PROCEEDINGS

4th IWA/WEF Wastewater treatment modelling seminar

WWTmod ≈ 2014

Spa, Belgium, March 30th – April 2nd, 2014

WWTmod2014 is the fourth international seminar on **wastewater treatment (WWT) modelling** after successful events in 2008, 2010 and 2012. WWTmod provides a platform upon which any relevant aspect of WWT modeling may be scrutinized. The main objective of WWTmod is consensus building. The process of consensus building is supported by obtaining insights from a diverse group of leading professionals: researchers, consultants, utilities, regulators, manufacturers, and software developers.

Stricter effluent limits for nutrients and other contaminants, and concerns about plant efficiency, climate change, and emerging contaminants are driving new model development efforts and more and more sophisticated application of modelling.

The widespread use of wastewater treatment models depends on the development of widely accepted standards and procedures. The organizers hope this seminar will contribute to the further development of “**Good Modelling Practice**” in this field.

FINAL PROGRAMME

Saturday, March 29th 2014

09:00 – 17:00 YWP Workshop

09:00-09:15 Overview

Part I: Data Issues in Process Modeling

09:15-10:15 Presentations

10:15-10:30 Coffee Break

10:30-11:45 Presentations

11:45-13:00 Lunch

Part II: Identifying Barriers to Innovation in Process Modelling

13:00-15:00 Presentations and Small Group Discussions

15:00-15:30 Coffee Break

Part III: Finding Solutions

15:30-16:00 Summary of small group discussions and of proposed solutions

16:00-16:45 Panel Discussion: Overcoming barriers to innovation

16:45- 17:00 Wrap-up, closing summary

YWP Workshop Organizing Committee:

Magnus Arnell, Lund University, Sweden

Hélène Hauduc, LISBP - INSA de Toulouse, France

Thomas Maere, Ghent University, Belgium

Adrienne Menniti, Clean Water Services, USA

Sunday, March 30th 2014

08:30-08:45 Welcome by *Ingmar Nopens (Chair Scientific Committee, Chair B-IWA)*

08:45-09:45 Opening Lecture by *Daniel A. Nolasco, Nolasco & Associates:*
Waste Water Treatment Plant (WWTP) Modeling from a consultant point of view.

09:45 – 17:15 Parallel full-day workshops

09:45-10:45 Presentations and Discussion

10:45-11:15 Coffee break

11:15-12:45 Presentations and Discussion

12:45-13:45 Lunch break

13:45-15:15 Presentations and Discussion

15:15-15:45 Coffee break

15:45-16:45 Presentations and Discussion

16:45-17:15 Wrap-up

Themes:

1. [Where are we and where should we go with MBR modelling?](#)

Thomas Maere and Joaquim Comas

2. [What do we need for “Total” Nitrogen Modelling?](#)

Peter Dold and José C. Porro

3. [How can modelling be effectively used for energy balance optimization?](#)

Adrienne Menniti, Tom Johnson and Leon Downing

4. [Revisiting phosphorus removal: do the models give the answers we want?](#)

Youri Amerlinck, Albert Guisasola and David Ikumi

5. [Linking WWTP modelling with Life Cycle Assessment \(LCA\) and other Holistic models](#)

Andrew Shaw and Lluís Corominas

6. [Wet-weather modelling: Why and how should we tame the beast?](#)

Lorenzo Benedetti and Peter Vanrolleghem

17:15-18:00 Report preparation (workshop chairs)

18:30 Welcome reception and dinner at Casino of Spa

Monday, March 31st 2014

08:30-08:45 Opening by IWA president Glen Daigger

08:45-09:15 Report from Saturday YWP workshop and Discussion

09:15-10:15 Reports and discussion from Sunday workshops 1&2

Moderator: Peter Vanrolleghem, Co-moderator: Kimberly Solon

10:15-10:45 Coffee break

10:45-12:15 Session 1: Influent characterisation for full scale modelling

Moderator: Bruce Johnson, Co-moderator: H       Hauduc

Characterization and separation of unbiodegradable matter in WRRFs

Majdala Mansour-Geoffrion, Peter L. Dold, Alain Gadbois, St       D       and Yves Comeau

Influent generator for probabilistic design of nutrient removal wastewater treatment plants

Mansour Talebizadeh, Evangelia Belia and Peter A. Vanrolleghem

12:15-13:30 Lunch

13:30-15:00 Session 2: Impact of diffusion

Moderator: Damien Batstone, Co-moderator: Marina Arnaldos

Increasing complexity in biofilm reactor models: How far do we need to go?

George Wells, Thomas Vannecke, Nathalie Hubaux, Eberhard Morgenroth and Eveline Volcke (Fusion paper)

The Case of the Ks: Diffusion versus Strategy

Andrew Shaw, Imre Takacs, Krishna Pagilla, Rumana Riffat , Haydee De Clippeleir, Christopher Wilson and Sudhir Murthy

15:00-15:30 Coffee break

15:30-17:00 Session 3: Nitrogen modeling extended/revisited

Moderator: Sylvie Gillot, Co-moderator: Magnus Arnell

Evaluating two concepts for the modelling of biological denitrification

Pan, Bing-Jie Ni, Huijie Lu, Kartik Chandran, David Richardson and Zhiguo Yuan

Calibration of nitrous oxide production models with continuous long-term process data

Mathieu Sp            , Mathieu Pocquet, Lisha Guo, Peter A. Vanrolleghem, Bing-Jie Ni and Zhiguo Yuan

19:00 Dinner at venue

Tuesday, April 1st 2014

08:30-09:15 Keynote lecture

Robert Schröder, Policy officer DG Environment
Water policy from a European perspective

09:15-10:15 Reports from Sunday workshops 3&4

Moderator: Andy Shaw, Co-moderator: Laura Snip

10:15-10:45 Coffee break

10:45-12:15 Session 4: WWTP modeling: back to the future

Moderator: Eberhard Morgenroth, Co-moderator: Sherri Cook

Towards BSM2-GPS-X: A plant-wide benchmark simulation model not only for carbon and nitrogen, but also for greenhouse gases (G), phosphorus (P), sulphur (S) and micropollutants (X), all within the fence of WWTPs/WRRFs

Peter Vanrolleghem, Xavier Flores-Alsina, Lisha Guo, Kimberly Solon, David Ikumi, Damien Batstone, Chris Brouckaert, Imre Takács, Paloma Grau, George Ekama, Ulf Jeppsson and Krist V. Gernaey

Population Balance Models: A useful complementary modelling framework for future WWTP modelling

Ingmar Nopens, Elena Torfs, Joel Ducoste, Peter A. Vanrolleghem and Krist V. Gernaey

12:15-13:30 Lunch

13:30-15:00 Session 5: Primary/secondary sedimentation

Moderator: Imre Takacs, Co-moderator: Adrienne Menniti

Modelling and characterisation of primary settlers in view of whole plant and resource recovery modelling

Giulia Bachis, Thibaud Maruéjols, Sovanna Tik, Youri Amerlinck, Henryk Melcer Ingmar Nopens, Paul Lessard and Peter A. Vanrolleghem

Modelling the impact of filamentous bacteria abundance in a secondary settling tank: CFD sub-models optimization using long-term experimental data

Elham Ramin, Dorottya S. Wágner, Lars Yde, Peter Szabo, Michael R. Rasmussen, Arnaud Dechesne, Barth F. Smets, Peter Steen Mikkelsen, Benedek Gy. Plósz

15:00-15:30 Coffee break

15:30-16:30 Reports from Sunday workshops 5&6

Moderator: Yves Comeau, Co-moderator: Elena Torfs

19:00 Gala dinner at Abbey of Stavelot

Wednesday, April 2nd 2014

08:30-08:45 Welcome address

WEF representative

08:45-10:15 Session 6: Models for new processes

Moderator: Eveline Volcke, Co-moderator: Bing-Jie Ni

Model based evaluation of mechanisms and benefits of nitrogen shortcut processes

Ahmed Al-Omari, Bernhard Wett, Ingmar Nopens, Haydee De Clippeleir, Mofei Han, Pusker Regmi, Charles Bott and Sudhir Murthy

Modeling of Organic Substrate Transformation in the High-Rate Activated Sludge Process: Why Current Models Don't Work and a Recommended Unified Model Approach

Thomas Nogaj, Andrew Randall, Jose Jimenez, Imre Takacs, Charles Bott, Mark Miller, Sudhir Murthy and Bernhard Wett

10:15-10:45 Coffee break

10:45-11:45 Closing session

11:45-12:00 Summary of WWTmod2014 by Josh Boltz (WWTmod2014 Chair)

12:00-12:15 Incoming Chair: Outlook on WWTmod2016

12:15-13:30 Lunch

Poster sessions

David L. F. Gaden and Eric L. Bibeau

Modelling bacterial selection during the plug-flow feeding phase of aerobic granular sludge biofilm reactors

David G. Weissbrodt, Christof Holliger, Eberhard Morgenroth

ASM input/output analysis

Should activated sludge models consider influent seeding of nitrifiers? Field characterization of nitrifying bacteria

Shameem Jauffur, Siavash Isazadeh and Dominic Frigon

Generation of (synthetic) influent data for performing wastewater treatment modelling studies

Xavier Flores-Alsina, Christoph Ort, Cristina Martin, Lorenzo Benedetti, Evangelina Belia, Laura Snip, Ramesh Saagi, Mansour Talebizadeh, Peter A. Vanrolleghem, Ulf Jeppsson, Krist V. Gernaey

A simple yet efficient colour-based system analysis tool for ASM

Amerlinck, Y., Cierkens, K., Nopens, I.

Greenhouse gas modelling

Modelling N₂O dynamics in the engineered N cycle: Evaluation of alternate model structures

Barth F. Smets, Carles Pellicer-Nàcher, Carlos Domingo-Félez, Marlene Mark Jensen, Elham Ramin, Benedek Gy. Plósz, Gürkan Sin, Krist V. Gernaey.

Modelling simultaneous anaerobic methane and ammonium removal in a granular sludge reactor

Mari- Karoliina. H. Winkler, Thomas P.W. Vannecke, Andrew Bogdan and Eveline I. P. Volcke

Risk assessment modelling of N₂O production in activated sludge systems; a knowledge-based approach

Jose Porro, Costanza Milleri, Joaquim Comas, Ignasi Rodriguez-Roda, Maite Pijuan, Lluís Corominas, Lisha Guo, Matthijs Daelman, Eveline Volcke, Mark van Loosdrecht, Peter A. Vanrolleghem and Ingmar Nopens

Estimation of dynamic apparent nitrification kinetics as the key for reliable greenhouse gas emission prediction

Haydee De Clippeleir, Imre Takacs, Bernhard Wett, Kartik Chandran and Sudhir Murthy

WORKSHOPS

Young Water Professional Workshop

The 2014 YWP workshop will be divided into two parts. We will explore data issues in process modelling for the morning session. The afternoon session will be a highly interactive look at barriers to innovation in process modelling and how we can overcome them. Our goal is to create a dialog on important topics relevant to young water professionals and encourage networking between young and senior water professionals. YWPs are invited to submit their questions or experiences on either topic to the LinkedIn forum: WWTmod 2014 YWP workshop. The contributions will be used as discussion starters in the workshop.

Data Issues in Process Modelling

Any simulation exercise has to rely on data to build, calibrate and validate the model. However, collecting data from wastewater treatment processes, lab or full scale, is always tedious and delicate. YWP, whether from academia, consultancy or utilities, are confronted with many questions, often without having enough experience to address them:

- Which kind of results are of interest to practitioners? Scientists? Are these results compatible with the data collected by utilities?
- Depending on the usage (knowledge build-up, scenario analysis, control), which data need to be collected (sensors, logbooks, dedicated measurement campaign) and at which frequency?
- How to deal with data storage? How to insure data quality (reconciliation, truncation, time stamps)?

Collecting and preparing a full-plant dataset that is reliable enough for a modelling exercise is a huge effort that may have additional value for other purposes. The question of sharing datasets, making them available for the whole community, will also be discussed in this morning session.

The workshop will contain 3 presentations from junior and senior experts on data issues and will be followed by a group discussion. The expert panel will also elaborate on data issues from the audience, which can be proposed through the LinkedIn forum: WWTmod 2014 YWP workshop.

Overcoming Barriers to Innovation in Process Modelling

Innovations in process modelling, as in any field, are encouraged by interdisciplinary collaboration, open exchange of ideas at conferences and in peer-reviewed publications, and freedom to explore without fear of failure. The process of transferring new ideas from academia to application relies on innovation by academics, consultants and utilities. As funding pressures in all three areas become more intense, the activities that foster innovation are reduced in favor of activities that increase the chances of winning research funding, improve profitability, or reduce “extraneous” operating expenses.

The three presentations will summarize the barriers to innovation in academia, consulting and utilities. Each presentation will be developed by a team of contributors to generate a consensus view that includes junior and senior viewpoints as well as male and female and European and north American. Each presentation will address the following questions:

- What are the contributions of each field to innovations in process modeling?
- What are the barriers to innovation?
- How do those barriers hinder YWP career development and vice versa?
- What solutions could address the issues identified?

The remainder of the afternoon will be spent in interactive discussion, exploring the topic further and brainstorming solutions.

Workshop Agenda:

Time	Topic	Potential Speaker
9:00 9:15	Overview	
Part I: Data Issues in Process Modeling		
9:15 9:45	<i>Presentation (20 minutes):</i> Data issues in process modelling: It all starts with sampling	Lina Belia, Primodal, Canada
9:45 10:15	<i>Presentation (20 minutes):</i> Mass balancing and sensor placement for data reconciliation and fault detection - Basic concepts	Kris Villez, Eawag, Switzerland
10:15 10:30	Break	
10:30 11:00	<i>Presentation (20 minutes):</i> Data validation and model calibration: which one needs to be perfect?	Jeroen Langeveld, TU Delft, the Netherlands
11:00 11:45	<i>Group discussion on issues from the audience</i>	
11:45 13:00	LUNCH	
Part II: Identifying Barriers to Innovation in Process Modelling		
13:00 13:25	<i>Presentation (20 minutes):</i> Barriers to Innovation in Academia	Christoph Ort, Eawag, Switzerland
13:25 13:50	<i>Presentation (20 minutes):</i> Barriers to Innovation in Consultancy	Leon Downing, Donohue & Associated, USA
13:50 14:15	<i>Presentation (20 minutes):</i> Barriers to Innovation in Utilities	Magnus Arnell, Lund University, Sweden

Thomas Maere	Ghent University, Belgium
Adrienne Menniti	Clean Water Services, USA

Workshop: Where are we and where should we go with MBR modelling?

