## Abstract

We document that firms appear disinclined to share underwriters with other firms in the same industry. We show that this disinclination is evident only when firms engage in product-market competition. This leads us to suggest that concerns about information leakage may motivate the patterns we see in the data. We discuss how these effects help us understand how the investment banking industry is structured, how banks compete, and how prices are set. At each step we exploit sources of exogenous variation that correspond to specific margins on which the effects of interest directly influence incentives and choices.

Key words: Investment banking; Securities underwriting; Competition; Bank deregulation; Bank entry; Glass-Steagall Act; Commercial banks.

JEL classification: G21, G24, G28, K22, L11, L14, L84.

# Competition and the Structure of Vertical Relationships in Capital Markets

April 1, 2008

## Abstract

We document that firms appear disinclined to share underwriters with other firms in the same industry. We show that this disinclination is evident only when firms engage in product-market competition. This leads us to suggest that concerns about information leakage may motivate the patterns we see in the data. We discuss how these effects help us understand how the investment banking industry is structured, how banks compete, and how prices are set. At each step we exploit sources of exogenous variation that correspond to specific margins on which the effects of interest directly influence incentives and choices.

Key words: Investment banking; Securities underwriting; Competition; Bank deregulation; Bank entry; Glass-Steagall Act; Commercial banks.

JEL classification: G21, G24, G28, K22, L11, L14, L84.

## 1. Introduction

Investment banks act as gatekeepers to the capital markets. Understanding how enterprises and banks interact is thus a crucial component in understanding how the wider economy operates. When a firm wishes to sell securities, it engages an investment bank to provide distribution services which include underwriting, promotion, and certification. Thus, borrowing from the industrial organization literature, firms and banks operate in a vertical market, with firms upstream and banks downstream.<sup>1</sup>

The finance literature documents that companies issuing securities tend to hire the same investment banks over and over again, both in the bond market (Yasuda (2005)) and in the equity market (Ljungqvist, Marston, and Wilhelm (2006)). Rather than employing long-term contracts or vertical integration, which are commonly observed in other industries, the vertical structure of investment banking is thus characterized by relationships.<sup>2</sup> These relationships are often viewed as a barrier to entry into investment banking.

We show that relationships endure in large part due to a desire to avoid sharing bankers with one's product-market competitors and present evidence that this affects pricing, and hence, competition, among banks. Consider Figure 1, which establishes a new stylized fact, namely that banks rarely serve more than one large firm in an industry. Using underwriting data from Thomson Financial going back to 1975, Figure 1a shows that the fraction of U.S. underwriters with multiple equity clients among the three, five, or ten largest firms in a four-digit SIC industry (ranked by annual Compustat net sales) rarely exceeds 5-10%. In other words, over the past three decades, few banks had more than one client among the largest firms in an industry. Debt underwriting relationships, shown in Figure 1b, appear similarly exclusive (though the level of exclusivity is somewhat lower than in the equity market).

---

<sup>1</sup> Tirole (1987) and Rey and Tirole (2007) provide introductions to the theory of vertical markets.

<sup>2</sup> For work on how contracting affects competition, see Gilbert and Hastings (2005), Asker (2004), Ho (2007), and Hortacsu and Syverson (2007).

Anecdotal evidence confirms that banks often refrain from working for competing firms. Hahn (2003) reports a CEO telling a banker during a pitch, “If you talk to my competitors, you are no longer welcome here.” The banker abandoned the pitch because he had a strong relationship with a competitor, commenting, “Effectively, you have to pick your horse.”

What accounts for the observed patterns of vertical relationships shown in Figure 1? The null hypothesis is that they reflect random matching between banks and firms; with sufficiently many banks and industries, banks might randomly serve few competing clients. We test, and reject, the null of such random matching in every piece of econometric analysis we conduct, at any significance level. Hence, we investigate the alternative that the patterns may be a response to more fundamental economic incentives. We consider three such possibilities.

First, a bank that works for two clients in the same industry uses the same resources to serve both clients’ needs, as investment banking teams typically specialize by industry. If resources are scarce, or time is of the essence, the bank may prioritize one client to the detriment of the other client. While concerns about such capacity constraints may explain why two firms in the same industry avoid sharing investment bankers, the reasons for doing so would be unrelated to actual product-market contact between the firms. For example, prior to energy-market deregulation in the U.S., two utilities in separate regional markets would be just as concerned about capacity constraints as two firms in direct competition, such as Coca-Cola and Pepsi.<sup>3</sup>

Second, working for two clients in the same industry may give rise to conflicts of interest. A prominent example is the bank’s conflicted role in situations where one of its clients launches a takeover bid for the other client. Ivashina et al. (2005), for example, show that the likelihood of an unsolicited takeover bid increases with the number of firms in a four-digit SIC industry a bank lends to. If managers dislike becoming takeover targets, perhaps because they fear a loss of private

---

<sup>3</sup> Our empirical investigation focuses on horizontal competitors. It is possible that a similar aversion to sharing underwriters extends to firms that are vertically related.

benefits of control, they have an incentive to avoid sharing investment bankers. Again, this argument does not require any product-market contact.

Third, firms may be concerned that privileged information which the bank obtains in the course of due diligence or other client contact is passed on to a competitor, whether explicitly, implicitly, or accidentally.<sup>4</sup> To return to the previous example, Coca-Cola has every incentive to prevent Pepsi from learning about Coke's production plans, product development, or distribution strategy. The two regional utilities, on the other hand, would be less concerned about information leakage, at least prior to deregulation. Thus, in contrast to the cases of capacity constraints and conflicts of interest, product-market contact is a necessary condition for information leakage concerns.

Our empirical findings suggest that product-market competition is an important determinant of the apparent exclusivity in issuer-bank relationships. Along with other evidence, this leads us to suggest that firms' reluctance to share underwriters is primarily due to concerns about information leakage concerns. Such concerns have been modeled in the banking literature (see Boot (2000) for a review). Raising capital from investors requires disclosure, to overcome adverse selection. Bhattacharya and Chiesa (1995) model the choice between revealing confidential information to a bank and public disclosure to the capital markets. Public disclosure suffers from a "two-audiences" signaling problem: It lowers the cost of capital but could benefit product-market competitors. A necessary condition for dealing with the bank then is that the bank not allow any sensitive information to leak to rivals. If the bank cannot precommit to keeping information confidential, or is unable to prevent accidental information leakage, competing issuing firms may seek to contain information leakage by avoiding sharing banks with rivals.<sup>5</sup>

Anecdotal evidence supports this view. In a submission to a Competition Commission inquiry

---

<sup>4</sup> We view information leakage as distinct from conflicts of interest. Information could leak accidentally or in ways that cannot be coordinated by the bank.

<sup>5</sup> For related theory models, see Anand and Galetovic (2000, 2006), Baccara (2005), Baccara and Razin (2004), and Zbojnik (2002). An interesting empirical study of similar issues in the pharmaceutical industry is Azoulay (2004).

into equity underwriting in the UK (Competition Commission (1999)), the London Investment Banking Association acknowledged that “Firms were understandably reluctant to make sensitive information more widely known than necessary” and thus had an incentive to restrict their dealing to a very limited number of investment banks. In the same inquiry, the submissions of Barclays Global Investors and Prudential Portfolio Managers, on the investor side, and the Ladbroke Group and CISCO, on the client side, raised the issue of information leakage in the context of underwriting relationships.

In 1987, Citicorp, a frequent debt issuer, asked First Boston, its investment bank, to resign from the underwriting syndicate of one of Citicorp’s competitors, Manufacturers Hanover. Eccles and Crane (1988, p. 59) recount that “First Boston denied a conflict of interest, but Citicorp apparently felt it was not worth the risk of having information [...] in the hands of its competitor.” Similarly, several disputes about information leakage have arisen in the M&A advisory context. Stuart (2006) reports market rumors that Goldman Sachs resigned from an advisory role after being accused of leaking confidential information from a previous engagement for the target to the bidder. Hahn (2003) reports similar allegations arising in a lawsuit against UBS filed by a former client.

Consistent with the notion that exclusivity is more prevalent in industries where the demand for secrecy may be higher, the data reveal greater exclusivity in relatively more concentrated industries, in industries that are relatively more dependent on intangibles, and in industries characterized by “soft” information (see Petersen and Rajan (2002) and Berger et al. (2005))). As Table 1 shows, these patterns hold both in the equity and in the debt markets.

Prompted by these preliminary findings, our empirical strategy proceeds as follows. Using a large set of equity and debt deals completed by large (and therefore strategically relevant) U.S. firms in 1975-2003, we examine firms’ choices on margins that allow us to control for the costs and benefits of sharing an investment bank. The costs may arise from either capacity constraints,

conflicts of interest, or the risk of information leakage. The benefits take the form of a bank's accumulated industry expertise: A bank serving other large firms likely has more experience of the issuer's industry, and thus greater credibility with investors, than a bank that has no other clients in the industry. Identification requires that we vary the costs while holding the benefits constant.

To unravel these effects, we begin by using plausibly exogenous variation from mergers among banks (Section 2). This enables us to hold industry expertise constant while varying the risk of sharing an underwriter. We find that both equity and debt issuers are more likely to switch away from their relationship bank if the merger increases the risk of sharing an underwriter than if it does not change that risk or if the bank has not been involved in a merger. The effect is to increase a client's switching probability by around thirty percentage points from the unconditional mean.

The results from the bank-merger test indicate that far from being random, the patterns in Figure 1 are the result of deliberate actions by firms to avoid sharing investment banks with other firms in their industry. In Section 3, we use industry deregulations as a source of exogenous variation in the extent of product-market contact among firms within industries. If capacity constraints or conflicts of interest account for the reluctance to share underwriters, firms *without* product-market rivals should be just as averse to their investment bankers serving other large firms in their industry as firms with product-market rivals, and deregulation should make no difference to their underwriter choices. If, on the other hand, choices reflect concerns about information leakage, we expect firms without product-market rivals to be indifferent to sharing underwriters prior to deregulation but to exhibit increased reluctance as their industry is deregulated. We find that reluctance to share underwriters is present only when firms have direct product-market rivals. Specifically, as an industry deregulates and competition increases, issuers start avoiding banks with ties to their rivals.

