pharmaceutical interventions.**

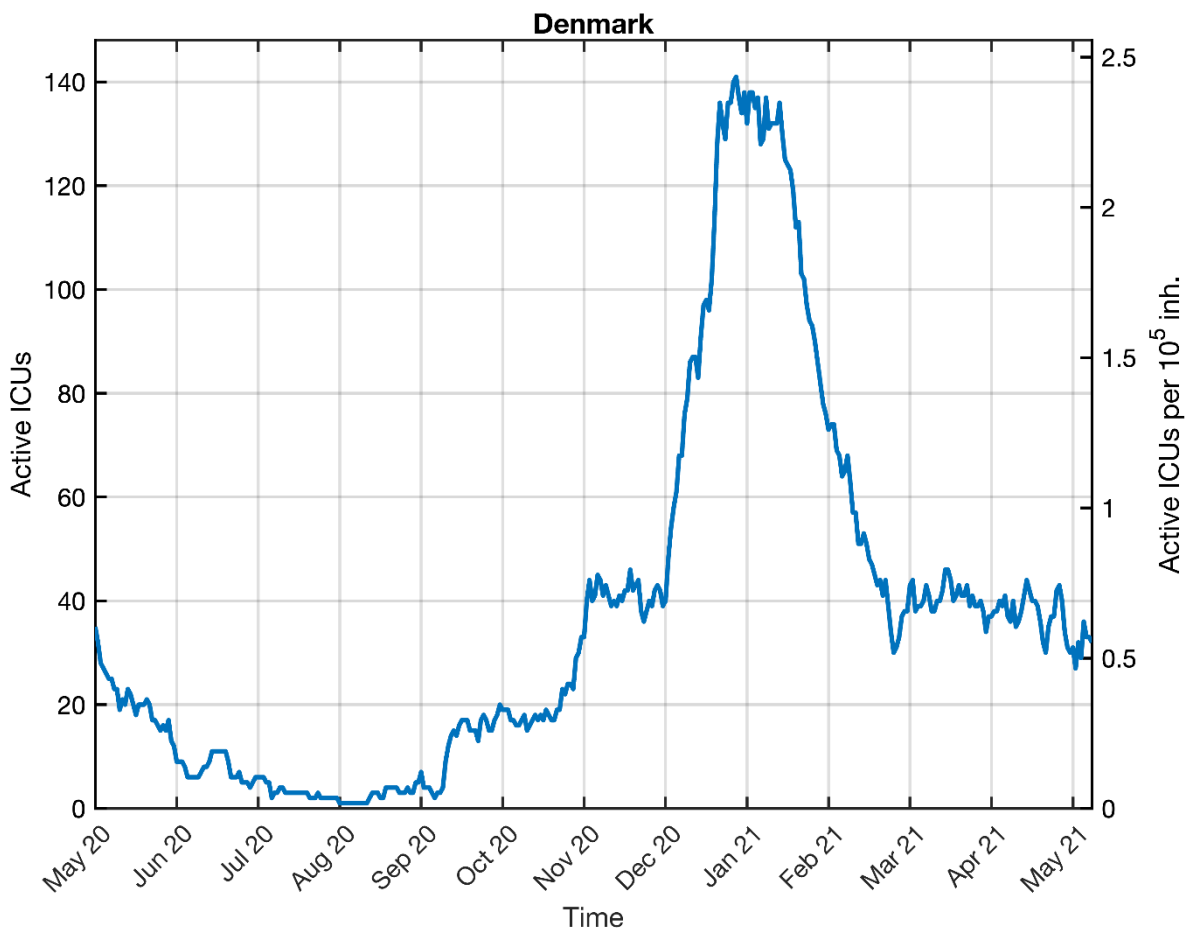

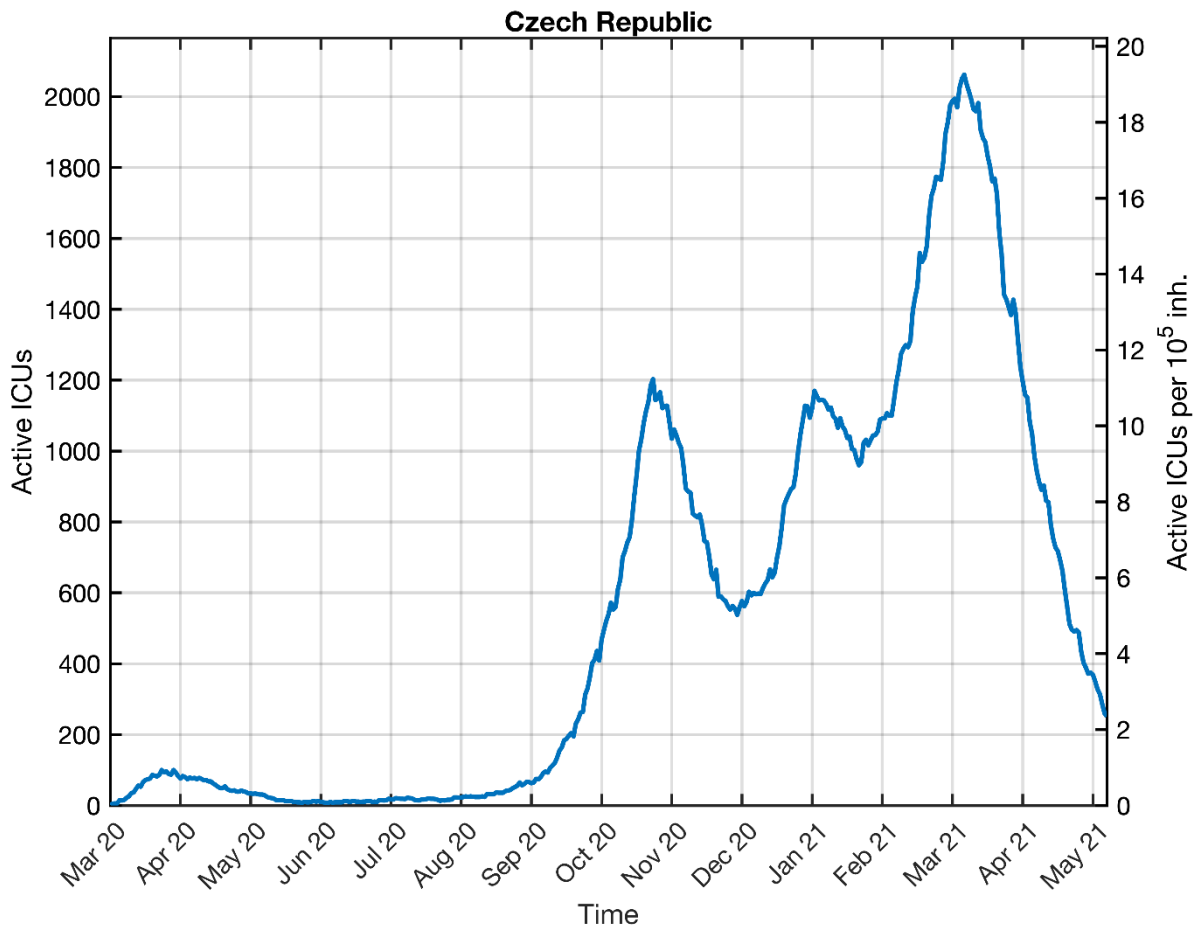

A final question mark in this analysis is whether, without the presence of the B.1.1.7, the other variants would have decreased exactly at the same rate that they did. In other words, if there is competition for resources like in an ecological habitat this would not be the case. Given the low level of immunization, it seems difficult to imagine that both variants would compete for hosts. However, we cannot disregard the possibility that society is formed by quite closed groups with different levels of risk behaviour. The penetration and spread in one of the groups with a higher risk of one variant prevent the other from taking a member of this group as a host easily if there is local herd immunity. An interesting future line of works is to analyse other substitution processes and the hierarchical nature of the different contacts to check if this competition is minimal or relevant.