The application of membrane bioreactors (MBR) for wastewater treatment has significantly increased over the last decades, despite the inevitable occurrence of membrane fouling which is one of the main drawbacks of MBR technology and is associated with high energy expenditures compared to conventional activated sludge technologies. Most of the MBR plants are working in a conservative way, with quite significant room for optimisation. The use of models for MBRs can be a really useful approach to optimise their operation. In this respect, the proposed workshop focuses on the current state of the art and the future needs in MBR modelling to move towards a) widely accepted MBR models and submodels and b) practically relevant models to describe the biological (aerobic and anaerobic) and filtration processes.

Expected discussions and results

The workshop consists of a series of invited presentations followed by moderated panel discussions in the morning and breakout sessions followed by a group discussion in the afternoon. The series of invited presentations focuses on the currently available models applied in MBR technology (where are we?). Specifically, the following main topics will be covered: (1) the modelling of the biological process, (2) the modelling of the filtration process, (3) current practices in optimisation and control of MBR systems. The breakout sessions will focus on future aspects of MBR modelling (where should we go?), with mainly 1) new modelling topics and frameworks and 2) full-scale applications.

The specialist presentation on biological process modelling will address the possibility of adapting the current plant-wide models or classical activated sludge models (ASM) and the anaerobic digestion model (ADM) for modelling the biological process in both aerobic and anaerobic MBRs, respectively. Therefore, this topic will focus on the necessity (or not) of adapting existing models based on membrane specificities (e.g. including soluble microbial products) in order to move towards an integrated MBR model. The importance to practice will be discussed.

The specialist presentation on filtration process modelling will focus on the necessity of developing feasible filtration process models which facilitate the design, operation and control of membrane technology. In particular, the applicability of the currently available deterministic and empirical models to different operating conditions, environments (aerobic and anaerobic), and membrane types will be discussed. The presentation will address the advantages and disadvantages of using integrated models or standalone filtration models as well. The link to practice will also be included.

The specialist presentation on optimisation and control will give an overview of current practices and tools used to optimise the operation and design of MBRs. A clear distinction will be made between tools that have been proposed in literature which have not yet been applied or validated, lab- and pilot-scale investigations and finally control systems that have been used in full-scale practice.

The breakout sessions are targeting the current needs and promising future paths in MBR modelling. Three presentations are planned: (1) new modelling topics (e.g. particle size distributions, viscosity, mixing, aeration, energy) and modelling approaches for these topics (e.g. computational fluid dynamics, population balance modelling); (2) full-scale applications (in response to a lack of full-scale studies in literature); (3) a topic from the audience which will be announced and decided upon through Linked-in and mail.

Each presentation will be prepared by 2-3 experts. The aim of having multiple people for a talk is to make sure that the various aspects of a topic are covered (academic, consultancy, utilities, companies). The presentations will be short, refreshing and thought-provoking to stimulate a lively discussion afterwards. The workshop is meant to be constructive and consensus-aiming.

We will sum up the main ideas highlighted by each speaker together with the key points from the specific discussions. Then, we will finish with a reflection on the main issues we wanted to cover within this workshop: “where we are in MBR modelling and where we need to go”, taking into account the practitioners’ point of view and demand from the field. Finally, we want to discuss if a review paper on certain topics is needed, or maybe even the formation of a task group focussed on crucial MBR modelling issues.

Workshop set-up

In the morning, the workshop is structured along a number of keynote presentations on the state of the art in biological and filtration modelling and control. The presentations are followed by moderated round table discussions to reach consensus. To assure an objective, critical and holistic view on the addressed topics, the presentations will be prepared by multiple people.

In the afternoon, outbreak sessions are planned on a couple of crucial topics, aiming to identify the key issues that have to be addressed and possible solutions. The day ends with an overview of the topics on which consensus is reached (or not) and future plans (e.g. formation of a task group, review paper, etc.).

In order to promote discussion, a discussion forum will be launched on Linked-in before the start of the conference. Important remarks and suggestions for topics will be taken into account in the actual workshop. Speakers and attendees will be invited to the forum.

Chairs / co-chairs

Chairs: **Thomas Maere** (Biomath, Ghent University, Belgium), **Joaquim Comas** (Lequia, University of Girona, Spain)

Co-Chairs: **Vicky Ruano** (Aqualia, Spain), **Ángel Robles** (University of València, Spain), **Ignasi Rodriguez-Roda** (Catalan Institute for Water Research, Spain), **Ingmar Nopens** (Biomath, Ghent University, Belgium)

Speakers / collaborators

From practice:

- Christoph Brepols (Erftverband, Germany)
- Murat Sarioglu (MWH global, Turkey)
- André Lerch (Samsung Cheil Industries, Germany)
- Marina Arnaldos Orts (Acciona Agua, Spain)
- Vicky Ruano (aqualia, Spain)

From academia:

- Ángel Robles (University of Valencia, Spain)
- Ignasi Rodriguez-Roda (ICRA, Spain)
- Joaquim Comas (University of Girona, Spain)
- Wouter Naessens (Ghent University, Belgium)
- Thomas Maere (Ghent University, Belgium)

- Ingmar Nopens (Ghent University, Belgium)

Target Participants

This workshop should draw the attention of experts in membrane bioreactor technology both from practice and academia, with or without specific modelling expertise, as well as general WWTP modelling experts (e.g. ASM, ADM, CFD, control, energy) who want to learn about the specificities of MBR modelling.

Programme

Time	Topic	Presenter/Moderator
09:45 - 09:55	Introduction: Motivation, scope, and objectives. Present workshop structure, participants, etc.	Chairs & co-chairs
09:55 - 10:20	Presentation #1: Biological process modelling for aerobic and anaerobic MBR	Team #1: - T. Maere - Á. Robles - M. Sarioglu
10:20 - 10:45	Discussion Period	Chairs & co-chairs
10:45 - 11:15	Coffee break	
11:15 - 11:45	Presentation #2: Filtration process modelling for aerobic and anaerobic MBR	Team #2: - Á. Robles - W. Naessens
11:45 - 12:15	Presentation #3: Control & optimisation: current practices	Team #3: - Q. Comas - M. Arnaldos Orts
12:15 - 12:45	Discussion Period	Chairs & co-chairs
12:45 - 13:45	Lunch break	
13:45 - 14:25	Outbreak session 1: New modelling topics and frameworks	Team #4: - I. Rodriguez-Roda - A. Lerch - I. Nopens
14:25 - 15:05	Outbreak session 2: Full-scale applications	Team #5: - V. Ruano - C. Brepols
15:05 - 15:15	Group discussion	Chairs & co-chairs
15:15 - 15:45	Coffee break	
15:45 - 16:15	Public outbreak session: Topics from the audience	Chairs & co-chairs
16:15 - 16:45	Plenum discussion <ul style="list-style-type: none"> • Future needs • Next steps 	Chairs & co-chairs
16:45 - 17:15	Wrap-up, composing summary, report and presentation	Chairs & co-chairs

Workshop: What do we need for “Total” Nitrogen Modelling?

Our community strives to provide models that reflect the behaviour in the many situations in wastewater treatment systems. Simulating nitrogen (N) transformations is challenging because there are many N states of concern (ammonia, nitrite, nitrate, NO, N₂O, N₂, organic N) with several organism groups involved, and components may be involved in multiple processes simultaneously.

Nitrogen transformations are implicated in so many issues: GHG emissions, energy reduction (e.g. nitrite shunt), alternative external carbon sources, attaining low TN limits, many sidestream treatment options, etc.

The proposed workshop will provide a forum to review, discuss and present ideas on the structure of models for nitrification and denitrification (and associated N₂O production). For each main topic discussed, a discussion on the following will be included:

- Model structure: How well do existing models reflect the mechanisms?
- Interactions: How well do models capture the interactions between competing processes?
- Mechanisms: What mechanisms may be at play that we are overlooking? How do we uncover them?
- Data needs: In what areas, if any, do we need more data for model development and testing?
- Can we unify models to achieve multiple objectives for a more holistic Total Nitrogen Modelling?

Expected discussions and results

The topic area of Nitrogen Modelling has been viewed as five subtopics (with interest areas in parentheses):

1. Nitrification
(SND and shortcut nitrite shunt)
2. Anammox processes
(model structure)
3. Heterotrophic denitrification
(Electron competition; model structure; pathways)
4. N modelling in practice
(Achieving Low TN limits)
5. Nitrous oxide production
(Mechanisms; model structure/performance; measurements; risk assessment modelling)

The day, from 9:30 a.m. to 5 p.m., will be mainly divided into series of presentation/discussion periods (see Programme) with morning and afternoon 30 minute coffee breaks and a 1 hour lunch break. The final slots in the morning and the afternoon are set aside for longer discussions on the topics.

Presenters will include a mix of academics and practitioners to ensure well-rounded discussions, linking research to practice.

A workshop report will be compiled upon the completion of the workshop summarizing the key points discussed, consensus gained on topics, and action items for the N modelling community to fill gaps in knowledge and practice.

Plans for the workshop subject include a white paper or journal article such as WS&T or WP&T.

Workshop set-up

The workshop set up will consist of a series of presentations followed by a discussion period. A larger discussion period will follow the presentation/discussion slots in each the morning and afternoon sessions. This format will generally lead to significantly more discussion time than presentation time. This will be critical for reach consensus on topics and identifying research and practice needs for advancing N modelling.

Chair and Co-chairs

Chair: Peter Dold (EnviroSim Associates Ltd., Hamilton, Ontario, Canada)

Co-Chair: José C. Porro (LEQUiA, University of Girona, Spain)

Speakers / Discussion Leaders

Dwight Houweling (CH2M Hill, Canada)

Weiwei Du (EnviroSim, Canada)

Zhiguo Yuan (University of Queensland, Australia)

Eveline Volcke (Ghent University, Belgium)

Ed Becker (ARCADIS, USA)

Barth Smets (DTU, Denmark)

Marlies Kampschreur (Waterboard Aa en Maas, The Netherlands)

Mathieu Spérandio (University of Toulouse, France)

Haydee De Clippeleir (Columbia University, USA)

Maite Pijuan (ICRA, Spain)

Target Participants

Target participants include researchers active in N modelling, seasoned professionals who can lend invaluable insight on approaches, and practitioners interested in applying various N models for wastewater treatment plant design and operations. Target participants will be interested in attending as the workshop will create opportunities for research and practice collaboration, building consensus on ongoing efforts, and understanding how different data collection/modelling approaches can be applied to best meet different objectives.

Programme

Time	Topic	Presenter/Moderator
9:45 - 10:05	Introduction: Motivation, scope, and objectives Present workshop structure, participants, etc.	P. Dold
10:05 - 10:25	Presentation/Discussion #1: Nitrite Shunt, SND in FS plants	D. Houweling
10:25 - 10:45	Presentation/Discussion #2: Experimental data and denitrification model structure	W. Du
10:45 - 11:15	Coffee break	
11:15 - 11:35	Presentation/Discussion #3: Electron Competition in denitrification	Z. Yuan
11:35 - 12:00	Presentation/Discussion #4: Anammox Processes and Models	E. Volcke
12:00 - 12:45	Nitrification / Denitrification / Anammox Discussion	P. Dold
12:45 - 13:45	Lunch break	
13:45 - 14:05	Presentation/Discussion #5: The state of N models for achieving Low TN limits in practice	E. Becker
14:05 - 14:45	Presentation/Discussion #6: N ₂ O emission from wastewater treatment: formation mechanisms and models	B. Smets, M. Kampschreur, E. Volcke
14:45 - 15:15	Presentation/Discussion #7: N ₂ O Model Calibration and parameters	M. Spérandio, H. De Clippeleir
15:15 - 15:45	Coffee break	
15:45 - 16:10	Presentation/Discussion #8: N ₂ O measurements – new methods and guidance	E. Volcke, M. Pijuan
16:10 - 16:25	Presentation/Discussion #9: N ₂ O knowledge-based approach and modelling	J. Porro
16:25 - 17:00	Total Nitrogen Modelling Checklist Discussion	P. Dold, J. Porro
17:00 - 17:15	Wrap-up, concluding remarks	P. Dold

Workshop: How can modelling be effectively used for energy balance optimization?

The wastewater industry is moving rapidly toward the goal of energy neutrality. As energy costs rise, improving the energy footprint for wastewater treatment is not just a sustainability goal but an essential step toward reducing operating costs. The ability to accurately predict energy consumption and production is critical to identifying and evaluating opportunities for energy balance improvement. The purpose of this workshop is to critically evaluate how modeling (both steady state and dynamic) can be effectively used for estimating a plant energy balance and its associated cost implications.

Expected discussions and results

Achieving the goal of energy neutrality requires a balanced approach of decreasing energy demand, increasing energy production, and justifying the capital expense. The workshop will emulate this by being organized into three main sections. We will first examine energy demand and energy production, concentrating on the two largest contributors to the plant energy balance – energy demand due to aeration and energy production from biogas. Next, the translation of energy predictions to costs is explored. Each section will involve brief presentations highlighting the approaches and challenges in a given area, followed by a focused discussion in both large and small group formats.

The end of the workshop will “bring it all together”, discussing the overall challenges with energy modelling in wastewater systems and identifying the key future prospects. The chairs will develop a summary of the first three sections during the afternoon break. An inspirational presentation followed by summary points from the earlier sessions will be used to stimulate an end of the day discussion focused on the workshop’s overriding question: *How can modelling be effectively used for energy balance optimization?*

The sections will be organized into the following categories:

Part I: Modeling Energy Reduction in Aeration Design and Operation

- Main question: How is modelling used for effective design of aeration systems and in aeration system control?
- Discussion format: guided group discussion focused on the Part I main question

Part II: Modeling Energy Production

- Main question: Where are the gaps in energy production modeling?
- Discussion format: guided group discussion focused on the Part II main question

Part III: Modeling the Cost Implications of Energy Reduction and Production

- Main question: Can we effectively model the energy balance and energy cost components in a wastewater system?
- Discussion format: small group discussions to address the question – which smaller energy uses make sense to model?

Part IV: Discussion of the overall challenges and opportunities in wastewater energy modeling

- Main question: What is the role of energy modeling, and where are the gaps?
- Presentation: Speaker will give a “motivational” speech on the importance of energy in wastewater modeling, with the aim to re-stimulate the workshop attendees
- Discussion format: the chairs will provide bulleted list of main takeaways from Part I, II, and III, and the a group discussion to identify the largest gaps/needs and key future prospects in energy modelling

How will you summarize results for larger WWTmod group?

The workshop results summary will focus on a major takeaway from Parts I, II, and III, and a list of the largest gaps/needs and key future prospects in energy modelling.

What are plans for workshop subject after WWTmod? (i.e. white paper, publications, other?)