The evidence from the deregulation test suggests that the patterns in Figure 1 are most consistent with concerns about information leakage. To get a sense of the magnitude of this effect,

Section 4 exploits firms' responses to a rival switching relationship banks. Our identifying assumption is that when a rival client ends its banking relationship for exogenous reasons, the bank continues to benefit from superior knowledge of the rival's operations for a while but no longer poses a risk that information might be leaked to the rival. Such a bank should thus be more attractive to other companies in the industry. We find that issuers avoid banks with ties to their product market rivals while showing a preference for banks that have recently lost clients in their industry. An equity issuer, for instance, is around 55% less likely to choose a bank that presents a risk of information leakage than one that does not.

These results suggest that leaving an existing bank carries the potential cost that the ex-relationship bank's incentive to contain information spillovers is diminished. If so, banks gain a measure of hold-up power over their clients, which could help explain why underwriting relationships tend to endure. This leads to the prediction that banks, appreciating that firms' reluctance to share underwriters reduces the pool of competing banks, will charge higher fees. In Section 5, we again exploit deregulations to show that banks increase their fees as product-market contact among firms in an industry – and so concerns about sharing banks – increases. This suggests that the vertical structure of the investment banking market has an impact on the fees banks charge.

Firms' aversion to sharing underwriters appears important in understanding the dynamics of vertical relationships in investment banking. In Section 6, we suggest that entry by commercial banks appears to have played a role in relaxing the constraint on issuers' underwriter choices since 1987 when the Federal Reserve began deregulating Glass-Steagall Act restrictions on commercial banks' underwriting activities. Entry has enabled large firms to establish relationships with multiple banks, while banks continue to serve at most one large client per industry. These trends are consistent with falling underwriting fees documented in the finance literature (see Gande et al. (1997), Gande, Puri, and Saunders (1999), or Song (2004)).

## 2. Evidence from Bank Merger Activity

Is the apparently low incidence of large firms sharing underwriters, shown in Figure 1, random or deliberate? In this section, we show how firms react to plausibly exogenous changes in the risk of sharing an underwriter with another firm in the industry. The consolidation of investment banking over the sample period provides the necessary exogenous shock.

### *2.1 Identification*

Consider two banks, each serving one client firm in an industry. At some point the banks merge and the clients find themselves potentially sharing an underwriter. Under the null that matches are random, the firms don't care, so the merger will have no effect. However, if the prospect of sharing an underwriter generates some significant disutility, the merger will lead to one of the client firms switching banks (though we cannot predict which).

We implement this as a difference-in-differences test. First, we compare the switching behavior of firms whose relationship bank has, since their last securities issue, merged with a bank serving other large clients in the industry (the treatment group) to the switching behavior of firms whose relationship bank has merged with a bank lacking such relationships (control group 1). If sharing an underwriter generates significant disutility, we expect greater switching in the treatment group. Second, we compare both groups to firms whose relationship bank has not undergone a recent merger (control group 2). This allows evaluation of the extent to which mergers induce switching for reasons unrelated to concerns about sharing underwriters.

Difference-in-differences tests are commonly used to remove biases due to omitted variables or endogeneity concerns (Ashenfelter and Card (1985)). In our setting, the underwriter's industry expertise, skill in executing the transaction, or some other unobserved quality variable may be positively correlated with the presence of a rival firm among its clients. This would negatively bias estimates that do not exploit sources of variation that are independent of industry expertise or

similar unobservable factors. The test structure proposed avoids such biases because the industry expertise of the population of banks, other than the merging banks themselves, is unaffected by the merger and, thus, is held constant. Likewise, it allows us to eliminate the effect of not controlling adequately for a bank's skill in executing the transaction or some other quality variable. If these were driving a firm's lead manager choice, we should find no difference, following a bank merger, in the switching behavior of firms in those industries where the banks have competing clients (the treatment group) and those where they do not (control group 1).<sup>6</sup>

## *2.2 Are Bank Mergers Plausibly Exogenous?*

There were 202 mergers involving sample banks over the 1970-2003 period, with some banks being serial acquirers. Figure 2 shows three distinct merger waves, with the last one, beginning in 1994 and ending in 2001, the most active. Our identification strategy requires a bank not just to merge, but to merge with a bank that has clients in the same industry. As it turns out, this is rarely the case. Among the 202 mergers, only 12 and 19 involve overlaps in the two banks' large equity and debt clients, respectively. Generally, when a merger involves overlap, the extent of overlap is small. On average, only 6.7% (12%) of the combined number of industries in which the merging banks served large equity (debt) clients overlap. Conditional on overlap, the average merger involves 3.9 industries in which both banks have large equity clients (47 industries in total) and 6.3 industries in which both banks have large debt clients (119 industries in total).

Our experiment requires that banks merge for reasons that are unrelated both to the existence of overlap among their large clients and to those clients' anticipated switching decisions. Scanning news sources available through Factiva for the merger reasons we find no mention of client overlap considerations. Instead, banks appear to motivate their mergers in strategic and synergistic terms.

---

<sup>6</sup> A merger may change a bank's underwriting capability. Control group 1 allows us the control for this, since any change in such capability should have an equivalent effect on both the treatment group and control group 1. That is, the difference between the effects on these two groups nets out any change in the bank's underwriting capability.

As Figure 2 shows, many mergers involve acquisitions of investment banks by commercial banks, such as the 1999 acquisition of investment banking boutique Hambrecht & Quist by Chase Manhattan. Due to Glass-Steagall constraints, commercial banks traditionally had few large investment banking clients on the debt side and even fewer (or none) on the equity side, which contributes to the low degree of industry overlap we find in our data. Acquisitions of (mostly niche-oriented) investment banks were seen as a way to expand market share as Glass-Steagall constraints were relaxed throughout the 1990s (see, for instance, Weidner (1999)).

In several other cases, investment banks with a primarily institutional focus acquired investment banks with extensive retail franchises, reputedly in an attempt to expand their distribution capabilities. Examples include the 1997 acquisition of Salomon Brothers by Travelers Group,<sup>7</sup> owner of retail brokerage firm Smith Barney; Morgan Stanley's 1997 acquisition of retail brokerage firm Dean Witter; and UBS's 2000 acquisition of PaineWebber.<sup>8</sup>

Occasionally, investment banks were acquired after being weakened by idiosyncratic shocks. For example, Kidder Peabody was acquired by PaineWebber in 1994 after it emerged that Kidder's head of government trading had created phantom trades to increase his bonus (see Siconolfi (1994)), while BT Alex. Brown was acquired by Deutsche Bank in 1999 after reportedly losing \$850 million in the Long-Term Capital Management crisis in 1998 (see Leander (1999)).

A rare example of a "voluntary" merger between two banks with similar strengths and thus material client overlap is the acquisition of Donaldson, Lufkin & Jenrette by CS First Boston, which overlapped in 23 industries for debt clients and 11 industries for equity clients. Why did they nonetheless merge? According to Sikora (2000), "DLJ brings First Boston a market-leadership position in high-yield bond [trading], a merchant banking portfolio, a middle market M&A practice,

---

<sup>7</sup> Reportedly, CEO "[Sandy] Weill [...] emphasized that the primary reason for the Salomon [Brothers] acquisition is to expand Smith Barney's global reach." See *Investment Dealers Digest*, Nov. 10, 1997.

<sup>8</sup> Sikora (2000) notes that "PaineWebber largely was coveted by Swiss-based UBS for its retail securities network and its lucrative business of providing investment services for high net worth people."

and an Internet-based securities trading arm while also gaining the chance to expand in Europe.”

While we have found no anecdotal support for the existence of unobservables that correlate both with banks’ merger reasons and their clients’ anticipated switching decisions, our empirical specifications include bank-specific effects in an effort to mitigate potential omitted variable biases.

Another potential concern is reverse causality. It is possible that a bank acquires another bank for defensive reasons, because it anticipates the loss of a key client.<sup>9</sup> If so, we would erroneously attribute increased switching in overlapping industries to companies’ reluctance to share underwriters rather than the bank’s desire to make up for a client loss it knew was going to happen anyway. If such reverse causality were a feature of the data, it would imply that acquirers lose more clients than targets. Controlling for whether a company’s previous underwriter was the target or acquirer in the bank merger, we find no support for this implication.

Finally, instead of switching, firms could choose not to raise external finance when their usual underwriter begins to serve a rival client following a bank merger. This selection effect would lead to downward bias in the estimation of the coefficient of interest.

### *2.3 Data*

To implement the difference-in-differences test, we estimate the probability that an issuer switches lead managers in consecutive equity or debt deals. Following the literature, a switch is defined as an equity (debt) issuer hiring as lead manager any bank other than the lead manager of its most recent equity (debt) deal (or, if that bank has since been acquired, its successor).<sup>10,11</sup>

Throughout the paper, we focus on underwritten transactions by non-financial and non-governmental U.S. issuers completed between 1975 and 2003 (though we include 1970-1974 data to construct certain lagged variables). As Table 2 shows, there were 19,331 equity and 30,797 debt

<sup>9</sup> We thank a referee for alerting us to this possibility.

<sup>10</sup> In the case of multiple lead managers, we code as a switch any failure to retain every lead manager from the previous deal. This is the most logical way to code the data, but our results are not sensitive to this coding choice.

<sup>11</sup> Many banks specialize either in equity or debt underwriting, so we follow the literature in modeling equity and debt underwriting choices separately. See, for instance, Yasuda (2005) or Ljungqvist, Marston, and Wilhelm (2006).

offerings by U.S. non-financial issuers between 1975 and 2003, according to Thomson Financial.

For estimation purposes, we require that each deal was lead-managed by one of the 50 largest underwriters ranked by market share in the year of the offering and discard deals underwritten by smaller banks. The 50 largest banks account for at least 85% of equity and 95% of debt capital raised in any given year. Furthermore, we focus on the ten largest firms (by Compustat net sales) in each four-digit SIC industry; only large firms have sufficient issuing volumes for capacity constraints to be a significant concern and large enough market shares to expect interactions in the product market to have a strategic element.<sup>12,13,14</sup> To avoid biased inferences if issuers pre-select their lead managers for a program of debt deals spaced some months apart, we also exclude so called debt “shelf registrations.”<sup>15</sup> This leaves 12,016 deals by 3,353 companies in 418 four-digit SIC industries raising \$1.3 trillion in constant 1996 dollars. These deals account for 24% of the deals completed and 27.9% of the amount raised by U.S. non-financial companies in underwritten offerings over the period 1975-2003. As Table 2 shows, nonconvertible bond and common stock offerings account for the majority of deals and proceeds.