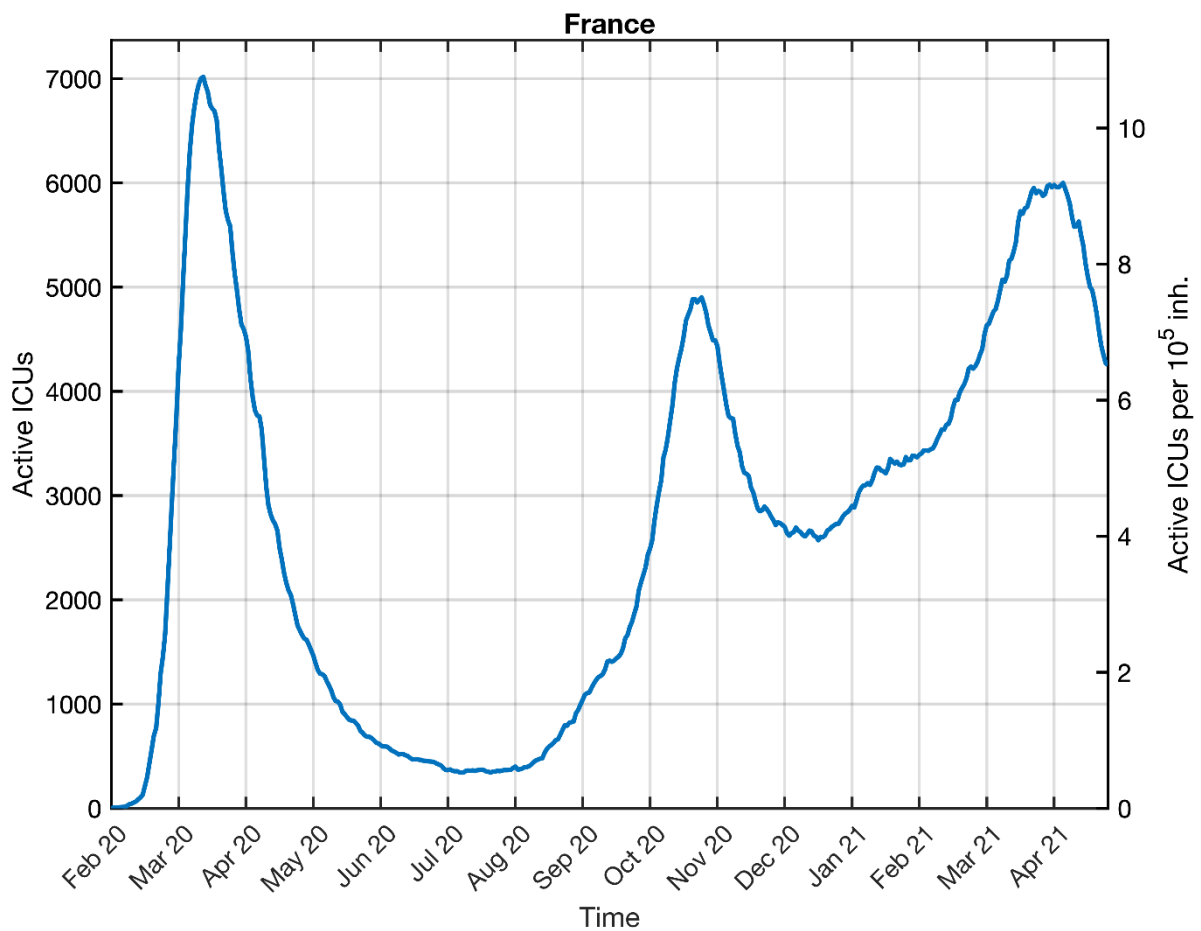

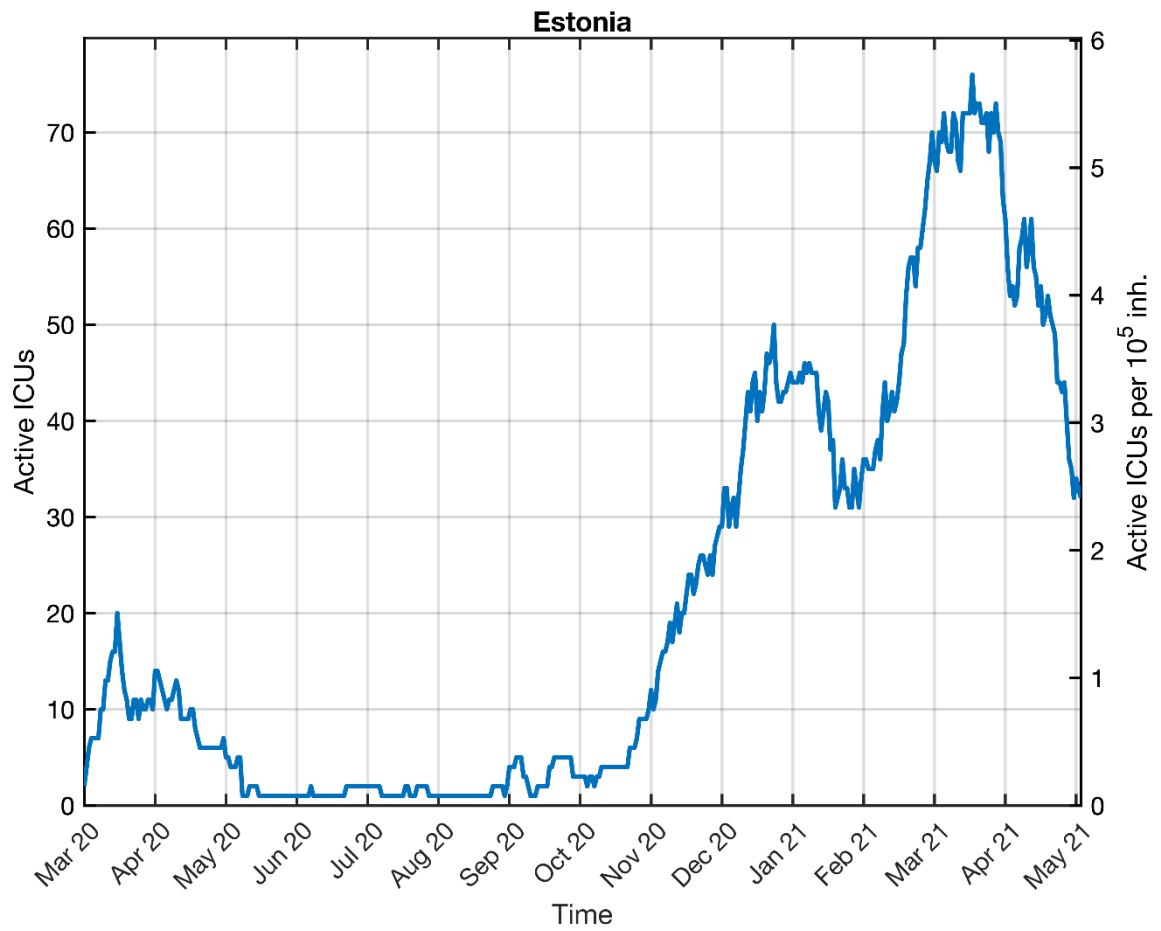

## Evolution of active ICUs in some EU countries

## Methods

## Methods

### (1) Data source

Data are daily obtained from European Centre for Disease Prevention and Control (ECDC)<sup>5</sup> and country official sources (when indicated). Daily data comprise, among others: total confirmed cases, total confirmed new cases, total deaths, total new deaths. It must be considered that the report is always providing data from previous day. In the document we use the date at which the datapoint is assumed to belong, i.e., report from 15/03/2020 is giving data from 14/03/2020, the latter being used in the subsequent analysis.

### (2) Data processing and plotting

Data are initially processed with Matlab in order to update timeseries, i.e., last datapoints are added to historical sequences. These timeseries are plotted for individual countries and for the UE+EFTA+UK as a whole:

- ✓ Number of cumulative confirmed cases
- ✓ Number of reported new cases
- ✓ Number of cumulative deaths

Then, two indicators are calculated and plotted, too:

- ✓ Case fatality rate: number of 14-day cumulative deaths divided by the number of 14-day cumulative confirmed cases of 21 days before, to account for the average 21-day delay between diagnosis and death.
- ✓  $\rho$ : this variable is related with the reproduction number, i.e., with the number of new infections caused by a single case. It is evaluated as follows for the day before last report ( $t-1$ ):

$$\rho(t-1) = \frac{N_{new}(t) + N_{new}(t-1) + N_{new}(t-2)}{N_{new}(t-5) + N_{new}(t-6) + N_{new}(t-7)}$$

where  $N_{new}(t)$  is the number of new confirmed cases at day  $t$  after applying a 7-day moving average to the new cases dataset, so that fluctuations (e.g., weekend effect) are smoothed. **Updated methodology to account for weekend effect is discussed and explained in reports #152<sup>6</sup> and #154<sup>7</sup>.**