The workshop outcomes will be summarized into a position paper: **Where are the Knowledge Gaps and Future Prospects in Wastewater Energy Modelling?** The paper will be submitted for consideration for publication in WS&T. One possible workshop outcome could be the generation of a working group to establish best practices for energy modelling.

Workshop set-up

The workshop will rely on large group discussions and breakout discussions. The discussions will be preceded by a collaborative presentation where the speakers highlight key considerations in each area of energy modelling. The group discussions will focus on how modelling is used in energy related wastewater applications, and where the gaps in current model structure and/or modelling practice exist.

Chairs

Adrienne Menniti, Clean Water Services (Portland, Oregon, USA)

Tom Johnson, CH2MHill (Charlotte, North Carolina, USA)

Leon Downing, Donohue & Associates (Sheboygan, Wisconsin, USA)

Speakers / Moderators

The speakers are all WWTMod veterans, and represent a cross section of the fields involved in wastewater modelling (academic, practitioners, utilities), as well as representatives from the Americas and Europe.

Speaker #1 Tom Johnson (CH2MHill, Charlotte, North Carolina, USA)

Speaker #2 Leon Downing (Donohue & Associates, Sheboygan, Wisconsin, USA)

Speaker #3 Sylvie Gillot (Irstea, France)

Speaker #4 Bernhard Wett (ARA Consult, Innsbruck, Austria)

Speaker #5 Sherri Cook (University of Michigan, Ann Arbor, Michigan, USA)

Speaker #6 Adrienne Menniti (Clean Water Services, Portland, Oregon, USA)

Speaker #7 Leiv Rieger (inCTRL Solutions, Oakville, Canada)

Speaker #8 Lluís Corominas (ICRA, Girona, Spain)

Speaker #9 Diego Rosso (UC Irvine, Irvine California, USA)

Revisiting phosphorus removal: do the models give the answers we want?

Looking from a whole plant perspective, including biological and chemical processes.

Whole plant modelling gets increasing attention (Grau et al., 2007) and deals with linking the different models available for activated sludge, anaerobic digestion and anoxic-aerobic digestion. Due to the complexities in modelling P removal, the whole plant models also will have to deal with the effect of combining the biological and chemical models and their effect on each other (Barat et al., 2008; de Haas et al., 2000; Schonborn et al., 2001). Describing and predicting phosphorus (P) removal means looking at both biological and chemical processes. Modelling these processes has evolved over the years and result in a different status.

Modelling of biological phosphorus removal and in particular enhanced biological phosphorus removal (EBPR) has gotten a lot of attention during the 1990s resulting in the publication of the ASM2d (Henze et al., 1999). In the same period metabolic models (Lopez-Vazquez et al., 2009; Schuler and Jenkins, 2003; Smolders et al., 1995) also have shown to be promising for modelling the EBPR. More recently, a lot of criticism arose about ASM2d concerning the inability to account for several processes and many extensions have been published (García-Usach et al., 2010; Larrea et al., 2002; Makinia et al., 2006; Manga et al., 2001).

Driven by problems of struvite precipitation, phosphate recovery and the need to predict pH, modelling chemical P removal has been getting a lot of attention in recent years, which led to the start of an IWA task group on a Generalized Physicochemical Framework (Batstone et al., 2012).

Today, it is clear that for modelling phosphorus removal at wastewater treatment plants a whole plant context is required, including both biological and chemical processes. But there are a lot of models and extensions of models available. The choice of model leads to a large uncertainty in the model outcome and reduces the confidence in its predictions.

Expected discussions and results

Questions

What are the prerequisites of the models to deal with practical questions (in regard to design and operation of wastewater treatment plants)?

- What unit processes (AD, primary sedimentation, secondary sedimentation...) are insufficiently modelled to describe the fate of phosphorus in a plant wide modelling context?
- What different populations do we need to consider in the model without including unnecessary detail and complexity?
- What are the missing links/components to truly model physical-chemical processes?
- What is the impact of EBPR on other biological processes and vice versa?
- Are the currently known models sufficient?

Is there a need for a consensus model to make the modelling of phosphorus removal a mature methodology?

How

The workshop will be organized using four different session styles.

The first session style is based on **presentations** to set the stage for further discussion. Several well-known researchers will give an overview of the state-of-art on different aspects of whole plant modelling for phosphorus removal.

The second session style is based on **repeated breakout sessions**. The four topics, guided by a moderator, will be discussed twice for half an hour with different groups. Participants can choose 2 out of the 4 topics: (i) From practical questions to whole plant model prerequisites, (ii) impact of the sulfate cycle on P removal, (iii) the impact of biological reactions on chemical conditions and vice-versa) and (iv) the effect of high temperature on EBPR. At the end of the two sessions, the moderators will present the results to the whole group.

The third session style is based on the ‘**Open Space Technology**’. This is a method for convening groups around a specific question or task of importance and giving them responsibility for creating both their own agenda and experience. In first instance the participants are invited to propose topics. In a second step the remaining participants choose the topic of their interest and discuss it. One fundamental in this process is ‘the law of two feet’. I.e. if at any time during the time together you find yourself in any situation where you are neither learning nor contributing, use your two feet, go to another discussion.

The fourth session style is a typical **round table discussion** around the questions the workshop wants to answer. The moderator will be in charge of challenging the audience in the round table and wrapping up the main conclusions in the final session

After

After the workshop we will work towards a **position paper**. As a first step we suggest to submit a **short report** (2-3 pages max.) with the final conclusions of the workshop. The report will be distributed to the IWA task group on a Generalized Physicochemical Framework, to the IWA task group on Benchmarking of Control Strategies for Wastewater Treatment Plants and it will be uploaded into the MIA web (or send to the MIA group). As a second step we will invite the participants to contribute to the position paper.

If the group sees an interest in a consensus model, the position paper can be the starting point for setting up an **IWA task group** with the goal of formulating a successor of ASM2d.

Chair/Co-chair

Chair *Youri Amerlinck* (BIOMATH, Ghent University, Ghent, Belgium)

Co-Chair#1 *Albert Guisasola* (Universitat Autònoma de Barcelona, Barcelona, Spain)

Co-Chair#2 *Hélène Hauduc* (Institut National des Sciences Appliquées de Toulouse, France)

Co-Chair#3 *David Ikumi* (University of Cape Town, Cape Town, South Africa)

Speakers / Moderators

Moderator #1 *Marjoleine Weemaes* (Aquafin, Aartselaar, Belgium)

Moderator #2 *Chris Brouckaert* (University of KwaZulu-Natal, Durban, South Africa)

Moderator #3 *Hélène Hauduc* (Institut National des Sciences Appliquées de Toulouse, France)

Moderator #4 *Guclu Insel* (Istanbul Technical University, Istanbul, Turkey)
 Moderator #5 *Albert Guisasola* (Universitat Autònoma de Barcelona, Barcelona, Spain)
 Moderator #6 *David Ikumi* (University of Cape Town, Cape Town, South Africa)
 Moderator #7 *Youri Amerlinck* (BIOMATH, Ghent University, Ghent, Belgium)

Speaker #1 *Yves Comeau* (Ecole Polytechnique de Montréal, Montréal, Canada)
 Speaker #2 *Damien Batstone* (University of Queensland, Brisbane, Australia)
 Speaker #3 *Imre Takacs* (Dynamita, Nyons, France)
 Speaker #4 *George Ekama* (University of Cape Town, Cape Town, South Africa)
 Speaker #5 *Juan Antonio Baeza* (Universitat Autònoma de Barcelona, Barcelona, Spain)

Target Participants

Everyone who is dealing with phosphorus removal (either chemical, biological or both) at wastewater treatment plants.

- Plant staff
- Consultants
- Researchers

Programme

Time	Topic	Presenter/Moderator
09:45 - 10:00	Introduction: Motivation, scope, and objectives.	Youri Amerlinck
10:00 - 10:20	Presentation: Microbiological aspects of EBPR.	Yves Comeau

Workshop: Linking WWTP modelling with Life Cycle Assessment (LCA) and other Holistic models.

The main goal of this workshop is to provide a forum for experts in wastewater treatment plant modelling to think about how current process modelling fits with LCA and how current models might be expanded to create more synergies with LCA and other holistic models.

Expected discussions and results

Decisions about wastewater treatment have traditionally been driven by considerations of technical aspects and cost-benefit analyses. In order to assess sustainability it is essential also to incorporate environmental and social aspects. In this line of thinking, several methods for sustainability assessment of wastewater treatment technologies have been proposed and evaluated in literature. Focusing on environmental performance, Life Cycle Assessment (LCA) (ISO 14040, 2006) is an accepted tool that has also been used to evaluate potential environmental impacts from environmental processes (Finnveden *et al.*, 2009) including wastewater treatment processes throughout their whole life cycle (Guest *et al.*, 2009). The success of this method is demonstrated by the large number of published studies which have applied LCA to the wastewater treatment field (Corominas *et al.*, 2013). The published studies so far have been applied to estimate the impact of different wastewater treatment plants (WWTPs) and to compare conventional and new wastewater treatment technologies.

The organization of this workshop links to current activities of the IWA Working Group for Life Cycle Assessment of Water and Wastewater Treatment (LCA-Water WG) which was established in September 2012 to facilitate the exchange of ideas, and develop consensual methodologies, to promote better use of LCA in urban water systems. One of the main activities is to organize workshops to disseminate the use of LCA and to create synergies with other organizations (e.g. Task groups or working groups within IWA). WWTmod2014 is a great opportunity to define the synergies between that working group and other task forces that the modelling community on wastewater systems is running. The outcomes from the workshop might be bidirectional: from one side the LCA community can provide the wastewater process modelling community with complementary tools that can be coupled to existing models to expand how they are used to include environmental impacts and at the same time the LCA community involved in the field of WWT may benefit from close collaboration with the wastewater process engineers and managers who have extensive firsthand experience, resulting in a clearer modelling of the environmental impacts (and associated processes' variability particularly important for, e.g. GHG air emissions on the Global Warming category). On the other side, the wastewater process modelling community can learn from the LCA community which are the key issues from an environmental assessment point of view that should be addressed in the future (e.g. answering the question on where to put more effort: in modelling greenhouse gases emissions or microcontaminants, for example? What is more relevant for the environment?). Hence, the key questions from the workshop will be:

- How can the wastewater process modelling community benefit from environmental assessment tools?

- Which are the key issues that should be addressed in the future research by the wastewater process modelling community to help filling the gaps in the environmental assessment field?
- What would be key issues in LCA models to address with future research in order to offer accurate models to be of use to the WWT process community?

How will the workshop go about answering the posed question?

In order to answer the questions above posed, some fundamentals on LCA will be introduced first and then, several group discussions will be organized where the following points will be addressed that cover the different steps of the LCA ISO standard:

- Goal and scope definition. To identify different types of studies where LCA coupled to wastewater treatment models might play an important role.
- Inventory analysis. To identify which data required in the LCA studies can be obtained from wastewater treatment models.
- Impact assessment. To establish the link between LCA impact assessment methods with current simulation platforms.
- Interpretation. To discuss which wastewater treatment modelling challenges are more relevant from an environmental assessment point of view.

In order to have dynamic presentations promoting discussion we will address these issues by presenting successful examples of LCA studies and practices.

Who will be presenting in the workshop, and how will they contribute to the discussions?

Members of the LCA-Water WG will be introducing general concepts and moderate the discussions and other invited speakers covering different areas of expertise within the wastewater treatment modelling community will be involved to ensure bilateral discussions. (LCA vs wastewater treatment modelling).

How will you summarize results for larger WWTmod group?

A wrap-up session is planned by the end of the meeting where the key points will be identified and a PowerPoint presentation will be prepared with the key messages of the workshop.

What are plans for workshop subject after WWTmod? i.e. white paper, publications, other?

A white paper on linking current wastewater treatment modelling practices with LCA.

Workshop set-up

The workshop will be organized as a round table discussion after some keynote presentations.

The workshop will briefly define some fundamentals on LCA supported by wastewater treatment examples and will present the state-of-the-art of LCA and wastewater treatment. Then, the workshop will move to a more interactive stage with brief presentations and examples followed by discussion.

Chair/Co-chair

Andrew Shaw (Black & Veatch and Illinois Institute of Technology, USA)

Lluís Corominas (ICRA, Spain)

Speakers / Moderators

Gonzalo Rodriguez-García (University of Santiago de Compostela, Spain and Helmholtz-Institute Ulm, Germany)

15:50 - 16:30	Panel discussion: Should WWTmod step out of its box to include LCA, integrated modelling etc?	Andrew Shaw (facilitator)
16:30 - 17:00	Wrap up and next steps	Lluís Corominas

Workshop: Wet-weather modelling: Why and how should we tame the beast?

Wet-weather (WW) events and periods have a large impact on the Water Resource Recovery Facility (WRRF) behaviour and on its capability to comply with regulations. There has been a significant increase in interest in this topic in recent years. Publications like “*Guide for Municipal Wet Weather Strategies*” published this year by the Water Environment Federation (WEF) as well as “*Design and Operational Considerations for the Management of Wet Weather Flows at Water Resource Recovery Facilities*” (to be published in early 2014 by WEF as well), are meant to provide guidance to those involved in solving the unique challenges associated with the management of WW events. Both of these publications emphasize the importance dynamic modelling plays in providing adequate support in understanding WW phenomena and in evaluating design and operation options with regard to their performance during WW events.

The workshop will tackle the issue by promoting discussion around three main questions:

- Why is WW modelling important?
- What is happening in a WRRF during WW and how can we model it?
- How can we model measures that mitigate the effects of WW?

Expected discussions and results

In recent years municipal utilities have been facing the need to provide significant improvements on how they manage WW-related flows in their WRRFs as the result of increased regulatory and public pressures. These flows and loads, which result from combined sewer systems or even separate systems that have significant amounts of infiltration and inflow, can in many cases exceed the treatment capacity of existing facilities. However, the overall approach necessary to identify, evaluate, and eventually select the “best” WW flow management scenario for a particular WRRF in terms of process units and operational requirements is one that contrasts significantly from that normally used by the same utilities in dealing with dry weather (DW) treatment needs.

It can be argued that one of the most appropriate fields of application of dynamic WRRF modelling is indeed the study of WW events and periods, given the extremely time-varying nature of such phenomena, with typical time scales ranging from minutes to days. The behaviour of the facility in WW is very different from DW, especially with regard to influent flows and loads, primary and secondary settling efficiency, mixing, biological treatment performance, oxygen transfer and solids inventory transfer between the biological reactors and secondary settling tanks. This requires additional modelling efforts compared to DW, to enable decision support regarding design and operation alternatives devised to achieve permit compliance of the facility.