For the purpose of implementing the difference-in-differences test, we further exclude first-time deals, which cannot involve a switch (though we include 1970-1974 data when identifying first-time deals). This leaves 3,198 equity deals and 4,341 debt deals over the 1975-2003 sample period.

#### *2.4 Bivariate Results*

On average, large firms switch lead managers in 52.4% of the equity deals and 62.0% of the

---

<sup>12</sup> This is based on a firm’s primary SIC code. To the extent that firms operate in multiple industries, this is a potential source of measurement error which would tend to bias our estimates towards zero. We have repeated each of our tests in a restricted sample of single-segment firms. This reduces the available sample by more than 90%. Where tests can still be estimated, we find results that are both qualitatively and quantitatively similar to those reported in the paper.

<sup>13</sup> The product-market share of the tenth largest Compustat firm in the average industry between 1975 and 2003 is 1.5%, with a range from nearly zero to 6.1%. This puts an upper bound on the market shares of excluded firms.

<sup>14</sup> If, instead, it is the small players that avoid sharing underwriters, our approach biases us against finding that reluctance to share underwriters has an impact on lead manager choice.

<sup>15</sup> See Foster (1989); Denis (1991) documents that equity issuers virtually never make use of shelf registrations.

debt deals.<sup>16</sup> Of the 3,198 equity deals, 630 follow a merger involving the bank lead-managing the issuer's previous deal. In 49 of these, the previous lead manager merged with a bank that had a relationship with another top 10 firm (defined as having lead-managed at least one equity issue for another firm ranked in the top 10 in the prior five years); focusing on firms ranked in the top 3, there are 18 cases. These events are clearly associated with increased switching: 17 of the 18 issuers (94.4%) and 38 of the 49 issuers (77.6%) switch in response to their relationship bank merging with the relationship bank of a top 3 or top 10 firm, respectively. For comparison, mergers with banks lacking relationships in the industry (control group 1) are followed by a 63.3% switching rate while issuers whose relationship bank has not undergone a recent merger (control group 2) switch 49.5% of the time. Statistically, the switching rates of the two control groups are significantly lower than those of the treatment groups (at the 2% level or better), and they are not significantly different from each other. This provides evidence against the null of random matching: Issuers are no more or less likely to switch underwriters if their relationship bank has undergone a merger, *unless* the merger resulted in sharing an underwriter with another large firm in the industry.

The corresponding results for debt issuers are statistically weaker. Of the 4,341 debt deals, 296 follow a merger. In the 23 (14) cases involving a target bank with relationships among the ten (three) largest firms in the issuer's industry, switching occurs 78.3% (85.7%) of the time. The switching rate for the two control groups is 61.8% if the merger involved no overlap and 63.3% in the absence of a merger. The switching rate in the 14 treatment cases is marginally significantly higher than in the two control groups ( $p=0.089$  and  $p=0.066$ , respectively).

### *2.5 Multivariate Results*

The bivariate results provide preliminary support for the hypothesis that issuers derive disutility from sharing an underwriter. However, they make no attempt to control for other determinants of

---

<sup>16</sup> For comparison, Ljungqvist and Wilhelm (2005) report a 35.9% switching rate between a company's IPO and its first seasoned equity offering. Thus, firms appear to switch lead managers more frequently as they mature.

the switching decision. Prior literature suggests that firms have a tendency to stick with their previous underwriter (Ljungqvist, Marston, and Wilhelm (2006)), to prefer prestigious banks (Krigman, Shaw, and Womack (2001)), and to switch the more time has elapsed since their last deal (Fernando, Gatev, and Spindt (2005)). We thus control for the strength of the firm's relationship with its previous underwriter, four proxies for the previous underwriter's reputation which we borrow from prior work, the size of the firm (using log real sales), and the log time since the firm's previous deal. Table 3 summarizes the construction of each control variable and lists relevant sources. In addition, we control for lead manager-specific random effects<sup>17</sup> and year fixed effects. The latter control for the possibility that mergers involving banks with competing clients might cluster in certain years which might also happen to be years with high frequencies of switching.

Table 4 reports the results of probit models of switching.<sup>18</sup> The control variables confirm prior evidence. Issuers are less likely to switch the stronger their relationship with the bank, the larger the bank's debt market share, if its bank is highly regarded by its peers (as measured by eigenvector centrality, a standard measure of social networking), and if the bank's clients tend to be more loyal. Switching propensity also increases with firm size and time since the previous deal. We also include a dummy variable indicating if the issuer's pre-merger lead manager was the target in the merger. If the target bank bears the brunt of post-merger layoffs and firms switch in response to the resulting organizational upheaval, then the coefficient on the target dummy should be positive and significant. Under the reverse causality argument outlined in Section 2.2, the coefficient should be negative and significant. The insignificant coefficients suggest that neither story appears to be an important component of the data generating process.

Controlling for these factors, we find a higher switching propensity among both equity and debt

---

<sup>17</sup> We use random effects as fixed-effects probit (or logit) suffers from an incidental parameters problem. In unreported robustness tests using bank fixed effects in a linear probability model, we find that the results are unaffected.

<sup>18</sup> Results are robust to alternative assumptions about the distribution of the error term, including: Random-effects logit; probit or logit without lead manager-specific random effects or without year effects; fixed-effects linear probability models; complementary log-log (extreme value) distribution; and Gompertz distribution (results available on request).

issuers following mergers involving a bank serving a top 3 firm (the treatment group). In column (1), equity issuers in the treatment group are more prone to switching, both compared to mergers that involve no client overlap (control group 1;  $p=0.043$ ) and when there has been no merger (control group 2, the base category in column (1);  $p=0.042$ ); there is no difference in switching between control groups 1 and 2 ( $p=0.860$ ). In column (3), debt issuers in the treatment group switch more often than firms in control group 1 ( $p=0.076$ ) and those in control group 2 ( $p=0.010$ ).

Economically, the treatment effects are very large. The average switching rate in the equity treatment group is 31.1 and 31.4 percentage points greater than in control groups 1 and 2, respectively, holding all other covariates in col. (1) at their sample means. The corresponding numbers for the debt treatment group shown in col. (3) are 27.5 and 34.7 percentage points, respectively. These differences are in line with those reported earlier for the bivariate comparison, indicating that the control variables included in Table 4 have little effect on this result. Like the bivariate difference-in-differences test, the probit results provide evidence against the null of random matching: Issuing firms do switch underwriters following mergers that upset the equilibrium match between banks and firms in their industry.

The evidence regarding sharing underwriters with smaller firms (those ranked 4<sup>th</sup> through 10<sup>th</sup>) is more mixed. While the coefficients are positive for both equity and debt issuers, we find a statistically significant effect only in the debt sample (see column (3)).

In columns (2) and (4) we exclude control group 2 to focus on firms whose previous lead manager has undergone a merger since the issuer's last deal. The positive coefficients estimated for firms in the treatment group confirm that it is a merger with a bank that has relationships with other large firms in the industry, rather than a merger per se, that induces greater switching. This provides additional evidence suggesting that firms do not switch underwriters simply to avoid any upheaval accompanying mergers.

### 3. Evidence from Deregulation

The results of the bank-merger test support the interpretation that firms are reluctant to share underwriters. What accounts for this reluctance? As we outlined in the introduction, three plausible explanations are concerns about capacity constraints, conflicts of interest (for example, in takeover contests), or information leakage. As we argued, product-market contact is a necessary condition only for the information leakage story. Firms in the same industry that are shielded from competition by statute should be just as concerned about capacity constraints and conflicts of interest as firms that compete with each other in the product-market. If capacity constraints and conflicts of interest lead to disutility from sharing underwriters, product-market deregulation should make no difference to their underwriter choices. However, if choices reflect concerns about information leakage, we expect firms without product-market rivals to be indifferent to sharing underwriters prior to deregulation, because such leakage would not put them at a strategic disadvantage absent competition, while their reluctance should increase following deregulation.

#### *3.1 Identification and Modeling*

To test this prediction, we focus on transactions from those four-digit SIC codes that are subject to a significant deregulatory (competition-increasing) shock over the sample period, as identified by Viscusi, Harrington, and Vernon (2005), a standard textbook on regulation and antitrust. We list these in Table A1 in the Appendix. Examples include the 1978 Airline Deregulation Act, the partial deregulation of the trucking industry in the 1980 Motor Carrier Reform Act, and the 1992 Energy Policy Act which introduced wholesale competition in electrical power. Twenty-three of the deregulating industries identified by Viscusi et al. are represented in our sample.

Under the null that capacity constraints or conflicts of interest account for issuers' reluctance to share underwriters, we expect issuers to avoid choosing underwriters that serve other large firms in their industry, both before and after deregulation. Under the alternative hypothesis of information

leakage, we expect issuers to be indifferent to a bank's other relationships before deregulation but to avoid their rivals' relationship banks after deregulation.

Due to the small number of cases in the intersection of bank mergers and deregulating industries, we cannot adapt the difference-in-differences approach of Section 2. Instead, we estimate a standard model of underwriter choice (see, for instance, Bharat et al. (2007), Yasuda (2005), or Ljungqvist, Marston, and Wilhelm (2006, 2007)). The unit of observation is a potential firm-bank pairing. The firm, having decided on the form of financing (i.e., debt or equity), chooses one or more banks to act as lead manager. Following Ljungqvist, Marston, and Wilhelm (2007), we take the issuer's choice set to be the 50 largest banks by market share.<sup>19</sup> Their combined market share averages 96.5% in the equity market and 99.5% in the debt market.

Identification should come from the deregulation events and not some unobserved confounding events. Ideally, therefore, we would want to restrict the sample to a narrow window before and after each deregulation event. Sample size considerations lead us choose a ten-year window centered on a deregulation event. This leaves us with 126 equity and 570 debt transactions.

Each issuing firm  $k$  is modeled as having a utility  $u_{kjt} = \alpha R_{jt} + x_{kjt} \beta + \nu_t + \eta_j + \varepsilon_{kjt}$  associated with giving each of the 50 competing banks  $j$  a lead manager mandate, where  $R_{jt} = 1$  if bank  $j$  already has another large client in the issuer's four-digit SIC industry, the  $x_{kj}$  are other determinants of lead manager choice,  $\nu_t$  and  $\eta_j$  are year and bank-specific effects, respectively, and  $\varepsilon_{kj}$  is an observation-specific idiosyncratic shock that is assumed to have a normal distribution. Faced with these utilities over choices, each firm chooses the bank associated with the greatest utility. The resulting model is estimated as a standard multivariate probit.<sup>20</sup>

As in the bank-merger test, we control for the strength of the firm's relationship with the

<sup>19</sup> By construction, a commercial bank is treated as competing for a lead-management mandate prior to the repeal of the Glass-Steagall Act only if it had a so called Section 20 subsidiary with the relevant securities underwriting authority.