### (3) Classification of countries according to their epidemic level: the scale Biocom-Cov

Countries are assigned a degree in the discrete Biocom-Cov scale, which aims to facilitate a simple way of assessing the situation of the country. It is based on the level of daily new cases per 100,000 inhabitants as follows:

Pandemic degree	Daily new incident cases per 10 <sup>5</sup> inh.
0	0
1	0-0.1
2	0.1-0.5
3	0.5-1.25
4	1.25-2
5	2-3
6	3-5
7	5-8

8	8-14
9	>14

#### **(4) Fitting a mathematical model to data**

Previous studies have shown that Gompertz model<sup>8</sup> correctly describes the Covid-19 epidemic in all analysed countries. It is an empirical model that starts with an exponential growth but that gradually decreases its specific growth rate. Therefore, it is adequate for describing an epidemic wave that is characterized by an initial exponential growth but a progressive decrease in spreading velocity provided that appropriate control measures are applied. Once in the tail, predictions work but the meaning of parameters is lost.

Gompertz model is described by the equation:

$$N(t) = K e^{-\ln\left(\frac{K}{N_0}\right)} e^{-\alpha(t-t_0)}$$

where  $N(t)$  is the cumulated number of confirmed cases at  $t$  (in days), and  $N_0$  is the number of cumulated cases the day at day  $t_0$ . The model has two parameters:

- ✓  $\alpha$  is the velocity at which specific spreading rate is slowing down;
- ✓  $K$  is the expected final number of cumulated cases at the end of the epidemic.

This model is fitted to reported cumulative cases of the UE and of countries that accomplish two criteria: 4 or more consecutive days with more than 100 cumulated cases, and at least one datapoint over 200 cases. Day  $t_0$  is chosen as that one at which  $N(t)$  overpasses 100 cases. If more than 15 datapoints that accomplish the stated criteria are available, only the last 15 points are used. The fitting is done using Matlab's Curve Fitting package with Nonlinear Least Squares method, which also provides confidence intervals of fitted parameters ( $\alpha$  and  $K$ ) and the  $R^2$  of the fitting. At the initial stages the dynamics is exponential and  $K$  cannot be correctly evaluated. In fact, at this stage the most relevant parameter is  $\alpha$ .

It is worth to mention that the simplicity of this model and the lack of previous assumptions about the Covid-19 behaviour make it appropriate for universal use, i.e., it can be fitted to any country independently of its socioeconomic context and control strategy. Then, the model is capable of quantifying the observed dynamics in an objective and standard manner and predicting short-term tendencies.

**The model and its results on predictions in European countries during the first wave has been published in Plos Computational Biology<sup>9</sup>.**

#### **(5) Using the model for predicting short-term tendencies**

The model is finally used for a short-term prediction of the evolution of the cumulated number of cases (3-5 days). The confidence interval of predictions is assessed with the Matlab function `predint`, with a 99% confidence level. These predictions are shown in the plots as red dots with corresponding error bar. For series longer than 9 timepoints, last 3 points are weighted in the fitting so that changes in tendencies are well captured by the model. **Updated methodology to account for weekend effect is explained in report #155<sup>10</sup>.**

#### **(6) Estimating non-diagnosed cases**

<sup>8</sup> Madden LV. Quantification of disease progression. *Protection Ecology* 1980; **2**: 159-176.

<sup>9</sup> Català et al, 2020, *Plos Comput Biol* 16(12): e1008431, <https://doi.org/10.1371/journal.pcbi.1008431>

<sup>10</sup> <https://upcommons.upc.edu/handle/2117/332350>

Lethality of Covid-19 has been estimated at around 1% for Republic of Korea and the Diamond Princess cruise. Besides, median duration of viral shedding after Covid-19 onset has been estimated at 18.5 days for non-survivors<sup>11</sup> in a retrospective study in Wuhan. These data allow for an estimation of total number of cases, considering that the number of deaths at certain moment should be about 1 % of total cases 18.5 days before. This is valid for estimating cases of countries at stage II, since in stage I the deaths would be mostly due to the incidence at the country from which they were imported. We establish a threshold of 50 reported cases before starting this estimation.

Reported deaths are passed through a moving average filter of 5 points in order to smooth tendencies. Then, the corresponding number of cases is found assuming the 1 % lethality. Finally, these cases are distributed between 18 and 19 days before each one.

**Full methodology and results have been published in Plos One<sup>12</sup>.**