The topics covered by the workshop comprise an introduction to regulatory requirements and benefits of WW dynamic modelling, an overview of the main phenomena occurring at WRRFs during WW and of modelling of selected design and operation WW strategies. The presenters are based in both Europe and North America, and from both academia and consultancy. Plenary open discussion (60% of the total time) is allocated after each of the three presentation blocks and at the

end of the workshop, with the participation of a panel of invited experts. “On the fly” model runs will be performed during the discussion periods to interactively illustrate/test specific aspects.

A summary of the presentations and of the discussion will be shared with the WWTmod group.

Expected outcomes:

- dissemination of current status in WW management and its modelling, with focus on implications for WRRF design and operation, leading the way to a deeper understanding of the aspects affecting the WRRF’s performance under WW;
- identification of main challenges, gaps and opportunities, both for model development and application;
- a white paper on the state of the art and challenges related to WW modelling, with contributions by the presenters and by interested workshop participants.

Workshop set-up

The workshop is organized as follows:

- one presentation provides an introduction to regulatory requirements related to WW, and a summary of dynamic WW modelling benefits; discussion follows
- two presentations illustrate the modelling (limitations) of the phenomena associated to WW, causing the facility’s disturbance by WW (influent flows and loads) and occurring at the plant (mixing, settling, oxygen transfer, etc.); discussion follows
- two presentations introduce design and operation options aimed at dealing with WW, and in particular their specific modelling (limitations) issues; discussion follows
- a last discussion period is dedicated to more clearly identifying and finding consensus on the current status, directions, opportunities and gaps in WW knowledge and modelling.

Chair/Co-chair

Lorenzo Benedetti (Waterways, Italy)

Peter Vanrolleghem (Université Laval, Canada)

Speakers / Moderators

Lorenzo Benedetti (Waterways, Italy)

Charles Bott (Chief of Research and Development, HRSD, USA)

Jose Jimenez (Brown & Caldwell, USA)

Dave Kinnear (HDR, USA)

Paul Krauth (Utah Division of Water Quality, USA)

Cristina Martin Andonegui (DEUSTOTECH, Spain)

Julian Sandino (CH2M HILL, USA)

Oliver Schraa (Hydromantis, Canada)

Peter Vanrolleghem (Université Laval, Canada)

Stefan Weijers (Waterschap De Dommel, Netherlands)

Invited panel (confirmed)

Gerda Hald (Director, Planning & Investments, VandCenter Syd, Denmark)

Jeroen Langeveld (RHDHV / Delft University, Netherlands)

Target Participants

- Utilities/operators: stimulate ideas on how to improve the performance of their systems.
- Consultants: find and show ways to better serve their clients.
- Academics: opportunity to show current activities and to identify research needs expressed by utilities and consultants.

Programme

Time	Topic	Speaker/Moderator
09:45 - 09:55	Introduction: Motivation, scope, and objectives. Present workshop structure, participants, etc.	Lorenzo Benedetti
09:55 - 10:15	Presentation #1: <i>"Why do we have to tame the beast?"</i> Regulatory, design and operational aspects of WW; support provided by modelling in design and operation.	Julian Sandino Stefan Weijers
10:15 - 10:45	Discussion Period: regulation	Paul Krauth
10:45 - 11:15	Coffee break	
11:15 - 11:35	Presentation #2: <i>"What is making the beast angry?"</i> Modelling WW influent aspects: flows, loads, and variability.	Cristina Martin Andonegui
10:35 - 11:55	Presentation #3: <i>"What are the aspects of the beast's anger?"</i> Modelling WW impact on plant behaviour: mixing, settling, aeration, etc.	Peter Vanrolleghem
11:55 - 12:45	Discussion Period: modelling	Dave Kinnear
12:45 - 13:45	Lunch break	
13:45 - 14:05	Presentation #4: <i>"How do we tame the beast? The hard way."</i> Modelling design options for WW mitigation.	Jose Jimenez
14:05 - 14:25	Presentation #5: <i>"How do we tame the beast? The soft way."</i> Modelling control options for WW mitigation.	Oliver Schraa
14:25 - 15:15	Discussion Period: mitigation	Charles Bott

Abstract

The purpose of this paper is to present a critical review on the characterization of influent unbiodegradable organic (trash) and inorganic (grit) particulate matter, to propose a fractionation of particulate unbiodegradable matter and to how the fractionation can be used to evaluate trash and grit removal efficiencies of physical separation units.

Keywords

Trash, grit, unbiodegradable organic, inorganic, characterization, fractionation, activated sludge

INTRODUCTION

The modelling of systems with long sludge retention times (membrane bioreactors, extended aeration and Cannibal-type systems) is particularly sensitive to the fractionation of wastewater unbiodegradable matter. Indeed, unbiodegradable influent particulate organic (trash; $X_{U,INF}$) and inorganic (grit; $X_{I,INF}$) matter directly affect predictions of sludge production in water resource recovery facilities (WRRFs). The purpose of this paper is to present a critical review of the characterization of trash and grit, to propose a fractionation of unbiodegradable organic and inorganic material in activated sludge and to show how the fractionation can be used to evaluate trash and grit removal efficiencies of physical separation units.

CHARACTERIZATION OF $X_{U,INF}$

Trash ($X_{U,Inf}$) can be defined as unbiodegradable particulate organic material originating from the influent. During model calibration, the $X_{U,Inf}$ fraction is sometimes modified so that the simulated and observed sludge productions correspond. It has been suggested that the development of methods to better represent $X_{U,Inf}$ would help avoid this fine-tuning (Choubert et al., 2013).

Trash is removed in the screenings at the headworks of WRRFs. Materials composing trash include toilet paper, hair, leaves, rags, sticks, food particles, plastics, bottle caps, tree roots, wood chips, etc. (WEF, 2010; Metcalf & Eddy, 2014). The lack of data on trash and screenings is often mentioned in the literature and may be attributed to analytical challenges (Clay et al., 1996; Le Hyaric et al., 2009). Several studies have focused on characterizing the quantity, specific gravity, organic matter (volatile fraction), nutrients and biodegradability of these materials (UKWIR, 2000; Le Hyaric et al., 2009; Mansour-Geoffrion, 2012). Screenings characteristics can be influenced by the type and

length of collection system, pumping stations (and whether screening is present at pumping station), rainfall, influent screen bar spacing, organic matter content, storage conditions, dewatering, solids content (Le Hyaric *et al.*, 2009; WEF, 2010). Short, gently sloping collection systems with low turbulence generally produce more screenings than long steep interceptor systems with pumping stations because of differing degrees of organic solids disintegration (WEF, 2010). Typically, the shorter the sewer network, the greater the amount of screenings removed at the WRRF. This can be explained by less dilacerations of suspended solids and the decreased likelihood of pumping stations (can favor settling during dry weather and disintegration of solids (Canler & Perret, 2004). Combined sewer systems produce several times the coarse screenings compared to separate systems (WEF, 2010). Peak wet-weather removal from combined systems may vary by as much as 20:1 on an hourly basis from average dry weather conditions (WEF, 2010).

Quantities and composition of $X_{U,Inf}$

Typical reported quantities and characteristics of screenings collected at WRRFs are presented in Table 1. The average consumption of toilet paper in the United States is 23 kg capita⁻¹ y⁻¹ (Haase, 2010). Assuming most of the toilet paper is flushed in the toilet and ends up in the sewer system, almost all of it should end up at the WRRF with the exception of combined sewer overflows. The average yearly screenings production at the influent of wastewater treatment plants in the United States was 4.5 kg/capita (Table 1), representing 20% of the toilet paper consumed. It can therefore be deduced that much of the toilet paper and most likely other materials considered to be trash are not entirely intercepted by influent screens and probably end up either in primary sludge, secondary sludge or effluents of WRRFs.

Reported solids content of screenings vary between 10 and 50%, while bulk densities, which depend (among other factors) on solids content, are 510 – 1100 kg/m³. As expected, screenings are mainly organic as evidenced by their high volatile fraction (0.77 – 0.90 g X_{VSS} /g X_{TSS}).

Typical components of trash were characterized and compared to characteristics of microscreenings obtained from experiments conducted on activated sludge from nine full-scale WRRFs in Quebec (Canada) and Morongo (California, USA; Table 2)). The Morongo WRRF was the only facility tested where a full-scale microscreen was installed on the return activated sludge stream for the purpose of trash removal from sludge. The f_{VT} (volatile to total suspended solids ratio), f_{CV} (chemical oxygen demand to volatile suspended solids ratio), phosphorus content (T_P) and total Kjeldahl nitrogen (T_N) content of toilet paper, brown paper (for drying hands), Kleenex, live plant leaves and dead leaves were measured. Samples were dried (103°C for 24 h), weighed, diluted in reverse osmosis water and blended (Ultra-Turrax ® T 25 digital, IKA) prior to X_{VSS} , X_{TSS} , T_{COD} , T_P

and T_N analyses. T_P and T_N were measured after digestion using an automated ion analyzer (Quickchem® AE model, Lachat Instruments, Inc., Loveland, CO) according to Standard Methods (APHA et al., 2005).

Results showed that paper products were almost entirely volatile ($f_{VT}=98-100\%$) while dead leaves contained more inorganic matter ($f_{VT}=90\%$) than live plant leaves ($f_{VT}=96\%$). The f_{CV} values obtained for microscreenings from Morongo and Quebec WRRFs were in the same range as the f_{CV} values measured on typical components of microscreenings.

Low f_{PV} and f_{NV} values measured on Morongo microscreenings were characteristic of values measured on typical components of microscreenings, with the exception of live plant leaves. Live plant leaves contained much more P and N than paper products and even dead leaves, but they are probably a minor component of microscreenings as indicated by the low f_{PV} and f_{NV} of microscreenings as well as observations.

Table 2. f_{VT} , f_{CV} , f_{NV} and f_{PV} of typical $X_{U,Inf}$ components, Morongo and Quebec sludge and microscreenings samples

Biodegradability of $X_{U,Inf}$

Materials composing $X_{U,Inf}$ are often assumed to be unbiodegradable (Lei et al., 2010), however there is evidence in the literature that cellulose (toilet paper) is biodegradable in activated sludge systems (Verachtert et al., 1982) and that activated sludge microscreenings, which have similar characteristics to influent screenings, exhibit a 20-day carbonaceous biochemical oxygen demand (X_{cBOD20} ; Mansour-Geoffrion, 2012). There is no standard procedure for the evaluation of screenings biodegradability. Several approaches for evaluating screenings biodegradability, such as manual sorting and identification of materials, biochemical oxygen demand and biomethane potential (BMP) have been proposed. The purpose of manually sorting screenings materials is to evaluate the variability of screenings composition and to identify biodegradable components of screenings. Screenings may be sorted into several categories (Table 3) after draining for thirty minutes (UKWIR, 2000) or after being partially dried at 80°C for 10 days (Le Hyaric, 2009).

Table 3: Categories for manual sorting of screenings materials (biodegradability evaluation)

UKWIR (2000)	Le Hyaric (2009)
Faeces	Fines (less than 20 mm)
Sanitary products	Sanitary textiles
Fine Paper	Vegetation
Leaves	Paper-cardboard
Other Material	Plastics
	Textiles
	Metals, Aluminum
	Composites
	Combustibles
	Incombustibles

BOD tests have also been used to evaluate screenings and microscreenings biodegradability, but procedures in the literature present some major differences. Microscreenings biodegradability was evaluated using the f_{BC} index (X_{cBOD20} to X_{COD} ratio) as an indicator of organic matter biodegradability: the higher the ratio, the more biodegradable the organic matter. Ten microscreening experiments were conducted on sludge from Quebec WRRFs and f_{BC} was measured on sludge fed to the microscreen (MSF) and on microscreenings (SCR). Results indicated that microscreenings were composed of biodegradable matter as they exhibited an X_{cBOD20} and were therefore not unbiodegradable as previously assumed (data not shown; Lei, 2010). Whether microscreenings are more or less biodegradable than the sludge they came from was unclear: in six runs microscreenings were more biodegradable than microscreen feed sludge ($f_{BC} SCR > f_{BC} MSF$) and in five runs they were less biodegradable ($f_{BC} SCR < f_{BC} MSF$). Difficulties evaluating the biodegradability, or rather “unbiodegradability”, of microscreenings were also encountered during the characterization of the MicronairTM system at the Winter Haven (Florida, USA) WRRF which included microscreening and hydrocycloning the return activated sludge stream for trash and grit removal and claimed “zero-biosolids disposal”. Oxygen uptake rate of activated sludge microscreenings was $0.81 \text{ mg kg}^{-1} \text{ h}^{-1}$ at the Winter Haven plant (Bizier, 1999), which would also correspond to an f_{BC} in the range of 0.2 to 0.3 $\text{g } X_{cBOD20}/\text{g } X_{COD}$. Another approach to using the BOD test to evaluate screenings biodegradability is to rinse a wet, 200 g sample of food-processed screenings ten times, to filter the sample (100 μm) while compressing it and to measure the BOD_5 on the filtrate (UKWIR, 2000). This approach assumes that the fraction of the sample greater than 100 μm does not contribute to BOD, which, considering the evidence in the literature of the biodegradability of screenings materials, seems to be unreasonable.

The slow biodegradability of at least some fraction of screenings and microscreenings is expected as cellulose forms one of the major structural components of all plant material such as wood and cotton (and hence paper products) and active cellulolysis has been shown to occur in activated sludge by enumeration of cellulolytic microorganisms, determination of cellulase activity, by the degradation of cellulose contained in Nylon bags suspended in mixed liquor at a WWTP and by the determination of cellulose and lignin in activated sludge and anaerobic digestion sludge (Verachtert *et al.*, 1982; Ramasamy & Verachtert, 1980; Cheung & Anderson, 1997).

CHARACTERIZATION OF X_{GRIT}

Typical reported quantities and characteristics of grit (X_{GRIT}) collected at WRRFs are presented in Table 4. X_{GRIT} definitions vary but they typically include inorganic particles between 50 and 1000 μm and a range of densities between 1.1 - 2.65 (Reddy & Pagilla, 2009; WEF, 2010). Sand, gravel,

pebbles, ashes and eggshells are considered to be a part of grit. Certain references surprisingly claim there is a volatile fraction to “grit” – this is most likely due to X_{GRIT} being wrongly defined as suspended solids removed by the grit removal system. Suspended solids removed by the grit removal system are not exclusively composed of X_{GRIT} and contain $X_{U,Inf}$ and other organics. X_{GRIT} is widely accepted as inorganic suspended solids originating from the influent by definition. The quantity, characteristics and particle size distribution of influent grit depend on several factors: type of sewer network, sewer condition, season, rainfall, industrial loading and nature of industries, maintenance work, construction work, gravel and salt spreading on roads, nature of soils in the area and the height of the water table (Reddy & Pagilla, 2009; Rippon *et al.*, 2010). Sampling location and methods can also influence the interpretation of grit characteristics due to spatial stratification inside pipes and channels (Reddy & Pagilla, 2009). Similarly to $X_{U,Inf}$, X_{GRIT} is typically removed in the headworks and primary clarifiers of WRRFs, but still accumulates in downstream processes. Inadequate X_{GRIT} removal at the headworks of WRRFs can damage process equipment (pumps, air diffusers) by abrasion. Insufficient grit removal can also lead to decreased capacity of bioreactors if X_{GRIT} is allowed to settle and accumulate in bioreactors (reduction of effective volume and treatment capacity). Much smaller quantities of X_{GRIT} are removed from WRRFS than $X_{U,Inf}$ as can be seen by comparing Tables 1 and 4. X_{GRIT} is more easily dewatered than $X_{U,Inf}$ and its density is typically higher than that of $X_{U,Inf}$.