<sup>20</sup> Our results are robust to alternative assumptions about the distribution of the error term, including random-effects logit and fixed-effects linear probability models. These results are available on request.

candidate bank, the four proxies for bank's reputation, log firm sales, and lead manager and year effects. Unlike in the bank-merger test, we cannot rely on a difference-in-differences argument to remove biases due to omitted variables. A likely omitted variable is a bank's industry expertise, which correlates both with serving other large firms in the industry and with a higher selection probability. We therefore include a proxy for industry expertise, measured as the combined concurrent product-market share of a bank's clients in the issuer's four-digit SIC industry. Product-market shares are computed from annual Compustat net sales data.

### 3.2 Results

To test the hypothesis that exposure to competition makes firms more reluctant to share underwriters, we allow the slope coefficients to vary between deals completed before the year of the first deregulatory shock ("pre") and those completed afterwards ("post").<sup>21</sup> The results shown in Table 5 support this hypothesis. In deals completed pre-deregulation, the effect of a bank having served one of the three largest firms in the issuer's industry is insignificant, suggesting that issuers were indifferent to whether a bank serves other large clients in the industry with whom they had no product-market contact. Post-deregulation, in contrast, the coefficient is significantly negative in the equity market ( $p=0.009$ ). In the debt market, it is large and negative but somewhat imprecisely estimated ( $p=0.114$ ). Moreover, we find evidence that debt issuers avoid underwriters serving smaller rivals (those ranked fourth through tenth in their industry) post-deregulation. A Wald test rejects the equality of the rival-client coefficients pre- and post-deregulation in the equity sample ( $p=0.058$ )<sup>22</sup> though not in the debt sample ( $p=0.284$ ). This suggests that product-market contact contributes to firms' apparent reluctance to share underwriters with other large firms in their industry, particularly in the equity market.

---

<sup>21</sup> In some instances, industries were deregulated in phases. It is reasonable for everyone to assume that once deregulation starts, it will continue. We therefore focus on the first significant deregulation event in each industry.

<sup>22</sup> The bank-specific effects are insignificant. Dropping them, this Wald test is significant with a  $p$ -value of 0.013.

Might this result be driven by omitted variables? Deregulation events may, to some extent, coincide with banking deregulation. This could mechanically drive our result if entry into the securities underwriting market reduces a bank's likelihood of serving multiple large clients. While our specifications include year and bank-specific effects, these may not be sufficient to completely remove potential omitted variable biases. We therefore turn to a Monte Carlo simulation.

Under the information leakage hypothesis, we expect a change in the degree of reluctance to hire a bank that serves a large rival *only* among issuers whose industries are being deregulated. In non-deregulating industries, we expect no significant change around the deregulation dates, *unless* those dates coincide with other, unobserved developments that affect all industries to some extent.

To test this counterfactual, we draw 500 random samples of 13 non-deregulating industries each (without replacement), match each industry randomly to one of the six deregulation dates shown in Table A1 that are relevant for the equity sample, and then test whether the “pre” and “post” coefficients estimated for the rival-client variable are different when we re-estimate the Table 5 specification for equity issuers in these non-deregulating industries. Using a Wald test as above, we reject the null of equal coefficients at the 5% level in 28 of 500 simulations (5.6%). This indicates the test has near-perfect size.

In sum, based on the Table 5 results, we are “94.2% confident” (1-0.058) that there is a change in the reluctance to share underwriters among equity issuers from deregulating industries, and based on the simulation evidence, we are “94.4% confident” (1-0.056) that there is no corresponding, contemporaneous change in the reluctance to share underwriters in non-deregulating industries.

Economically, the effects in Table 5 are large. Post-deregulation, a relationship with an issuer's top 3 rival reduces a bank's chances of lead-managing an equity deal by 32.8%, from the one in 50 unconditional likelihood, holding all other covariates at their sample means. Compared to the two variables identified in prior work as the main determinants of underwriter choice, the effect of rival

relationships is larger than that of a one-standard-deviation increase in bank-issuer relationships (+13.7%) or the bank's reputation (+20.3%, as measured by eigenvector). The pattern is similar though economically smaller for debt issuers.

Summarizing the effects of the controls, we find that a candidate bank's chances of becoming lead manager improve significantly, the stronger its prior underwriting relationship with the issuer; the greater its market share and reputational standing; and the greater its industry expertise. These findings mirror those in the bank-merger test presented in Section 2.

#### **4. Evidence from Client Switching**

The evidence in Section 3 is most consistent with the hypothesis that firms avoid sharing banks due to concerns that confidential information might be leaked to rivals. If the information leakage hypothesis is true, information concerns may be offset not only by greater industry expertise as argued before, but also by the potential for a firm to *benefit* from sharing a bank because it might learn useful information about a rival. That is, there are both costs and benefits to information leakage. We now attempt to disentangle these costs and benefits, and in so doing, estimate the economic magnitude of the costs under the maintained assumption of information leakage.

##### *4.1 Identification*

Identification exploits firms' responses to a rival discontinuing a banking relationship. Our identifying assumption is that a rival's switch away from its former relationship bank presents an attractive opportunity for other firms in the industry. This bank has both general industry expertise and specific knowledge of the rival, both of which are beneficial to an issuer, but following the end of the relationship with the rival, there is no longer a risk of information leakage. In contrast, banks that continue to serve rivals have general industry expertise and offer both an information benefit (in the form of specific knowledge of the rival) and an information cost (in the form of possible information leakage). By comparing the propensity of firms to match with these two types of

underwriters, we can isolate the cost of information leaking to a rival via a shared underwriter.

This identification strategy makes three assumptions:

- 1) A bank's industry expertise and other unobserved quality attributes are unaffected by the switch, at least within the timeframe after the switch we consider.
- 2) The information benefit is unaffected by the switch.
- 3) The client switch is orthogonal to any bank unobservables, i.e., the switch is exogenous.

Assumption 3) would be violated if firms switch underwriters when quality of service has deteriorated. Thus, we run the risk of our treated banks being poor quality relative to the untreated set, which would decrease the estimated magnitude of the cost of information leakage. Conversely, a firm may switch because it knows that its usual underwriter will soon work for a competitor, reducing its capacity. Or having lost a client, a bank may cut its fees in an effort to keep its industry desk occupied.<sup>23</sup> In either case, a positive correlation between the probability that a given bank is chosen as lead manager and the fact that it has recently lost a client would be unrelated to information leakage, and so we would overestimate the information leakage effect.

To address possible biases introduced by these sorts of stories, we use merger activity among issuing firms to identify plausibly exogenous switches, in addition to a more data-driven definition of a discontinued relationship. We discuss the precise nature of these two approaches below.

#### *4.2 Discontinued Relationships*

We focus on two types of discontinued relationships. First, we consider a firm's rival to have switched relationship banks if the rival was acquired by another firm at some point in the five years preceding the deal for which an issuing company is selecting a lead manager. We use CRSP delisting codes 200 and 300 to identify acquisitions. Our maintained assumption is that the (rival) merged firm's CFO will most likely use the bank with which he has an existing relationship, leaving

---

<sup>23</sup> However, coding lost clients as in Section 4.2 below, we find no evidence that banks cut fees after losing clients, controlling for other common determinants of fees as in Section 5 below.

the target's relationship bank in the position of having lost an important (rival) client.

The second type of switch exploits variation in the duration of relationships. We deem a firm's rival to have switched if it has awarded no underwriting business to its previous relationship bank for  $T$  years.  $T$  is arbitrary, and we report results for  $T=3$  and  $T=5$ . Within  $T$  years of its most recent deal, a rival firm is coded as an active client of the bank's. After  $T$  years, it is coded as a former or inactive client. We assume the bank's information about the rival client to decay following a switch, and so code the bank as having an inactive rival client for only one year following the switch (i.e., in year  $T+1$ ). Beyond that, the bank is coded as no longer having a rival client in the industry.

#### 4.3 Estimation

We implement the client-switching identification strategy by adapting the probit model of the previous section. Specifically, we adjust the reduced-form utility of a company  $k$  choosing bank  $j$ ,  $u_{kjt} = \alpha R_{jt} + x_{kjt} \beta + v_t + \eta_j + \varepsilon_{kjt}$  (where  $R_{jt} = 1$  if the bank has a rival client in  $k$ 's industry), so that

$$u_{kjt} = \alpha R_{jt}^{ns} + \gamma R_{jt}^s + x_{kjt} \beta + v_t + \eta_j + \varepsilon_{kjt}$$

where  $R_{jt}^{ns} = 1$  if bank  $j$  has a large rival client in the issuer's industry and that client has not switched (i.e., it remains an active rival client) and  $R_{jt}^s = 1$  if the bank had a large rival client that has recently switched (i.e., an inactive rival client). We estimate this model in the whole sample (not just for deregulating industries). This sample is described in block (2) of Table 2.

To see where identification is coming from, we decompose  $\hat{\alpha}$  and  $\hat{\gamma}$ . Let

$$\hat{\alpha} = \text{industry expertise} + \text{information benefit} + \text{information cost}$$

$$\hat{\gamma} = \text{industry expertise} + \text{information benefit}$$

so that  $\hat{\alpha} - \hat{\gamma} = \text{information cost}$

The function  $\hat{\alpha} - \hat{\gamma}$  can be constructed from estimated parameters; standard errors are computed using the delta method (see Greene (2003, p. 916)). Under the hypothesis that firms avoid sharing

underwriters to minimize the risk of information leakage, the sign of  $\hat{\alpha} - \hat{\gamma}$  should be negative.