Table 4: Summary of quantities and characteristics of grit collected at WRRFs

Parameter	Units	Metcalf & Eddy (2014) (Handbook)	MOP 8 (WEF, 2010) Survey of 328 U.S. WRRFs	Borneman & Gress (2011) WEFTEC 2011 - Grit Workshop	Canler & Perret (2004) Literature review

PROPOSED FRACTIONATION OF ACTIVATED SLUDGE

Activated sludge matter can be fractionated according to size, volatility and biodegradability (Figure 1). Total solids (TS) can be fractionated into volatile (VS) and inorganic (IS) solids depending on whether they are volatilized at 550°C. VS are assumed to be organic. VS and IS can each be fractionated according to size into filtered (FVS and FIS; < 0.45µm) and suspended (VSS and ISS; > 1.2 µm) solids. Particles sized between 0.45 and 1.2 µm - too large to be considered “filtered” and too small to be considered “suspended” – are in a no man’s land of the solids tests and are thus not considered with regards to fractionation. Filtered matter is commonly termed “soluble” but since colloidal material (0.08 – 1 µm; Odegaard, 2000) is present in both filtered and unfiltered samples, the term filtered rather than soluble is preferred. Total activated sludge organic matter (volatile solids, VS) can be classified as biodegradable (T_B) and unbiodegradable (T_U) organic matter. Each of these can be further fractionated according to size into filtered (0.45 µm) and particulate (1.2 µm) biodegradable organic matter (X_{SB}), filtered unbiodegradable matter (S_U) and particulate unbiodegradable matter (X_U). X_{SB} includes filtered (S_B) and particulate (X_B)

biodegradable matter that can be used as substrate for biomass growth and heterotrophic biomass (X_H). Filtered and particulate unbiodegradable organic matter (S_U and X_U) can originate in the influent ($S_{U,Inf}$ and $X_{U,Inf}$) or from endogenous respiration (S_E and X_E). $X_{U,Inf}$ (trash) and X_{GRIT} are the main focus of this paper. Salts are an example of filtered inorganic matter (S_{Ig}). Particulate inorganic matter can be classified as associated to biomass cellular material $X_{Ig,Cel}$ such as cell membranes or intracellular inorganic compounds of X_H ($X_{Ig,H}$) and X_E ($X_{Ig,E}$). Inorganic compounds associated to $X_{U,Inf}$ ($X_{Ig,U,Inf}$) are also included in $X_{Ig,Cel}$. Grit (X_{GRIT}) and precipitates (X_{PPT}) make up the extracellular particulate inorganic compounds ($X_{Ig,EC}$) of activated sludge. Important issues with fractionation include recognizing the type of filter used to define “filtered” components (0.45 vs 1.2 μm) and the categorization of colloidal material.

TS	VS	FVS	T_B	XS_B	S_B	ORGANICS	
		VSS			X_B		
				T_U	X_H		X_H
					S_U		$S_{U,Inf}$
							S_E
	IS	FIS	T_{Ig}	$X_{Ig,Cel}$	$X_{U,Inf}$		
					X_E		
					S_{Ig}		S_{Ig}
				$X_{Ig,EC}$	$X_{Ig,H}$		
			X_{GRIT}				
		ISS	T_{Ig}	$X_{Ig,EC}$	$X_{Ig,U,Inf}$		X_{PPT}

Figure 1: Activated sludge fractionation.

EVALUATION OF $X_{U,Inf}$ and X_{GRIT} REMOVALS USING PROPOSED FRACTIONATION

Lab, pilot and full-scale tests were conducted on microscreens for trash removal and hydrocyclones for grit removal on activated sludge from nine WRRFs in Quebec (Canada) and Morongo (CA, USA). Below are presented the approaches used to

$X_{U,Inf}$ removal by microscreen

The maximum removal of $X_{U,Inf}$ from microscreen feed sludge (MSF) by microscreening was calculated according to equations 1 and 2.

$$Max \% removal X_{U,Inf} = \frac{MX_{VSS_SCR}}{MX_{U,Inf_MSF}} \quad (1)$$

$$MX_{U,Inf_MSF} = f_{X_{U,Inf_SRT}} \cdot MX_{VSS_MSF} \quad (2)$$

where:

MX_{VSS_SCR} = mass of X_{VSS} in microscreenings (g X_{VSS});

MX_{U,Inf_MSF} = mass of trash in MSF (g X_{VSS});

fX_{U,Inf_SRT} = mass fraction of trash in MSF at sampling day solids retention time (SRT; g VSS/g VSS); and

MX_{VSS_MSF} = mass of X_{VSS} in MSF (g VSS).

The fraction of $X_{U,Inf}$ (fX_{U,Inf_SRT}) in the activated sludge samples from each WRRF was determined knowing the solids retention time (SRT) at the facility on the sampling day. Three underlying assumptions were made:

- influent wastewater fractionation at the WRRFs was typical for raw influent and primary effluent (characterization from Dold, 2007);
- SRTs calculated by WRRFs were correct; and
- all X_{VSS} retained by microscreen is trash (hence “maximum”).

Using this approach to fractionate the activated sludge solids, it was determined that 14% of trash contained in activated sludge from WRRFs with no primary clarification could be removed by microscreening, while only 3% of trash in activated sludge from WRRFs equipped with primary clarifiers could be removed (Figure 2).

Figure 2: Maximum amount of $X_{U,Inf}$ removed by the lab-scale microscreen (data from Quebec WRRFs). Data grouped according to presence/absence of primary clarifiers (PC).

X_{GRIT} removal by hydrocyclone

Concentration factors (CF) for X_{VSS} and X_{Ig} ($X_{VSS,underflow}/X_{VSS,feed}$; $X_{Ig,underflow}/X_{Ig,feed}$) were used to describe hydrocyclone performance. CFs were also calculated for $X_{Ig,Cel}$ (intracellular inorganic particulate matter) and $X_{Ig,EC}$ (extracellular inorganic particulate matter) by assuming $X_{Ig,Cel}$ had the same CF as X_{VSS} since $X_{Ig,Cel}$ are associated to the organic matter. Another assumption made was that the inorganic content of the volatile matter was 0.08 g $X_{Ig,Cel}$ /g X_{TSS} (Ramdani et al., 2010). The $CF_{X_{Ig,EC}}$ ($\approx CF_{GRIT}$ if no precipitates) could then be calculated by mass balance. Results for lab-scale hydrocyclone experiments on activated sludge are presented in Figure 3 (data grouped according to presence/absence of primary clarifier). Results indicated that the hydrocyclone was more efficient at

separating grit ($X_{Ig,EC}$) from activated sludge in WRRFs with no primary clarifiers than from sludge from WRRFs with primary clarifiers.

Figure 3: Influence of primary treatment on hydrocyclone concentration factors for a 13 mm lab-scale hydrocyclone and activated sludge samples from Quebec and Morongo WWTPs. UF: underflow, PC: primary clarifier, $X_{Ig,EC}$: extracellular inorganic suspended solids, VSS: volatile suspended solids.

Abstract

The availability of influent wastewater time series is crucial when using models to assess the performance of a wastewater treatment plant (WWTP) under dynamic flow and loading conditions. Given the difficulty of collecting sufficient data, synthetic generation could be the only option. In this paper a hybrid of statistical and conceptual modeling techniques is proposed for synthetic generation of influent time series. The time series of rainfall and influent in DWF conditions were generated using two types of statistical models (a periodic-multivariate time series model for influent in DWF conditions and a two-state Markov chain-gamma model for rainfall). These two time series serve as inputs to a conceptual sewer model for generation of influent time series during WWF conditions. The effect of total model uncertainty on the generated outputs is taken into account through a Bayesian calibration and is communicated to the user by constructing uncertainty bands with a desired level of confidence. The proposed influent generator is a powerful tool for realistic generation of the influent time series and is well-suited for risk-based design of WWTPs as it considers both the effect of input variability (i.e. variability in rainfall and influent during DWF) and total model uncertainty in the generation of the influent. Considering the fact that the proposed influent generator only requires readily-available or easy-to-obtain information and data on climate and the general characteristics of sewershed, it is an attractive tool for practical applications.

Keywords

Bayesian estimation; uncertainty analysis; urban hydrology; wastewater composition; probabilistic design

INTRODUCTION

One of the major sources of uncertainty/variability that both plant designers and operators must deal with is the dynamics of the influent. The recent advances in mathematical modeling and improved computational power have enabled researchers to better understand the performance of different WWTP design alternatives (Hao *et al.*, 2001; Salem *et al.*, 2002) and/or evaluate control strategies under dynamic flow and loading conditions. However, the application of mathematical models used for simulating the performance of a WWTP could be misleading unless, among others, models are provided with representative influent time series. One of the problems that arise in this regard is the scarcity or even lack of long-term influent data. To remedy this problem, some researchers have proposed models for synthetic dynamic influent time series scenarios (Bechmann *et al.*, 1999; Gernaey *et al.*, 2011).

One of the simplest approaches in synthetic generation of influent time series is the application of empirical stochastic models (Capodaglio *et al.*, 1990; Martin *et al.*, 2007). However, these models may have a poor performance especially during wet weather flow conditions as different complex processes affect the dynamics of the influent. Indeed, such statistical models do not consider the underlying elements and processes that govern the generation and the dynamics of the influent. To

consider the underlying phenomena that are involved, some researchers have advocated the use of detailed and physically-based models (Hernebring *et al.*, 2002; Temprano *et al.*, 2007). The application of these complex models might be useful for certain purposes, (e.g. evaluating the performance of different operating strategies in a sewer system). However, in cases in which the overall behavior of the influent time series is of interest, they might not be very useful as they require detailed information on the sewage system and running them for a large number of times could be computationally expensive.

Some researchers have proposed parsimonious conceptual models as an alternative to the complex mathematical models that require detailed information and data (Achleitner *et al.*, 2007; Gernaey *et al.*, 2011). In these models a conceptual view of the main phenomena and interactive processes contributing to the influent are formulated in terms of mathematical equations. Despite successful application of these models (at least in giving an overall view of the system), the performance of these models to a great extent depends on the proper choice of model parameters. Since some of the parameters may not have a clear physical meaning they are usually estimated through model calibration. In cases in which there is no measured data available for model calibration, only a rough estimate or a range of values could be inferred from the values reported in literature. Besides, it is almost impossible to have a complete similarity between the model output(s) and the observed values owing to the inextricable uncertainties (e.g. input data uncertainty and/or model structure uncertainty) in any modeling exercise (Belia *et al.*, 2009; Freni and Mannina, 2010).

Given the importance of the issue of uncertainty, several studies have been conducted to consider its effect on both water quality and quantity in urban drainage modeling (Freni *et al.*, 2009; Dotto *et al.*, 2012). However, in these studies, only the effect of model uncertainty under a set of historical rain events (WWF conditions) has been considered (i.e. the time series of rainfall and also the contribution of wastewater in DWF conditions were known *a priori*). In this study on the contrary not only are we interested in considering the effect of model uncertainty, but also in the variability of rainfall and influent time series in DWF conditions which significantly affect both the amount and the dynamics of the influent.

PROPOSED INFLUENT GENERATOR

In this paper, a hybrid of statistical and conceptual modeling tools is proposed for synthetic generation of influent time series considering both the effect of model uncertainty and input variability. Given the importance of rainfall time series in the generation of the influent, a two-state Markov chain-gamma model (Richardson, 1981) in conjunction with two time series disaggregation methods were used for stochastic generation of rainfall time series with a high temporal resolution (i.e. 15-minute). To generate the influent time series in DWF conditions taking into account the daily periodic variation, auto-correlation, and cross-correlation in time, a multivariate time series models was developed and its parameters were estimated using the methodology proposed by Neumaier and Schneider (2001). The proposed stochastic model is superior to previous attempts in the generation of influent, as in previous studies the diurnal variation of the influent in DWF conditions was modeled using univariate time series models (Martin *et al.*, 2007), or by multiplying the daily average influent values to a set of coefficients representing the ratio of influent at different times of a day to its average value with or without addition of a noise term to the generated time series (Achleitner *et al.*, 2007; Langergraber *et al.*, 2008; Gernaey *et al.*, 2011). The outputs of the two statistical models used for the generation of rainfall and influent time series in DWF conditions are then input to a conceptual model for modeling the influent time series in WWF conditions. In this study the CITYDRAIN model (Achleitner *et al.*, 2007) was selected as the conceptual model

owing to its flexibility and parsimony. The CITYDRAIN model of the sewershed is calibrated using the measured influent data through a Bayesian calibration procedure to account for the *total model uncertainty*. Finally, different realizations of the influent time series can be generated by running the calibrated CITYDRAIN model using an instance of a generated time series of rainfall and an instance of influent under DWF conditions (i.e. the two stochastic input time series). Figure shows the schematic of the proposed influent generator.

Figure 1 Schematic of the proposed influent generator

The main objective of the proposed influent generator is to produce a dynamic influent time series of flow and traditional wastewater component concentrations (TSS, COD, TN, TP, NH_4) with 15-min temporal resolution in order to capture the sub-daily time variations of the influent which could affect the operating parameters and the performance of WWTPs. One of the constraints was that the generator should only be using limited information on climate and the general characteristics of combined sewer systems. Depending on the biological model that would be used for modelling the biological processes inside a WWTP system, an influent fractionation block must be added to convert the generated traditional wastewater composition into state variables of the adopted biological models, e.g. the ASM models. The generated influent time series using the proposed tools can be used among others for the design of WWTPs under uncertainty (Martin *et al.*, 2012).

Data and case study

The Eindhoven WWTP with a design capacity of 750000 population equivalent (PE) is the third largest WWTP in the Netherlands. The sewershed served by the Eindhoven WWTP has a total area of approximately 600km² and comprises of three main sub-sewersheds called Nuenen/Son, Eindhoven Stad, and Riool-Zuid. The influent data used in this study are related to sensor data of flow, ammonia (measured using an ion-selective sensor) soluble COD, total COD, and TSS (the latter 3 measured using an UV/VIS-based sensor) in the period of September 2011 to September 2012 at the outlet of the Nuenen/Son, Eindhoven Stad, and Riool-Zuid sub-sewersheds. It should be noted that the raw sensor data were cleaned up using visual inspection and a wavelet-based denoising strategy (details are not included in this paper).

The long-term daily rainfall data and also rainfall data with finer temporal resolution provided by KNMI (Royal Netherlands Meteorological Institute) and Waterschap De Dommel were used for estimating the parameters of the weather generator proposed in this paper.

Weather generator

Realistic generation of rainfall time series is crucial as it is one of the most important factors that affect the dynamics of the influent during WWF conditions. In this study a stochastic model proposed by Richardson (1981) was used for the synthetic generation of daily rainfall and air temperature time series. According to this method the sequence of dry and wet days is generated using a two-state Markov chain model with parameters $P(W|W)$ and $P(W|D)$ which represent the probability of having a wet day at day t given a wet day at day $t-1$ and the probability of having a wet day at time t given a dry day at time $t-1$ respectively (Figure).

Figure 2 Schematic of a two-state Markov chain, i.e. wet (W) or dry (D)

The other two parameters of the transition matrix needed for generation of dry and wet days (i.e. $P(D|D)$ the probability of having a dry day at day t given a dry day at day $t-1$ and $P(D|W)$ the probability of having a dry day at day t given a wet day at day $t-1$) can be calculated using Equation 1 and Equation 2.

$$P(D|D) = 1 - P(W|D) \quad \text{Equation 1}$$

$$P(D|W) = 1 - P(W|W) \quad \text{Equation 2}$$

Once the sequence of wet and dry days is generated, the amount of rainfall in a wet day is generated by sampling from a gamma probability distribution (Equation 3)

$$f(x) = \frac{(x/\beta)^{\alpha-1} \exp(-x/\beta)}{\beta \Gamma(\alpha)} \quad \text{Equation 3}$$

where x is the depth of daily rainfall, α and β are the two parameters of the distribution, and $\Gamma(\alpha)$ represents the gamma function evaluated at α . The time series of minimum and maximum air temperature are generated conditioned on the state of the day (i.e. wet or dry) using a multivariate linear first-order time series model (Matalas, 1967). The above weather generator is suited for random generation of daily rainfall and temperature. However, in this study we need to generate rainfall time series with a finer temporal resolution than daily resolution (15-min temporal resolution, comparable to the temporal resolution of rainfall in the BSM influent model (Gernaey *et al.*, 2011)). Some methodologies have been proposed for random generation of hourly rainfall time

series based on historical hourly rainfall data. However, long-term hourly rainfall data may not be available in every region and using a limited hourly rainfall record for random generation of long-term hourly rainfall time series may result in misrepresentation of the inter-annual variability in rainfall.

That being said, in this study it is proposed to combine the Richardson-based weather generator (i.e. which is used for daily rainfall generation) with two time series disaggregation techniques. In other words, daily rainfall time series is first generated using the Richardson (1981) method and then two time series disaggregation models, including a daily-to-hourly model (Koutsoyiannis and Onof, 2001) and an hourly-to-15-minutes model (Ormsbee, 1989) are applied for generation of long-term rainfall time series with 15-minute temporal resolution. Moreover, the original Richardson-based weather generator is also suited for the generation of daily air temperature. However, in this study not the air temperature but the wastewater temperature is of interest as it affects the rate of many biological processes taking place in the bioreactors. To estimate the wastewater temperature a simple linear regression model was fitted between the daily air temperatures and the corresponding wastewater temperature measured during the period of September 2011 to September 2012. The fitted regression model was used to calculate the daily wastewater temperature as a function of daily air temperature generated using the Richardson-based weather generator.

Influent generation in DWF conditions

The influent time series in DWF conditions usually shows specific periodic patterns which can be mainly attributed to the socio-economic fabric of society and also to the physical characteristics of the wastewater collection system. To mimic these variations in time, it is common practice to estimate representative values (e.g. multiplying flow per person to the total population for estimating flow) for flow and loads and then multiplying them to a set of normalized coefficients reflecting diurnal, weekly and seasonal time variation of the influent time series (Jeppsson *et al.*, 2007; Gernaey *et al.*, 2011; Flores-Alsina *et al.*, 2014). Moreover, Gernaey *et al.* (2011) proposed to add a noise term to the deterministic influent profile in order to avoid generating the same influent time series in subsequent days. In this study the application of a multivariate auto-regressive model (Neumaier and Schneider, 2001) with periodic components is proposed.

To estimate the parameters of the proposed time series model, the influent time series during DWF conditions were extracted and analyzed for estimating the parameters of the multivariate auto-regressive model. First, the seasonal (e.g. associated to groundwater infiltration) and diurnal periodic components of flow and other wastewater constituents were estimated using different Fourier series approximations and removed from the original influent time series to calculate the residual time series. The zero-mean residual time series of influent flow and composition were furthered standardized to have an influent time series with a zero mean and unit standard deviation. The parameters of the multivariate autoregressive model in Equation 4 (i.e. p, A_t, C) were then estimated through a stepwise least square algorithm proposed by Neumaier and Schneider (2001).

$$v_t = \sum_{l=1}^p A_l \times v_{t-l} + \varepsilon_t \quad \text{Equation 4}$$

In Equation 4, v_t is an m-dimensional vector (i.e. for our application $m=5$ which corresponds to the flow and the four wastewater compositions) containing the generated influent component at time t , p is the order of the auto-regressive model, A_1, \dots, A_p are the coefficient matrices of the auto-regressive model, and ε_t is a noise term generated from an uncorrelated zero-mean multivariate normal distribution with the covariance matrix C (i.e. $\varepsilon_t \sim N(0, C)$). Different realizations of the

residual influent time series can be generated using this time series model and converted to the original scale depending on the mean and standard deviation of the original influent time series.

Influent generation in WWF conditions

Synthetic generation of the influent time series during WWF conditions is relatively more complicated than the generation of the influent time series during DWF conditions. Difficulties arise as various phenomena are occurring during WWF conditions and as the availability of measured data is usually scarce for these periods. Hence, using a purely statistical model may result in significant discrepancies between simulated and observed time series. Therefore, we used a combination of statistical modeling techniques and a conceptual model to generate the time series of the influent during WWF conditions. The CITYDRAIN model (Achleitner *et al.*, 2007) was selected as the conceptual model as it takes into account the basic phenomena that govern the amount and dynamics of the influent and also requires only a small number of parameters whose values or ranges of values can be inferred from the basic information of a sewershed.

Flow

CITYDRAIN calculates the amount of effective rainfall by adopting the concept of virtual basins in which effective rainfall is calculated by subtracting the initial loss from rainfall and then multiplying it with the runoff coefficient. The height of the effective rainfall is then multiplied by the fraction of sewershed area which contributes to the generation of runoff to calculate flow. A simplified routing method based on the well-known Muskingum method is then used for routing flow and pollutants inside the sewer system.

Composition

For the generation of pollutant time series in WWF conditions, CITYDRAIN uses a rather simplistic approach in which a fixed pollutant concentration is imposed to the system:

$$\begin{cases} C(t) = C \text{ if } h_e > 0 \\ C(t) = 0 \text{ if } h_e = 0 \end{cases} \quad \text{Equation 5}$$

where, $C(t)$ is the generated pollutant concentration in time, C is a model parameter representing the concentration in WWF conditions, and h_e is the effective rainfall. Given the importance of the influent time series in WWF conditions, a more appropriate conceptual model was used for simulating the accumulation-wash off processes corresponding to the particulate concentrations. To this aim, a new block was developed and implemented in CITYDRAIN to generate the pollutant concentration time series in WWF conditions. Equation 6 shows the mathematical formulation of the selected accumulation-wash off model (Kanso *et al.*, 2005).

$$\begin{cases} \text{Accumulation model: } \frac{dM_{(t)}}{dt} = K_a (m_{\text{lim}} \times S_{\text{imp}} - M_{(t)}) \\ \text{Wash off model: } \frac{dM_{(t)}}{dt} = -W_e \times I_{(t)}^w \times M_{(t)} \end{cases} \quad \text{Equation 6}$$

where, $M_{(t)}$ is the available pollutant mass on the sewershed at time t (kg), K_a is the accumulation coefficient (1/day), m_{lim} is the maximum accumulated mass (kg/ha), S_{imp} is the impervious area (ha), $I_{(t)}$ is the rainfall intensity (mm/hr), W_e , and w are calibration parameters.

Bayesian model calibration and long-term influent generation

As explained in the previous section, the dynamics of the influent time series in WWF conditions is modeled using the CITYDRAIN model. However, one should be aware of the fact that modeling the influent time series in WWF conditions using a conceptual model may not lead to reliable results unless the model is calibrated and the effect of different sources of uncertainties on the outputs (e.g. flow and other pollutants) are taken into account. To this aim, a Bayesian framework was used to update the ranges of values that were initially assigned to the parameters of the CITYDRAIN model (i.e. estimating the *posterior distribution* of parameters using their *prior distribution* and the measured data on flow and pollutant concentrations). In general, the *posterior distribution* of parameters using Bayes' theorem can be formulated by Equation 7.

$$h(\theta | Data) = \frac{f(Data | \theta) p(\theta)}{f(Data)} \quad \text{Equation 7}$$

where $h(\theta | Data)$ is the *posterior distribution*, $p(\theta)$ is the *prior distribution*, $f(Data)$ is merely a proportionality constant so that $\int h(\theta | Data) = 1$, and $f(Data | \theta)$ constitutes the *likelihood function* which measures the likelihood that the data correspond to the model outputs with parameter set θ . Assuming homoscedastic uncorrelated Gaussian error terms the *likelihood function* can be formulated according Equation 8 (Bates and Campbell, 2001; Marshall *et al.*, 2004).

$$f(Data | \theta) = (2\pi\sigma^2)^{-n/2} \prod_t^n \exp \left\{ -\frac{[Data_t - R(x_t; \theta)]^2}{2\sigma^2} \right\} \quad \text{Equation 8}$$

where n is the number of observations, σ^2 is the variance of the residual error (i.e. the difference between model predictions and observed values), $Data_t$ is the observed variable at time t , x_t is the set of inputs at time t , θ is the set of model parameters and $R(x_t; \theta)$ represents the model output as a function of x_t and θ .

A specific form of Markov chain Monte Carlo (MCMC) sampler known as differential evolution adaptive Metropolis or DREAM (Vrugt *et al.*, 2008) was used to efficiently estimate the *posterior distribution* of the CITYDRAIN model parameters given the time series of flow and influent composition of the Eindhoven WWTP. It should be noted that the proposed Bayesian approach is not only capable of capturing the effect of model parameter uncertainty, but also of capturing the effect of other sources of uncertainties that could result in some discrepancies between the simulated influent time series and the observed series.

Once the uncertainty ranges of the CITYDRAIN model parameters are updated, synthetic influent time series for a desired number of years considering the variability in the inputs of the CITYDRAIN model (i.e. rainfall and influent time series in DWF conditions) and also the total uncertainty can be obtained as follows:

1. Synthetic generation of the 15-minute time series of rainfall for one year
2. Synthetic generation of the 15-minute time series of the influent in DWF conditions for one year
3. Sampling a point from the *posterior distribution* of the CITYDRAIN model parameters

4. Inputting the generated time series 1) and 2) and the parameters sampled in 3) and running the CITYDRAIN model for one year
5. Repeating 1) to 4) for a desired number of years

RESULTS AND DISCUSSION

This section presents the outputs and some discussion on the results of different components of the proposed influent generator. The performance of the weather generator and the influent generator under DWF conditions are evaluated by comparing the statistical properties of the generated time series with those of the historical time series. The results corresponding to the Bayesian calibration of CITYDRAIN model are explained and at the end a 7-day snapshot of generated one year influent time series is presented and discussed.

Synthetic generation of rainfall

The parameters of the statistical Markov-gamma model were estimated using the recorded rainfall data in the studied Eindhoven catchment. The results indicate that not only are the basic yearly statistics (i.e. average and variance) of the generated rainfall time series consistent with the recorded rainfall time series, but also the seasonal variations in rainfall intensity and frequency of wet days are respected (Figure and Table 1).

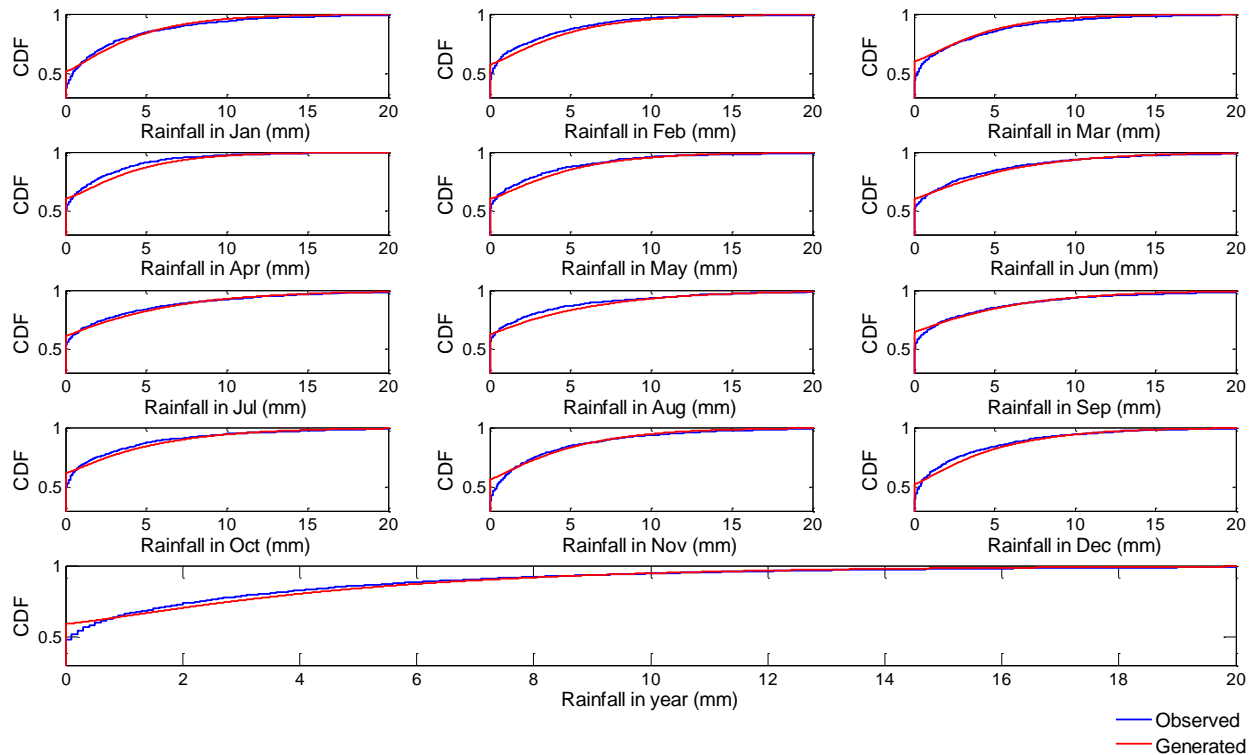

Figure 3 Cumulative distribution function of daily rainfall in the studied Eindhoven catchment

Moreover, Table shows that the hourly time series of rainfall which was generated using the time disaggregation method (i.e. disaggregation of daily to hourly time series) has the same statistical characteristics as the observed one. Overall, the synthetic generation of rainfall in which the statistical properties of the time series is respected across different time scales is a significant

improvement compared to the rainfall generation in for instance the BSM influent generator in which there is no clear way for extracting and incorporating the statistical properties of available recorded rainfall data into synthetic rainfall time series generation. Besides, the flexibility of the proposed rainfall generator allows users to define different scenarios reflecting future changes in precipitation regime (e.g. due to climate change (Chen *et al.*, 2010)) and its effect on the influent time series (e.g. what would happen if the amount of precipitation increases by 20%).