#### 4.4 Results

Table 6 reports the three probit specifications, using firm mergers and client switches with T=3 and T=5, respectively, to identify active and inactive rival clients. To conserve space, we report only the coefficients estimated for the active and inactive rival relationship dummies and the difference between the two. As per the above decomposition, this difference measures the net effect of concerns about information leakage. The control variables behave in line with those shown in the deregulation models in Table 5.<sup>24</sup>

The results provide support for the hypothesis that information spillover concerns have a first-order effect on firms' choice of lead manager. The function  $\hat{\alpha} - \hat{\gamma}$  is consistently negative and significant in five of the six specifications for the case of top 3 rivals. The economic magnitude of the information cost, shown in the columns labeled dF/dx, is very large. An equity issuer, for instance, is around 55% less likely to choose a bank that presents a risk of information leakage than one that does not. Debt issuers have a zero probability of choosing such a bank.

Relationships with smaller rivals (those ranked fourth through tenth in an industry) also have a negative effect on a bank's chances of being hired as lead manager, though this effect is both statistically and economically weaker.

Finally, note that  $\hat{\gamma}$  is not only mostly positive and significant but also frequently large economically. Depending on the specification, a bank is between 42% and 132% more likely to be chosen if it *used to* have relationships with one of the issuer's main rivals. This suggests that industry expertise and an intimate knowledge of key rivals do play a key role in underwriter selection, consistent with our identification strategy.

---

<sup>24</sup> Our results are robust to alternative assumptions about the distribution of the error term, including random-effects logit and fixed-effects linear probability models. These results are available on request.

## 5. The Price of Exclusivity

Deregulation allows us to explore possible pricing consequences of a reluctance to share banks. If such a reluctance is well-founded (reflecting, say, information spillover concerns), it reduces an issuer's effective choice set and thus competition. Depending on the magnitude of information leakage concerns, it may even give the bank hold-up power because ending a relationship may increase the risk that the bank will spill its knowledge of the issuer to future clients.<sup>25</sup> As a result, banks may charge higher underwriting fees after deregulation.

So far, we have implicitly modeled fees as a component of unobserved bank characteristics, for the simple reason that we cannot observe fees in the entire choice set: Fees quoted by banks that didn't win an underwriting mandate are not publicly disclosed. But we can exploit the deregulation events to test whether banks exploit their increased bargaining power by increasing fees as firms in deregulating industries begin to have concerns about sharing underwriters.

We estimate standard fee regressions, where the dependent variable is the fee (or "gross spread") paid to the underwriter or underwriting syndicate, measured as a fraction of issue proceeds times 100. The main variable of interest is an indicator identifying deals from deregulating industries completed after a competition-increasing deregulation event. We control for economies of scale in underwriting by including issue proceeds and log issue proceeds (see Ljungqvist, Jenkinson, and Wilhelm (2003)) and for issuer and offer characteristics. We also include lead manager fixed effects and year effects. Collectively, these controls account for between 31.2% and 73.2% of the variation in fees in Table 7.

Column (1) shows that average fees increased by 91 basis points in the equity sample post-deregulation.<sup>26</sup> In column (2), we restrict the sample to deals occurring in a ten-year window

---

<sup>25</sup> For an analysis of hold-up in *lending* relationships, see Sharpe (1990), Rajan (1992), and Petersen and Rajan (1995).

<sup>26</sup> To the extent that regulated industries are more transparent, it may be that deregulation raised underwriting costs as risk discovery and disclosure became more burdensome. If so, this may introduce an upward bias to our estimates.

centered on each industry's first deregulatory event. This reduces the estimated fee increase, post-deregulation, to 52 basis points. Debt offerings display similar patterns, with fees estimated to increase post-deregulation by 38 basis points in the full sample (see column (3) or by 83 basis points when we impose the ten-year window (see column (4)). The evidence from both equity and debt fees thus supports the view that a reluctance to share underwriters enables banks to charge higher fees for their services.<sup>27</sup> Monte Carlo simulations along the lines of Section 3.2 again confirm that there are no corresponding changes in fees in non-deregulating industries.

## **6. Implications for Vertical Relationships in Investment Banking**

Our evidence indicates that large firms, when issuing securities, are reluctant to share a bank with a product-market rival, contributing to the low incidence of banks working for multiple large clients in an industry as shown in Fig. 1. The deregulation test suggests that a likely driving force is concerns about possible information leakage. We now explore how these findings affect how we interpret the changing structure of vertical relationships in the U.S. investment banking industry.

The most notable force shaping the structure of the investment banking industry over the last two decades has been deregulation of the Glass-Steagall separation of commercial and investment banking. In a series of steps beginning in 1987, commercial banks were allowed to enter securities underwriting, culminating in the repeal of the Glass-Steagall Act in 1999.

From the point of view of an issuing firm, entry expands the set of banks that are unencumbered by a prior relationship with a rival. This makes the entrant an attractive choice relative to many incumbents. Assuming firms felt constrained in their underwriter choices, we would expect that the effects documented in the paper have made entry easier, as commercial banks unencumbered by existing relationships were in a relatively good position to gain market share as Glass-Steagall

---

<sup>27</sup> Fees may increase post-deregulation simply because deregulation itself increases demand for external capital while the supply of underwriting services in the short-run is fixed. In unreported regressions, we include the amount of capital raised in the same year or quarter by other firms in the same industry but find no systematic evidence that fees are impacted by this. Similarly, controlling for the number of deals done by firms in the same industry has no effect.

constraints were relaxed. A specific prediction that follows is that we should observe an increased propensity for firms to establish multiple banking relationships, as entry increases the number of banks toward the point where firms can maintain multiple relationships without having to share bankers. In this section, we present evidence that is consistent with this prediction.

Figures 3a and 3b show the annual number of commercial banks active in equity and debt underwriting in the U.S., respectively, as well as their combined market share. Entry by commercial banks appears to have been very successful, especially after 1999. As a group, commercial banks captured 70% of the debt underwriting market and 38% of the equity underwriting market by 2004. A handful of commercial banks, including Citigroup and JP Morgan Chase, emerged as substantial competitors to the incumbent investment banks.

Figures 4a and 4b show the extent to which issuing firms have tended to concentrate their underwriting business with a single bank. We measure this by calculating the total amount raised by each issuing firm in a given window and then looking at how this was shared among the one or more banks acting as lead manager. (For the purposes of the figures, we use one-, two-, and three-year windows.) From this we construct a Herfindahl index of the concentration of each issuer's bank relationships. A Herfindahl of one indicates an exclusive bank relationship. We then take a weighted average over firms in a quarter, weighting by the total proceeds raised by each firm over the relevant window. Weighting has the effect of reducing average exclusivity, indicating that larger issuers are more likely to have more than one relationship bank.

The patterns in Figures 4a and 4b are striking. Prior to the mid 1990s, bank relationships were nearly all exclusive. They have since become considerably less exclusive. For the average equity issuer, concentration has fallen from around 0.95 to between 0.62 and 0.7 in 2003Q4, depending on the window used, suggesting that by the end of the sample period, the dominant model is no longer an exclusive-bank relationship but a set of multiple relationships around a core bank that is awarded

a disproportionate share of the average issuer's underwriting business. This may be the result of efforts to engender competition among banks.<sup>28</sup> In the debt market, the decline in exclusivity has been even steeper. By the end of the sample period, average relationship concentration had fallen to between 0.39 and 0.47, depending on the window, a level consistent with a stable two- or three-bank relationship. These data are consistent with the prediction that increased entry makes it easier for firms to establish multiple investment banking relationships.

## 7. Conclusions

This paper presents evidence suggesting that firms seek to avoid sharing investment bankers with their product-market rivals when possible. To establish this finding, the paper uses a range of novel sources of identification aimed at isolating margins on which any such disinclination would have a meaningful economic effect.

What might cause such behavior? The results best support the hypothesis that firms seek to avoid sharing underwriters in order to avoid commercially sensitive information leaking to rival firms. Unlike alternatives, this hypothesis predicts that the propensity to avoid sharing underwriters appears important only when firms have direct product-market contact with other large firms in their industry. Evidence using deregulation events is consistent with this view.

Whatever the reason for the reluctance to share underwriters, we find that banks appear to set higher prices as firms become more concerned about the risk of sharing underwriters. This suggests that a desire to avoid sharing underwriters limits firms' choice set and, hence, effective competition. It constrains competition because, with a limited number of banks capable of executing large or complex deals, there may simply be too few banks to allow each firm to have multiple relationships while at the same time avoiding sharing banks with a major rival. At the very least, this constrains the issuer's choice set of underwriters. However, paradoxically, the same phenomenon may also act

---

<sup>28</sup> Alternatively, it is possible that commercial banks leaned on their borrowers to share their underwriting business in return for preferential loan terms (Drucker and Puri (2005)).

as an aid to entry: An entering bank benefits from being unencumbered by existing relationships that would otherwise prejudice a firm's underwriter choice.

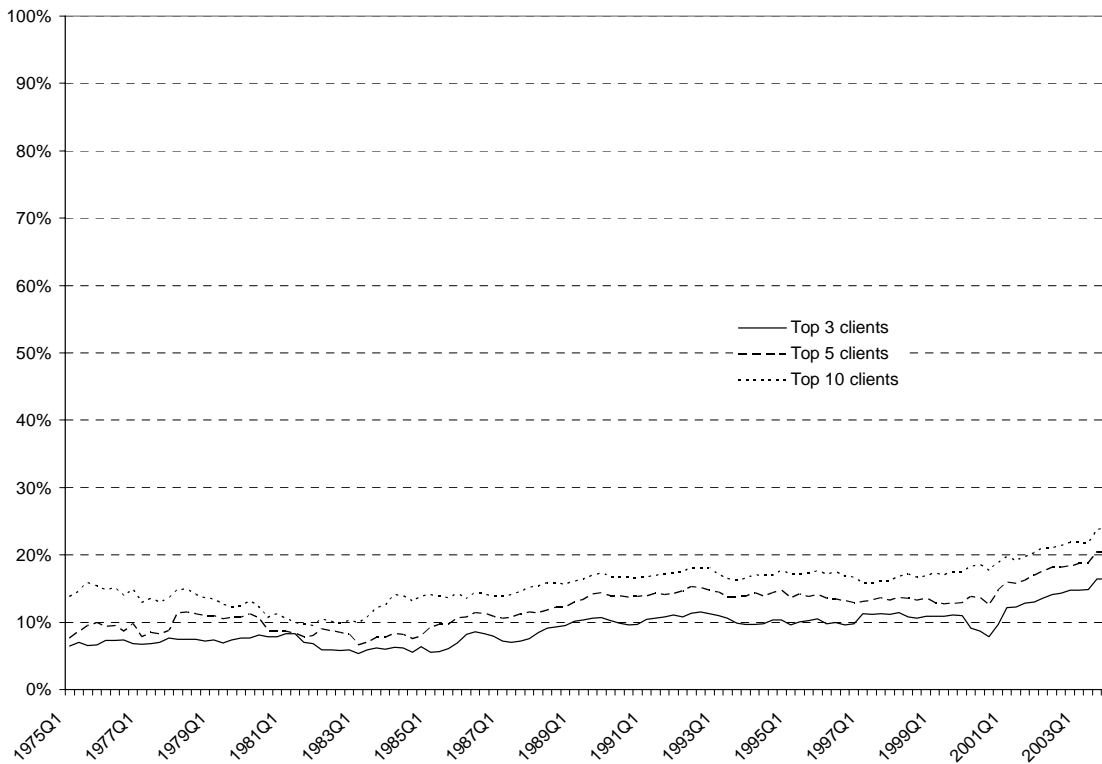

### Figure 1a. Exclusivity of Bank-firm Equity Relationships

The graphs show the quarterly fraction of equity or debt underwriters with multiple clients among the three, five, or ten largest firms in a four-digit SIC industry (ranked by Compustat net sales), conditional on having at least one such client. We code a bank as having a client in industry  $i$  in quarter  $t$  if it has lead managed one or more securities issues for a firm in that industry over the five years ending in quarter  $t-1$ . The variables are constructed using underwriting data from Thomson Financial going back to 1970.