Table 1 Average rainfall amount and number of wet days for Eindhoven catchment

Month	Amount of Rainfall (mm)		Expected number of Wet Days	
	Observed	Generated	Observed	Generated
Jan	72.3	67.0	16	14

Synthetic generation of influent temperature

As mentioned in the methodology section, the daily temperature of wastewater is estimated through a linear regression model which relates the daily average wastewater temperature to the daily average air temperature. Figure illustrates a random generation of air and wastewater temperature time series for one year. The linear model in Figure shows that the average wastewater temperature can be estimated reasonably ($R^2 = 0.70$) as a linear function of air temperature. To further disaggregate the daily average wastewater temperature into a time series with 15-minute temporal resolution, the average diurnal variation of wastewater temperature which was extracted and smoothed using a first order Fourier series estimate (Figure c) was multiplied to the daily average wastewater temperature. Despite the fact that the diurnal variation pattern in Figure c clearly shows a periodic behavior in time (which corresponds to the diurnal variation of wastewater temperature), there is no significant difference between the highest and lowest temperature throughout a day (i.e. the highest temperature is only around 1.001 times the daily average wastewater temperature and

the lowest temperature is around 0.9985 times the daily average wastewater temperature). Therefore, in practical applications (at least for the case study in this research), the diurnal temperature variation can be ignored.

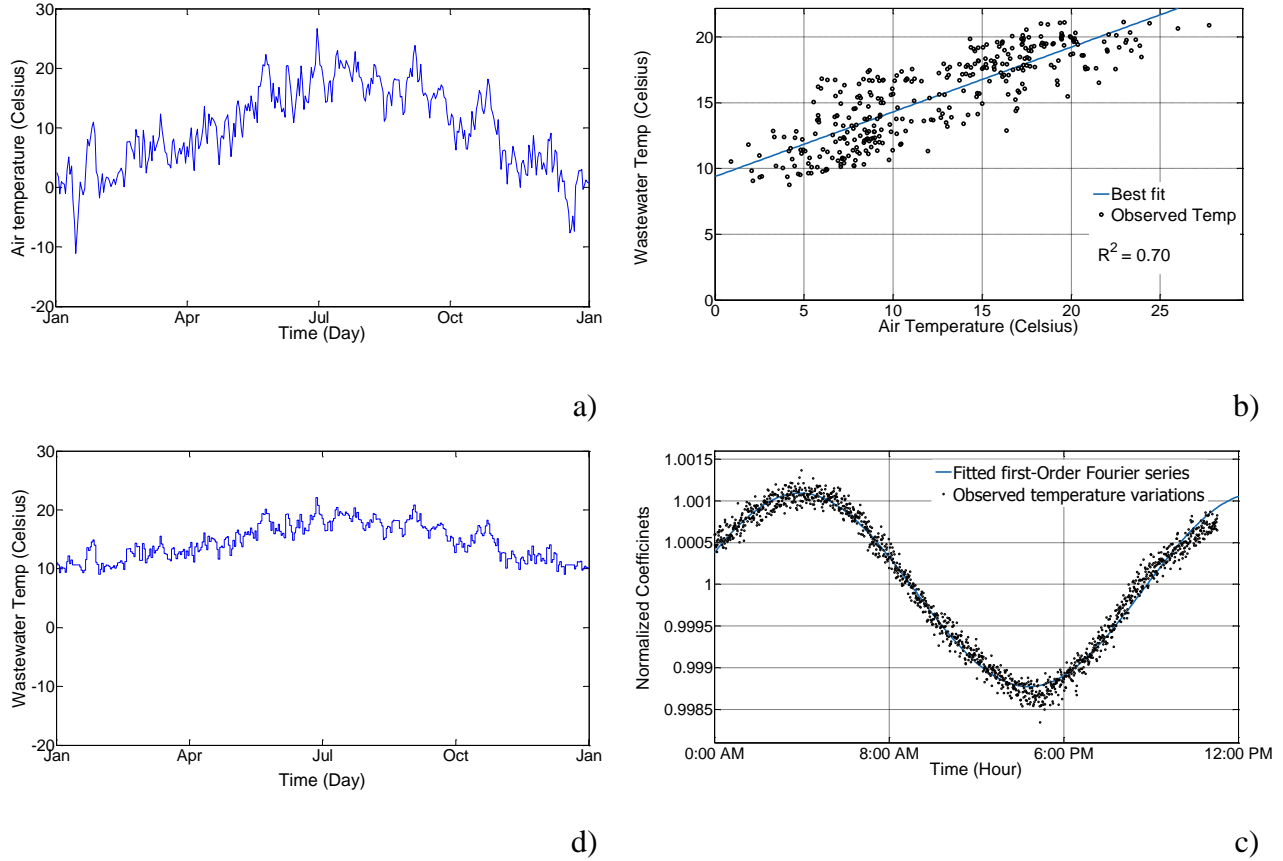

Figure 4 Random generation of air and wastewater temperature for one year for the Eindhoven WWTp: a) Randomly generated average daily air temperature for a year, b) linear regression model for calculating the average daily wastewater temperature as a function of average daily air temperature, c) the average and fitted normalized coefficients (the normalized coefficients for each day were calculated by dividing the influent temperature at different moments of a day by the daily average influent temperature in the same day) for calculating the diurnal wastewater temperature variations, and d) randomly generated wastewater temperature time series with 15-minute temporal resolution.

Multivariate auto-regressive model for DWF generation

As explained, the parameters of the multivariate auto-regressive model were estimated using a specific least square algorithm (Neumaier and Schneider, 2001). Figure shows a continuous 3-day DWF influent time series with the results corresponding to the fitted multivariate auto-regressive model. The uncertainty band was generated through random generation of the noise term (i.e. p, A_i in Equation 4 were fixed and the noise term was generated from $\varepsilon_i \sim N(0, C)$).

One of the main advantages of the proposed multivariate time series model over univariate time series models (Martin *et al.*, 2007) or the DWF generator in the BSM influent generator (Gernaey *et al.*, 2005) is that not only are the auto-correlation structures in time respected but also the cross-correlation structures. Table shows the correlation matrix for the randomly generated and observed influent time series in DWF conditions.

Figure 5 Observed and simulated influent time series under DWF conditions

Table 3 Correlation matrix for the generated and observed influent time series in DWF

Generated influent time series						Observed influent time series

CITYDRAIN model calibration and synthetic influent generation

As explained in the methodology section, the CITYDRAIN model was used for modeling the dynamics of the influent time series during WWF conditions. Uniform distributions representing the initial knowledge on parameters were selected as *prior distributions* and their corresponding *posterior distributions* were estimated by sampling from Equation 7 using the DREAM sampler. Figure and Figure show the *posterior distributions* of the CITYDRAIN model after calibrating the model for flow and TSS time series in WWF conditions (three days of simulations were used as the warm-up period to set the initial conditions of the system).

As indicated in Figure and Figure , there exists some correlation among the parameters of the CITYDRAIN model. For example in Figure , the parameters that affect the generation of effective rainfall (i.e. runoff coefficient, initial loss, and permanent loss) are correlated meaning that different combinations of these parameters could result in the same amount of effective rainfall given the same inputs and values for other parameters. However, given the narrow ranges associated to the parameters that affect the amount of rainfall, the uncertainty band for flow relating to the *total model uncertainty* is mainly affected by the standard deviation of the residual error (i.e. Sigma in Figure) and not by the uncertainty of the CITYDRAIN model parameters.

The parameters that affect the accumulation of pollutant (i.e. m_{lim} , and K_a) and those that affect the wash-off of pollutants are also correlated. Given the different correlation structures that exist among some parameters it is very important to sample from the joint distribution of parameters to propagate the effect of parameter uncertainties to the outputs.

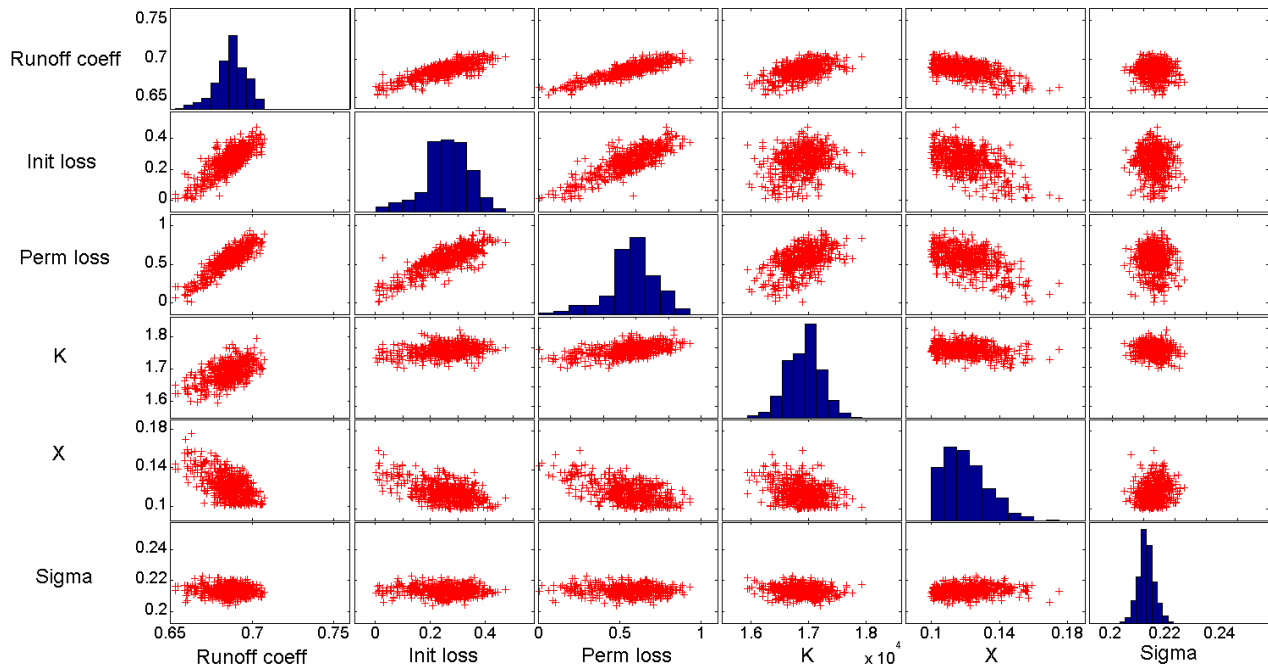

Figure 6 Posterior distribution of parameters for flow calibration where, runoff coeff, init loss, and perm loss are respectively the runoff coefficient, initial loss (mm), permanent loss (mm/day) parameters in the virtual basins model that is used in the CITYDRAIN model, K (sec) and X are the routing parameters used in the Muskingum method, and Sigma is the standard deviation of the residual error.

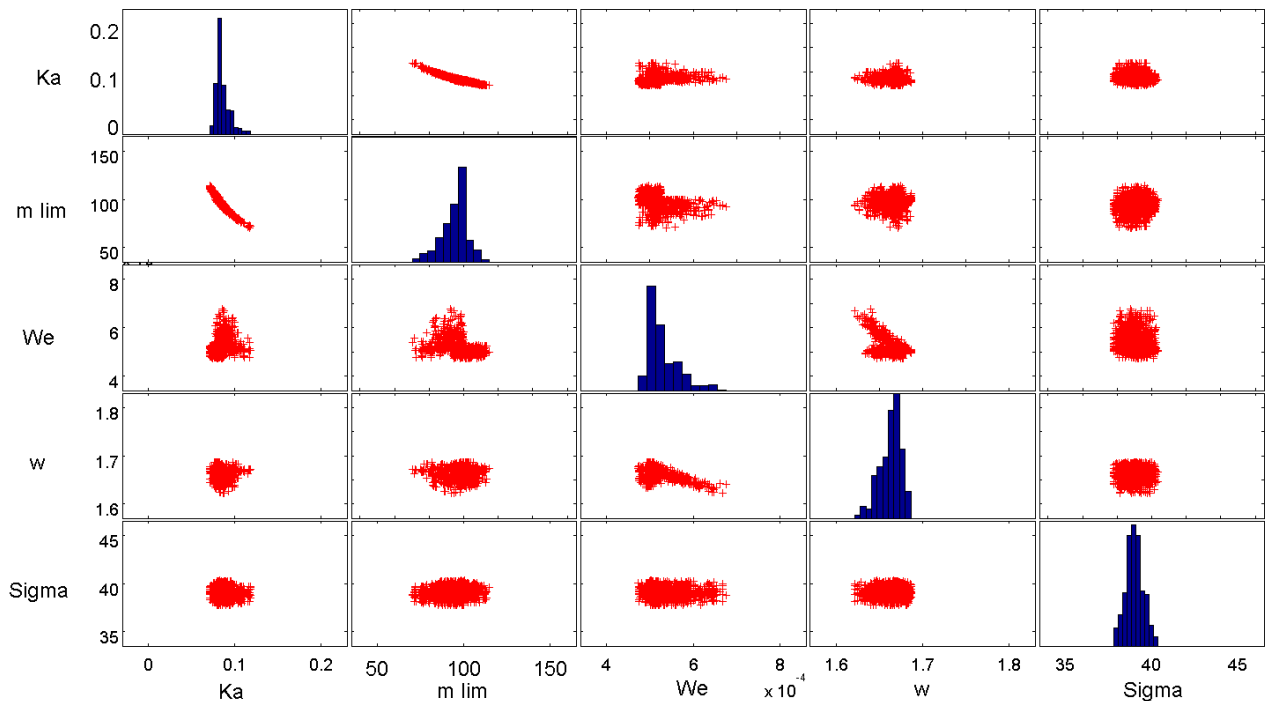

Figure 7 Posterior distribution of parameters for TSS calibration where Ka is the accumulation coefficient (1/day), m_lim is the maximum accumulated mass (kg/ha), We, and w are the calibration parameters (Equation 6).