### Figure 1b. Exclusivity of Bank-firm Debt Relationships

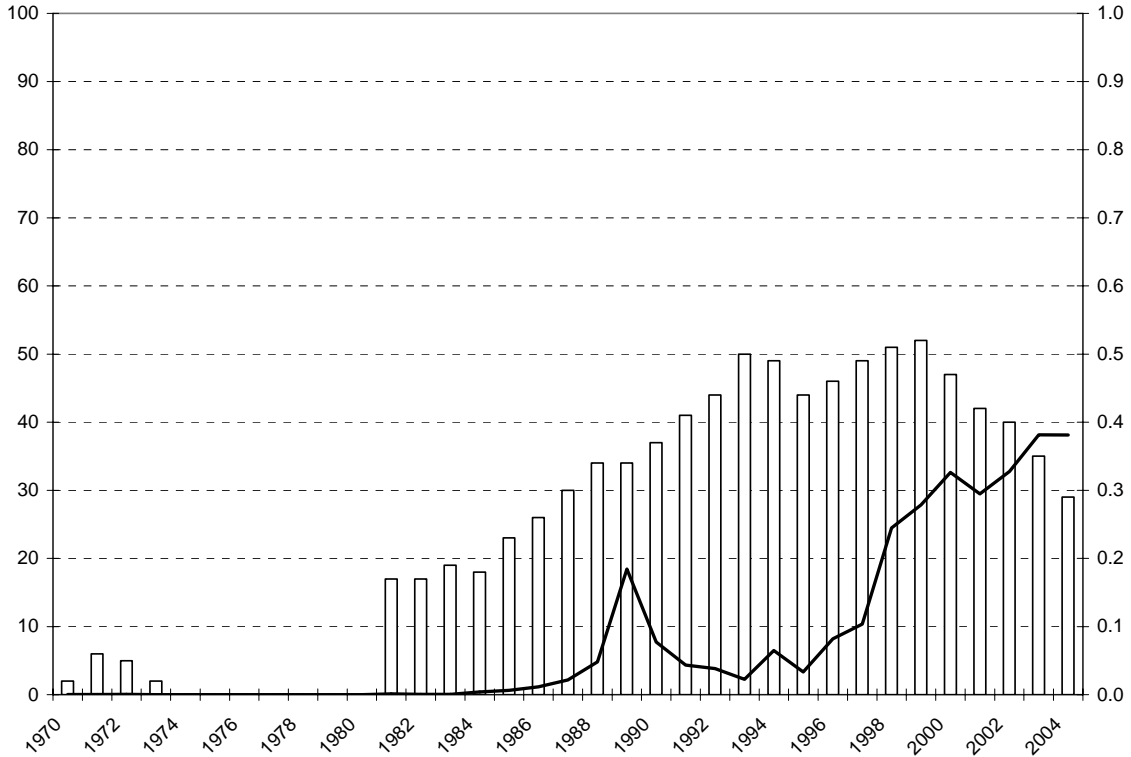

## Figure 2. Annual Number of Bank Mergers

The figure shows the annual number of bank mergers. We distinguish three cases: Mergers between two investment banks (IB-IB); mergers between two commercial banks (CB-CB); and acquisitions of investment banks by commercial banks (CB-IB). We continue to call a commercial bank a commercial bank after it has acquired an investment bank. We include all mergers (and in two cases, joint ventures of the two banks' capital markets divisions) by any bank involved in securities underwriting in the U.S. capital markets, according to Thomson Financial, between 1970 and 2003. As a consequence, the figure includes mergers between foreign banks, such as the 1984 merger between two Canadian commercial banks, Harris Bankcorp and Bank of Montreal. The total number of mergers included in the figure is 202.

### Figure 3a. Number and Combined Equity Market Share of Commercial Banks

The graphs show the combined equity (in 3a) and debt (in 3b) market share of commercial banks (on the right-hand axis) and the number of commercial banks that have positive market share in each year (on the left-hand axis). Deregulation began in 1987 and the Glass-Steagall Act was repealed in 1999. There is underwriting by commercial banks prior to 1987 as some banks had grandfathered underwriting rights; due to the inclusion of foreign banks active in the U.S. capital markets; and because we include private placements, which fell outside the Glass-Steagall restrictions.

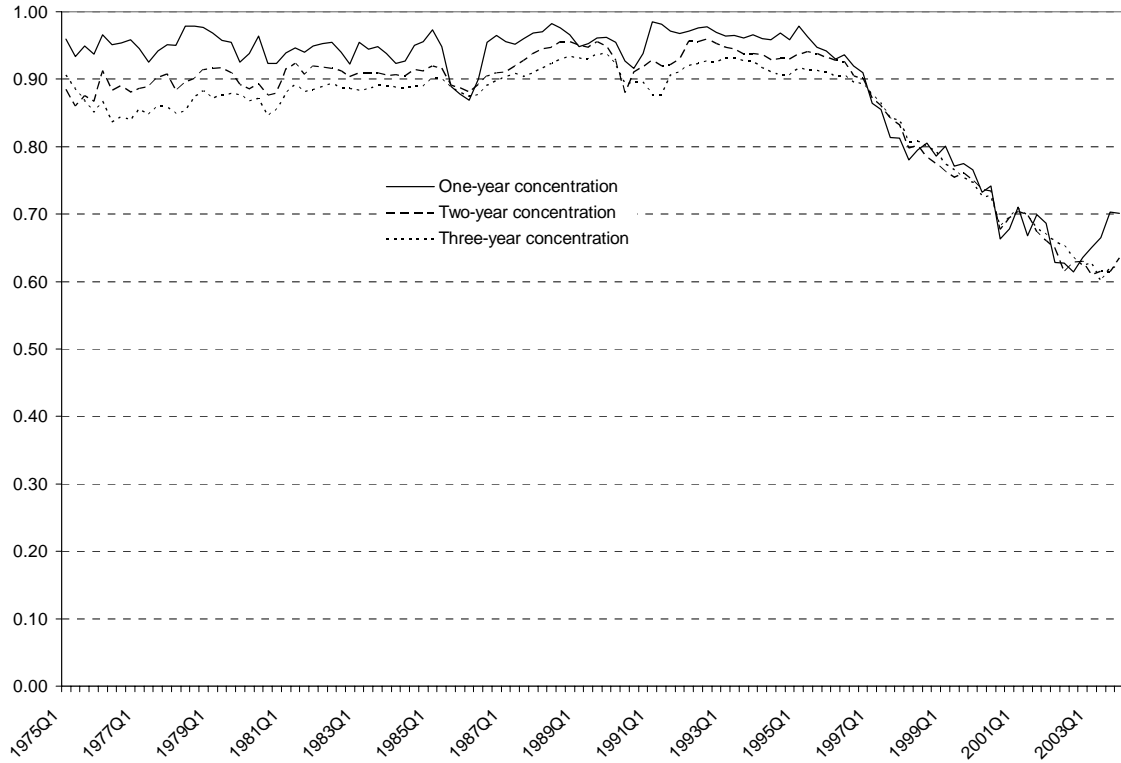

### Figure 3b. Number and Combined Debt Market Share of Commercial Banks

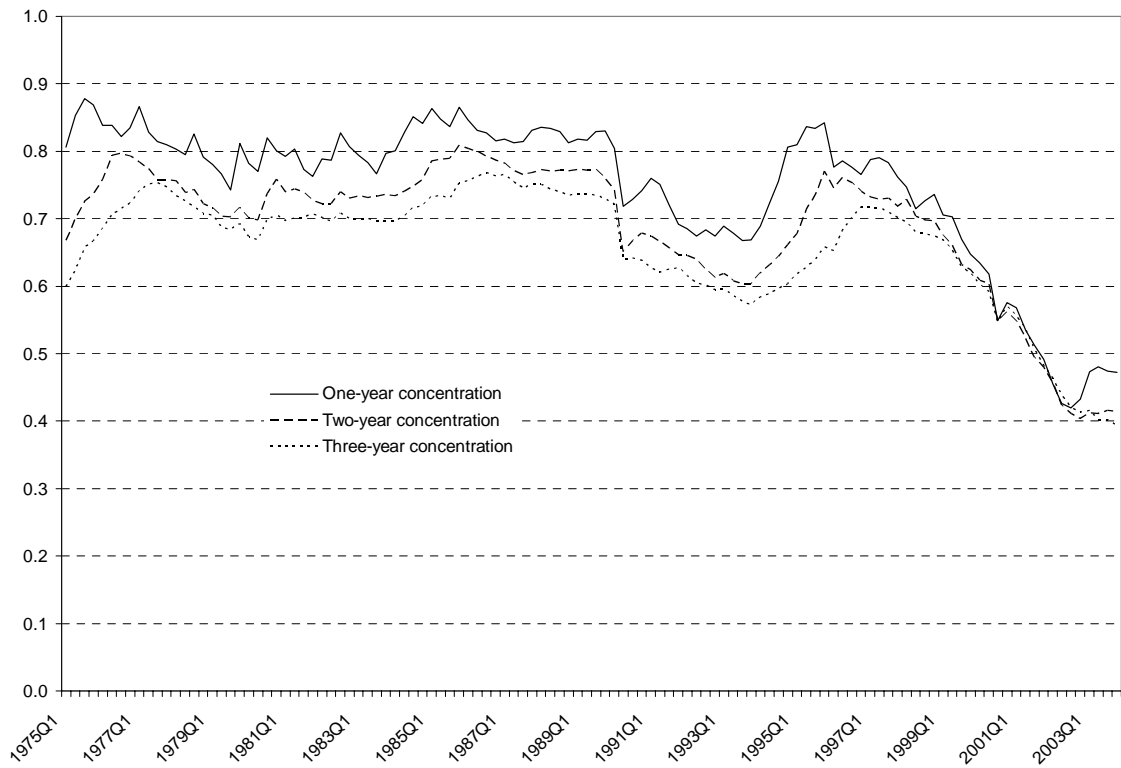

### Figure 4a. Concentration of Bank-firm Equity Relationships

The graphs show the Herfindahl concentration index of bank-firm relationships, measured over the prior one, two, or three years, of the average U.S. issuer (weighted by each issuer's cumulative proceeds over the relevant window).

### Figure 4b. Concentration of Bank-firm Debt Relationships

**Table 1. Exclusivity of Bank-firm Relationships and Proxies for Secrecy**

This table provides descriptive statistics consistent with the notion that exclusivity is more prevalent in industries where the demand for secrecy may be a higher. As in Figures 1a and 1b, we compute the quarterly fraction of equity or debt underwriters with multiple clients among the three largest firms in a four-digit SIC industry (ranked by Compustat net sales), conditional on having at least one such client. A larger fraction implies less client exclusivity. We then compute the time-series average such fraction for each of three sample splits, and test for equality of fractions for each sample split using a standard Z-test. To proxy for the demand for secrecy, we split four-digit SIC industries a) at the median Herfindahl concentration index, b) at the median asset tangibility, and c) according to whether information is predominantly “hard” or “soft” in the industry. The Herfindahl concentration index is computed as the sum of the squared market shares of firms in the industry, based on Compustat net sales. The median value in the sample of industries with securities issuers in our sample is 0.332. An industry’s asset tangibility is defined as the industry’s median ratio of property, plant, and equipment (Compustat item #8) divided by total assets (Compustat item #6). The definitions of hard and soft information follow Landier, Nair, and Wulf (2006) who compare two snapshots (1987 and 1998) of the mean distance between firms and bank lenders per industry at the 2-digit SIC level. In industries that are predominantly characterized by hard information, they expect mean distance to have increased as banks have begun to rely more on impersonal means to collect information, whereas in soft-information industries, banks need to stay closer to their corporate borrowers and so it is harder to increase geographic distance. A hard-information industry is then defined as one whose percentage increase in mean distance between 1987 and 1998 is above the median such increase across industries. The measure of distance to nearest bank is computed using data from the National Survey of Small Business Finances (1987 and 1998) conducted by the Federal Reserve. A small business is defined as a for-profit, non-financial, non-farm, non-subsidary business enterprise that had fewer than 500 employees and was in operation at the time of the survey. Where a business was served by more than one bank, the average distance across all relevant banks was computed for that business. Averages across businesses were computed taking into account the sampling weights from the survey. Observations where the distance was not recorded were omitted. We use <sup>\*\*\*</sup>, <sup>\*\*</sup>, and <sup>\*</sup> to denote significance at the 1%, 5%, and 10% level (two-sided), respectively.

		Equity	Debt
Industry Herfindahl	“concentrated” (above-median Herfindahl)	1.5%	4.5%
	“unconcentrated” (below-median Herfindahl)	3.1%	12.2%
	<i>Z-statistic</i>	9.95 <sup>***</sup>	34.60 <sup>***</sup>
Asset tangibility	“predominantly intangible” (below-median PPE/total assets)	2.0%	4.2%
	“predominantly tangible” (above-median PPE/total assets)	2.6%	11.4%
	<i>Z-statistic</i>	4.13 <sup>***</sup>	29.81 <sup>***</sup>
Information	“soft” (below-median distance increase)	2.2%	6.9%
	“hard” (above-median distance increase)	2.6%	9.0%
	<i>Z-statistic</i>	2.06 <sup>**</sup>	9.44 <sup>***</sup>

**Table 2. The Sample of Capital-raising Transactions**

The first block of columns shows a breakdown of all capital-raising transactions listed in Thompson Financial's SDC database completed between January 1975 and December 2003, after excluding non-underwritten issues; transactions by financial firms (SIC code 6) and government issuers (SIC code 9); and offerings by non-U.S. corporations. The second and third blocks of columns show the samples used in the econometric analyses. These samples are limited to deals lead-managed by one of the 50 largest underwriters active that year involving the ten largest firms (by Compustat net sales) in each four-digit SIC industry and exclude debt shelf offerings conducted under Rule 415. In addition, the third block screens out first-time deals. All currency amounts are in 1996 constant dollars, deflated using the quarterly GNP deflator.

	Deals by the ten largest firms per industry underwritten by 50 largest banks							
	All underwritten transactions completed in 1975 – 2003 (1)				Excluding shelf offers (2)		Excluding first- time deals and shelf offers (3)	
	No. of deals	% of deals	Aggregate amount raised (\$m, real)	% of amt.	No. of deals	Aggregate amount raised (\$m, real)	No. of deals	Aggregate amount raised (\$m, real)
<b>Equity offerings</b>

**Table 3. Main Variable Definitions**

---

<b>Bank-rival relationships</b>	
equity/debt relationship with a top 3 firm	=1 if the bank has lead-managed at least one equity or debt issue for a firm ranked among the 3 largest firms in a four-digit SIC industry (ranked by Compustat net sales), excluding the issuer itself, in the prior five years.
equity/debt relationship with a top 4-10 firm	=1 if the bank has lead-managed at least one equity or debt issue for a firm ranked among the 4-10 largest firms in a four-digit SIC industry, excluding the issuer itself, in the prior five years.
<b>Strength of bank-firm relationships</b>	
bank's share of issuer's equity/debt deals	Following Ljungqvist, Marston, and Wilhelm (2006), let $P_{j,k,t}^d$ denote the aggregate proceeds company $k$ raised in deals lead-managed by bank $j$ over the four quarters preceding quarter $t$ in deals of type $d = \{equity, debt\}$ . The strength of company $k$ 's type- $d$ relationship with bank $j$ is $R_{j,k,t}^d = P_{j,k,t}^d / \sum_j P_{j,k,t}^d$ . This ranges from zero (no relationship) to 100% (if the company maintained an exclusive bank relationship). Constructed from Thomson Financial/SDC data.
<b>Bank reputation proxies</b>	
equity/debt market share	A bank's share of the equity/debt underwriting market during the prior calendar year; see Megginson and Weiss (1991). Following a merger, the surviving bank is credited with both predecessors' market shares. Underwriting data come from Thomson Financial/SDC. These variables are constructed using data for all issuers (not just the ten largest firms in each industry).
<i>eigenvector</i> centrality	Measures a bank's standing based on data on its syndication relationships with other banks; see Ljungqvist, Marston, and Wilhelm (2007). Assuming that status and influence derive, in part, from being networked to others who themselves are well-networked (Bonacich (1972)), we weight a bank's ties to others by the importance of the banks it is tied to. Formally, $eigenvector_{j,t}^d \equiv E_{j,t}^d = \sum_i p_{i,j,t}^d E_{i,t}^d$ . The weights are the reciprocal of the principal eigenvector $p_i^d$ of a square and symmetric matrix $A_{i,j,t}^d$ whose cells $(i,j)$ record whether or not banks $i$ and $j$ syndicated one or more transactions of type $d = \{equity, debt\}$ in the preceding year. Constructed using data for all issuers (not just the ten largest firms in each industry).
loyalty index	Measures how often a bank retains its clients in consecutive deals as a control for unobserved factors such as execution capability that affect an issuer's choice: Banks whose clients are generally loyal likely have more desirable characteristics; see Ellis, Michaely, and O'Hara (2005). Let $I_{ck}$ and $I_{rk} = 1$ if bank $j$ managed $k$ 's penultimate and most recent deals, respectively, in prior five years, and 0 otherwise. Then $j$ 's loyalty index $= \sum_k I_{ck} I_{rk} / \sum_k I_{ck}$ (the number of retained clients over the total number of clients). The loyalty index varies between zero and 100%. Constructed using data for all issuers (not just the ten largest firms in each industry).
<b>Expertise</b>	
bank's industry expertise	Measures a bank's industry expertise as the combined concurrent product-market share of its clients in the issuer's four-digit SIC industry. Product-market shares are computed from annual Compustat net sales data.

---

**Table 4. Lead Manager Switches Following Bank Mergers**

We estimate the probability that an issuing company switches lead managers in consecutive equity or debt deals. A switch is defined as an equity (debt) issuer hiring as lead manager any bank other than the lead manager of its most recent equity (debt) deal (or, if that bank has since been acquired, its successor). In the case of multiple lead managers on a deal, we code as a switch any failure to retain every lead manager from the previous deal. We focus on deals involving a firm ranked among the ten largest by Compustat net sales in its four-digit SIC industry that year. All variables are defined in Table 3, except log real sales which is based on Compustat net sales deflated using the 1985=100 quarterly GDP deflator. The bank variables refer to characteristics of the lead manager in the previous deal measured as of the time of the current deal. The models are estimated using probit with lead manager-specific random effects and year fixed effects. Results are robust to alternative assumptions about the distribution of the error term, including: Random-effects logit; probit or logit without lead manager-specific random effects or without year fixed effects; fixed-effects linear probability models; complementary log-log (extreme value) distribution; and Gompertz distribution. Intercept and year fixed effects are not shown. Heteroskedasticity-consistent standard errors are shown in italics. We use <sup>\*\*\*</sup>, <sup>\*\*</sup>, and <sup>\*</sup> to denote significance at the 1%, 5%, and 10% level (two-sided), respectively.

**Table 5. Lead Manager Choice in Deregulating Industries**

We estimate the probability that a given bank is chosen to lead-manage a particular securities transaction over the period 1975 to 2003. We focus on transactions involving a firm ranked among the ten largest by Compustat net sales in its four-digit SIC industry that year, and treat the 50 largest underwriters by market share that year as being in competition for each deal. (Note there were only 35 banks active in equity underwriting in 1975 and there were fewer than 50 banks active in debt underwriting in 1975-1980 and in 2002.) The unit of observation is a bank-deal pair. The dependent variable equals 1 if the bank won the lead-management mandate and 0 otherwise. We restrict the sample to deals from four-digit SIC codes that are subject to a significant deregulatory (competition-increasing) shock between 1975 and 2003, as identified by Viscusi, Harrington, and Vernon (2005). Twenty-three of these deregulating industries have equity or debt transactions in the sample; see Table A1 in the Appendix for a list of deregulation events. The debt sample also excludes shelf registrations. To test the hypothesis that exposure to competition makes firms more reluctant to share underwriters, we allow the slope coefficients to vary between deals completed in the five years before the year of the first deregulatory shock (“Pre”) and those completed in the following five years (“Post”). All variables are defined in Table 3, except log real sales which is based on Compustat net sales deflated using the 1985=100 quarterly GDP deflator. The models are estimated using probit with lead manager-specific random effects and year and industry fixed effects. Results are robust to alternative assumptions about the distribution of the error term. Intercept and fixed effects are not shown. Standard errors are shown in italics. We use <sup>\*\*\*</sup>, <sup>\*\*</sup>, and <sup>\*</sup> to denote significance at the 1%, 5%, and 10% level (two-sided), respectively.

**Table 6. Lead Manager Choice Following Rival Client Switches**

The models shown here are identical to the specifications shown in Table 5, except that we 1) include all non-shelf deals (not just those in deregulating industries) and 2) split the effect of rival relationships into those that are “active” as of the time of the deal in question and those that are “inactive”. We consider three definitions of active and inactive. The first (labeled “mergers”) considers a candidate bank’s rival client to be inactive if it has been acquired by another firm during the previous five years (based on CRSP delisting codes 200 and 300). The second and third (labeled “switches”) consider a candidate bank’s rival client to be inactive if the firm has awarded no underwriting business to the bank for five or three years, respectively. We assume the bank’s information about the rival client to decay following a switch, and so code the bank as having an inactive rival client for only one year following the switch (i.e., years 6 and 4, respectively). Beyond that, the bank is coded as no longer having a rival client (active or inactive). Choosing a bank that has an active rival client runs the risk of information leakage to one of the issuer’s product-market competitors, though there are two potential offsetting benefits in the form of the bank having greater industry expertise or disclosing information about the rival client to the issuer. Choosing a bank that has an inactive rival client runs no corresponding risk but still offers both potential benefits. Therefore, the difference between the coefficients estimated for active and inactive rival clients isolates the effect of concerns about information leakage on underwriter choice. The models are estimated using probit with lead manager-specific random effects and year and industry fixed effects. Results are robust to alternative assumptions about the distribution of the error term. The unit of observation is a bank-deal pair. The estimation dataset consists of 5,272 equity deals and 6,744 debt deals completed by firms ranked among the ten largest in their four-digit SIC industries (based on Compustat net sales) between 1975 and 2003, for each of which the 50 largest banks are deemed to compete to become lead manager (except where fewer than 50 banks were active in the market at the time). This gives a sample of 262,580 bank-deal pairs for equity and 325,780 for debt. To conserve space, we report only the coefficients estimated for active and inactive rival relationships, and the difference between the two (as a measure of the net effect of concerns about information disclosure). Standard errors are shown in italics. The standard errors for the difference between each pair of coefficients are calculated using the delta method. We also report marginal effects (denoted dF/dx; the units are percentage points). For comparison, the unconditional likelihood of a bank becoming lead manager is about 2.2%. We use <sup>\*\*\*</sup>, <sup>\*\*</sup>, and <sup>\*</sup> to denote significance at the 1%, 5%, and 10% level (two-sided), respectively.

**Table 7. Determinants of Underwriter Fees**

In this table, we explore the conjecture that after deregulation, the underwriter's hold-up power increases, leading to an increase in fees. The dependent variable is the fee (or "gross spread") paid to the underwriter or underwriting syndicate, measured as a fraction of gross proceeds the issuer raises, times 100. We estimate ordinary least squares regressions with lead manager and year fixed effects. The sample includes either all transactions from four-digit SIC industries subject to competition-increasing deregulatory shocks (in columns (1) and (3)) or those deals completed within a ten-year window centered on the deregulation event (in columns (2) and (4)). See Table A1 in the Appendix for a definition of these events. The main variable of interest is a dummy identifying deals completed after a deregulation event. We control for economies of scale in underwriting by including issue proceeds and log issue proceeds and for issuer and offer characteristics. Intercepts, lead manager fixed effects, and year fixed effects are not shown. Heteroskedasticity-consistent standard errors, clustered on lead manager, are shown in italics. We use <sup>\*\*\*</sup>, <sup>\*\*</sup>, and <sup>\*</sup> to denote significance at the 1%, 5%, and 10% level (two-sided), respectively.

	Fees in equity deals (in %)		Fees in debt deals (in %)

## Table A1. Deregulation Events

This table lists deregulation events relevant to the construction of Tables 5 and 7. The main source is Viscusi, Harrington, and Vernon (2005). Additional industry-specific details are taken from: <http://www.cato.org/pubs/regulation/reg18n2f.html>, <http://www.corp.att.com/history/history3.html>, [http://www.sec.gov/rules/concept/s72899/buck5.htm#P471\\_99506](http://www.sec.gov/rules/concept/s72899/buck5.htm#P471_99506), [http://www.centennialofflight.gov/essay/Commercial\\_Aviation/Dereg/Tran8.htm](http://www.centennialofflight.gov/essay/Commercial_Aviation/Dereg/Tran8.htm), and <http://www.Lawdog.com/transport/tp1.htm>. We omit deregulation events affecting the financial sector (e.g., the Gramm-Leach-Bliley Act 1999), those impacting product mix rather than competition (e.g., the elimination of the Fairness Doctrine by the FCC in 1987), and those that were simple asset sales (e.g., the sale of Conrail in 1987). Where the same industry is affected by multiple deregulation events, we take as the relevant date for the construction of Tables 5 and 7 the first such event, since further deregulation events will likely be anticipated well in advance. Superscript “e” indicates that the industry is in the equity sample used in Tables 5 and 7, while superscript “d” indicates inclusion in the debt sample (using in each case only the first deregulatory event for each industry).

Year of event	Relevant legislative or executive action	Description	Four-digit SIC codes impacted
1977	Air Cargo Deregulation Act	Deregulation of air cargo industry	4512 <sup>e,d</sup> , 4522 <sup>d</sup>
1978	Airline Deregulation Act	First stage of deregulation of Airlines (gradually implemented between 1978 and 1982)	4512, 4522
	Natural Gas Policy Act	Partial deregulation of natural gas prices	1311 <sup>e,d</sup> , 4922 <sup>e,d</sup> , 4925
1979	Deregulation of satellite earth stations	Deregulation of satellite earth stations	4841 <sup>d</sup> , 4899
	Urgent-mail exemption (Postal Services)	Allows competition with the US Postal Service on urgent mail, charging more than a certain amount	4513 <sup>e,d</sup> , 4311, 4215, 7389 <sup>e,d</sup>
1980	Motor Carrier Reform Act	Partial Deregulation of Trucking	4213 <sup>d</sup> , 4212, 4142, 4131
	Household Goods Transportation Act	Apply deregulatory measures in Motor Carrier Reform Act to household moving services	4212, 4214
	Staggers Rail Act	Deregulated Railroads	4011 <sup>d</sup> , 4741, 4789, 4013
	International Air Transportation Competition Act	Second stage of deregulation of Airlines (gradually implemented between 1978 and 1982)	4512, 4522
	Deregulation of cable television (FCC)	Precursor to 1984 Cable Television Deregulation Act	4841
	Deregulation of customer premises equipment and enhanced services (FCC)	Precursor to 1984 Cable Television Deregulation Act	4841, 4899
1981	Decontrol of crude oil and refined petroleum products (executive order)	Oil price controls lifted by Reagan	4612, 1311, 1381 <sup>e,d</sup> , 2911 <sup>e,d</sup> , 2992, 2869, 5171 <sup>d</sup> , 5411 <sup>e,d</sup> , 2865, 5172 <sup>d</sup>
	Deregulation of Radio (FCC)	Lifts requirement that radio stations have to provide news content - lowers costs and facilitates entry and diversity of service	4832
1982	Bus Regulatory Reform Act	Partial Deregulation of bus and trucking industries - entry and exit of bus services facilitated and pricing controls eased. Trans-border trucking deregulated.	4111, 4151, 4142
	AT&T Settlement (Breakup of AT&T)	AT&T has to split, divesting the local exchange service providers. An earlier consent decree (1956) restricting AT&T's scope of business is lifted.	4813 <sup>e,d</sup> , 4812 <sup>e,d</sup> , 4899, 3661 <sup>e,d</sup> , 4822 <sup>d</sup>
1984	Cable Television Deregulation Act	Barred regulation in communities where there was "effective competition," which was defined by the FCC to be more than three broadcast stations	4841
	Shipping Act	Deregulated ocean shipping	4412 <sup>d</sup> , 4491
1986	Trading of Airport Landing Rights	Trading of Airport Landing Rights	4581 <sup>d</sup> , 4512, 4522
1989	Natural Gas Wellhead Decontrol Act of 1989	Removed natural gas price controls	4925, 1311, 4922

**Table A1. Deregulation Events (continued)**

Year of event	Relevant legislative or executive action	Description	Four-digit SIC codes impacted
1992	Cable Television Consumer Protection and Competition Act	Regulated cable TV rates	4841
	Energy Policy Act	Opened up wholesale competition by giving FERC the authority to order vertically integrated utilities to act as a common carrier of electrical power	4911 <sup>e,d</sup>
	FERC Order 636	Required pipelines to unbundle the sale and transportation of natural gas	4925, 4922, 4924 <sup>e,d</sup>
	Negotiated Rates Act	Eliminated regulatory distortions related to trucking rates	4213, 4214, 4212
	Trucking Industry and Regulatory Reform Act	Eliminated remaining interstate and intrastate trucking regulation	4213, 4214, 4212
1996	Telecommunications Act	Deregulated cable TV rates, set conditions for local telephone companies to enter long distance markets, mandated equal access to local telephone systems	4841
	FERC Order 888	Removed impediments to competition in the wholesale bulk power market	4911