To consider the effect of *total model uncertainty* on the outputs of CITYDRAIN model, a Monte Carlo simulation was performed by sampling from the joint *posterior distribution* of parameters and running the model for 1000 times for a particular rainfall time series. Figure illustrates the 95% uncertainty band for flow and TSS which was constructed by selecting the 2.5 and 97.5 percentiles of the cumulative distribution of flow and TSS as the lower and upper limits of uncertainty of simulation with the rainfall time series shown in the figure. The figure also presents the observed and the best simulated time series. The latter corresponds to the set of parameters that has the highest *likelihood function* value.

Figure 8 Uncertainty bands for flow (left) and TSS concentration (right) in a 4-day wet weather period

To further analyze the statistical properties of the simulated influent time series during both the DWF and WWF conditions, the cumulative distribution function (CDF) of the simulated and observed influent flow and pollutant load were compared in Figure and Figure 4. The simulated and observed influent time series with 15-minute temporal resolution were aggregated to construct the corresponding daily and hourly influent series. Figure and Figure 4 show that the influent generator has excellent performance when it comes to predicting the daily and hourly influent flow and pollutant load values.

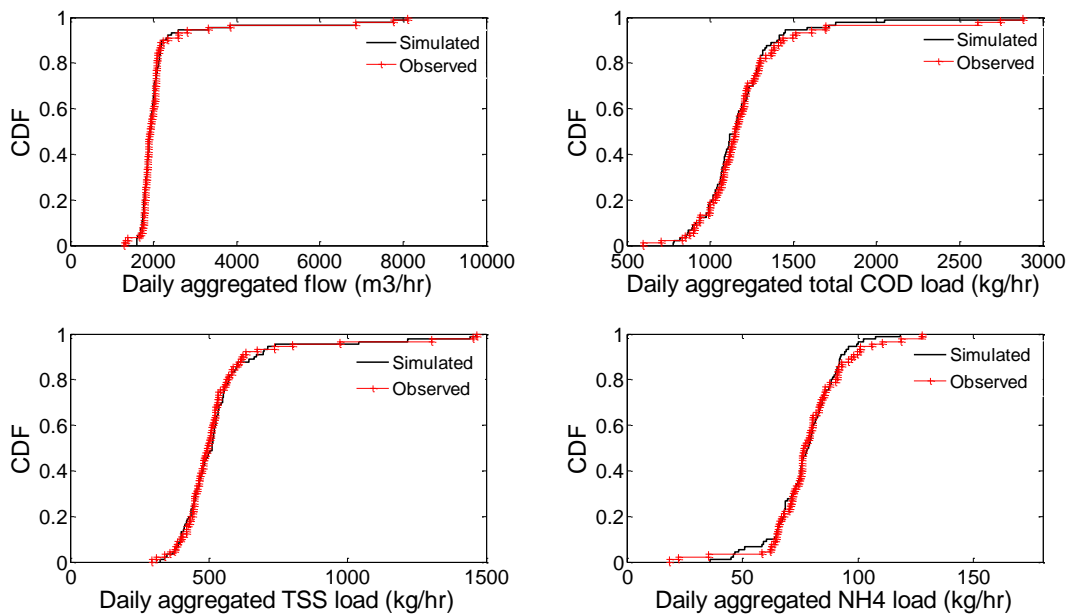

Figure 9 CDFs of daily-aggregated influent flow and load of influent pollutants

Figure 4 CDFs of hourly-aggregated influent flow and load of influent pollutants

It can be concluded from Figure 3 and Figure 4 that the statistical properties of the simulated time series are similar to the properties of the observed series once the model is fed with the observed rainfall time series. As explained in the methodology section, synthetic generation of a one year influent time series with 15-minute temporal resolution is thus possible by sampling from the posterior distribution of the CITYDRAIN model parameters and inputting the model with synthetically-generated rainfall and influent time series for DWF conditions (both with 15-minute temporal resolution). The latter two series are to be generated using the proposed rainfall and DWF generators respectively.

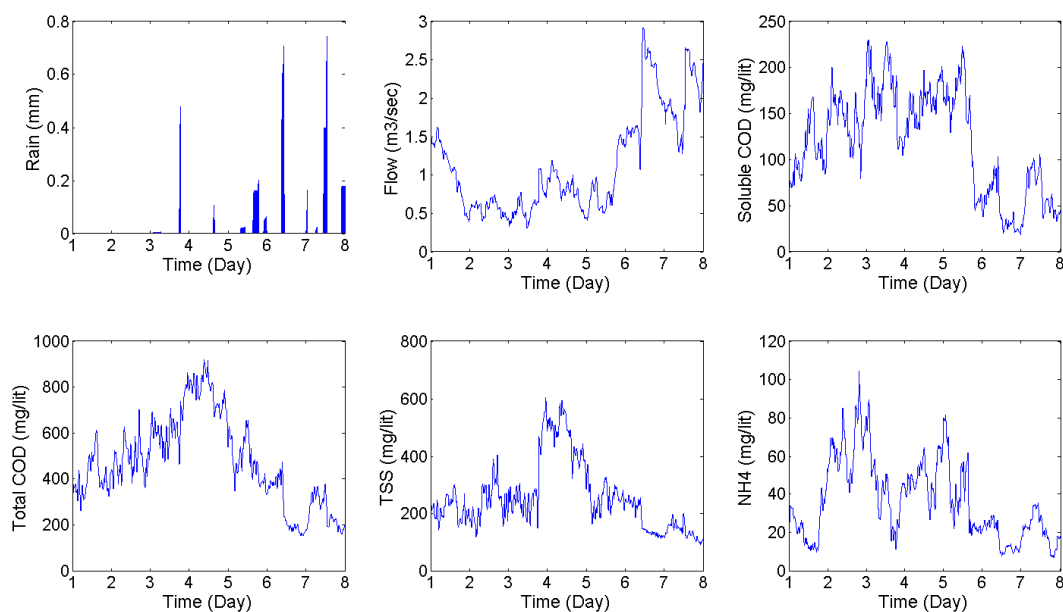

Figure 5 A 7-day realization of rainfall and influent time series

Figure 5 shows a 7-day snapshot of a generated one year influent time series. During the hours of the first day the time series of flow has a descending trend as the runoff produced by rainfall event just before the first day (not depicted in Figure 5) exits the sewer system and the flow time series reaches its DWF conditions with a typical periodic pattern (the second day in Figure 5). During the last hours of the third day another rainfall event occurs and the flow time series increases while the time series of soluble COD and ammonia drop due to dilution of wastewater by runoff. However, during the same period of time there is a sudden increase in the total COD and TSS concentrations due to the wash-off of particulate material. After the wash-off of the particulates during the last hours of the fourth day, the dilution effect starts to dominate again and the time series of total COD and TSS drop due to the dilution of the wastewater by runoff.

CONCLUSION

In this paper a combination of statistical and conceptual modeling tools was proposed for synthetic generation of dynamic influent time series of flows and pollutant concentrations with 15-minute temporal resolution. The rainfall generator is capable of considering the annual and inter-annual rainfall regimes and keeping the consistency of the generated rainfall time series across different temporal resolutions. Comparison between observed and simulated influent time series for the Eindhoven case study proved the capability of the proposed multivariate auto-regressive model in generating realistic influent time series in DWF conditions. Moreover, long-term generation of influent time series under dry and wet weather conditions could be achieved by running the CITYDRAIN model of the sewershed using the generated stochastic inputs (i.e. rainfall and influent time series in DWF condition). Uncertainty could be captured by sampling different vectors of the model parameters from the posterior distribution obtained after Bayesian parameter estimation on the basis of the case study data.

Overall, the proposed influent generator provides a clear and coherent method to incorporate the general and easy-to-obtain information on the physical characteristics of the sewershed as well as climate conditions of the region into the synthetic generation of the influent of a treatment plant. The flexibility of the presented influent generator allows the users to define different scenarios reflecting the projected change in climate and the characteristics of the sewershed (e.g. population growth, change in pervious area) and evaluate their effect on the generated influent time series.

ACKNOWLEDGEMENT

The authors would like to thank Stefan Weijers, and Petra van Daal-Rombouts from Waterschap De Dommel (Eindhoven, The Netherlands) and Youri Amerlinck from BIOMATH-Ghent University (Belgium) for providing the influent and rainfall data for this study. This research work was funded by the Natural Sciences and Engineering Research Council of Canada (NSERC) and Primodal Inc. as well as the financial support of Hampton Roads Sanitation District, Virginia. Abstract

A model should be as simple as possible – but not simpler. The appropriate level complexity depends both on the type of system and on the intended use of the model. This paper addresses the critical question of which purposes justify an increased complexity of biofilm (reactor) models. Additional model features considered are (1) of the distinction between flocs and granules in putatively granular sludge reactors and (2) the inclusion of microbial diversity, distinguishing between different species performing the same function. The impact of these features are assessed for a partial nitrification-anammox process and a conventional nitrification process, respectively. It was shown that the addition of a small level of flocs (5% of total biomass) can have a significant impact on macroscale process performance and on microbial population and activity distributions in putatively granular sludge reactors. With a multispecies model considering interspecies diversity (10 species of ammonium-oxidizers and 10 species of nitrite-oxidizers), it was demonstrated that a constant macroscopic reactor performance not necessary reflects steady state conditions on the microscale. The biomass distribution in time and in space could be explained through the underlying microbial characteristics. Based on these case studies, we argue that increased complexity in biofilm (reactor) models will be likely more useful when the focus is on understanding fundamental microscale outputs, particularly under dynamic conditions or in cases of microbial cross-feeding and/or balanced aerobic/anoxic conditions. When the focus is on macroscale outputs (e.g. substrate removal rates, optimal bulk conditions), this complexity is likely not always necessary. However, under specific conditions, additional model features can be critically informative for bulk reactor behavior, prediction, or understanding.

INTRODUCTION

Mathematical biofilm (reactor) models are excellent tools for both predicting patterns of behavior in overall process performance (macroscale outputs) and for understanding fundamental phenomena such as microbial interactions, segregation, or competition (microscale outputs). Deciding which features to include in biofilm or biofilm reactor models is a critical component of model structure selection. Wanner *et al.* (2006) emphasize the value of identifying model features that can be omitted without decreasing the utility of the model for its intended purpose, as summarized in their “golden rule” of modeling: “a model should be as simple as possible, and only as complex as needed.” In essence, decreasing model complexity via simplifying assumptions can greatly ease computational requirements and interpretation of model outputs. The level of complexity to include in a model depends in large part on its intended use, but determining this level is not always straightforward.

One example of the utility of increasing biofilm model complexity in certain circumstances is the use of multidimensional (2D, 3D) simulations instead of the simpler, and more common, 1D models. Multidimensional models have been shown to be highly useful when the intent of the model is to understand the impact of microscale physical heterogeneity in biofilm solid matrix - for example, shape or local density variations that lead to microscale multidirectional concentration gradients - or when transport processes outside of molecular diffusion (e.g. advection or turbulent dispersion) of dissolved components in the biofilm liquid phase are of interest (Morgenroth *et al.* 2000a; Picioreanu *et al.* 2004; Eberl *et al.* 2006). If average microscale concentration profiles or macroscale outputs alone are of interest to the model user and in case vertical gradients are orders of magnitude higher than those in the directions parallel to the carrier surface, conventional 1D models that are much less computationally intensive can often perform well (Wanner & Gujer 1986; Morgenroth *et al.* 2000a).

A range of complexity exists even within numerical 1D biofilm models. We focus our efforts here on numerical 1D biofilm models with stratification of biomass, multiple substrates, and multiple functional guilds. Two common simplifying assumptions in such biofilm models are: 1) to ignore mesoscale heterogeneity in aggregate structure (e.g. size distribution of granules, or variation in transport properties of a hybrid mixture of aggregate types, such as flocs and granules), and 2) to neglect microbial diversity and resulting internal microbial competition within function guilds. However, experimental observations have highlighted routine coexistence of multiple types of biomass aggregate types in a single biofilm reactor. Specifically, for granular nitrification-anammox reactors, flocs are commonly observed to be present in putative granular sludge reactors and reciprocally granules in suspended sludge reactors, suggesting that these two types of biomass aggregates coexist more often than a priori supposed (Innerebner *et al.* 2007; Vlaeminck *et al.* 2009; Vlaeminck *et al.* 2010; Winkler *et al.* 2012). In addition, experimental observations have demonstrated diverse assemblages of microbial populations within individual functional guilds in, for example, nitrifying biofilm reactors, where several genetically different populations of ammonium-oxidizers (Schramm *et al.* 2000; Bernet *et al.* 2004; Lydmark *et al.* 2006; Volcke *et al.* 2008; Terada *et al.* 2010; Almstrand *et al.* 2013) or nitrite-oxidizers (Schramm *et al.* 1998; Schramm *et al.* 2000; Downing & Nerenberg 2008) were observed to coexist in the biofilm.

Moreover, and of critical importance to this paper, both diversity within functional guilds and heterogeneous aggregate characteristics have been proposed to influence macroscale reactor performance and process stability (Wittebolle *et al.* 2005; Siripong & Rittmann 2007; Wett 2007). Indeed, the possible role of suspended biomass in influencing performance in biofilm reactors, and the general lack of consideration of this fraction in biofilm models, was noted as a possible oversimplification by Morgenroth *et al.* (2000b). Also, mathematical models including microbial

community information have proven useful in investigating the link between observed microbial community shifts and the macroscopic reactor behavior (Downing & Nerenberg 2008; Volcke *et al.* 2008; Ramirez *et al.* 2009; Nielsen *et al.* 2010; Wett *et al.* 2011; Brockmann *et al.* 2013; Vannecke *et al.* 2014). Taken together, these previous experimental studies suggests that, in at least some cases, increasing model complexity by incorporation of these often neglected features of biofilm systems (mesoscale heterogeneity in aggregate structure, and microbial diversity) may illuminate important aspects of both macroscale and microscale outputs.

We focus in this paper on the critical question of which purposes increases in complexity in standard biofilm or biofilm reactor models may be justified by providing two case studies of increases in complexity beyond standard biofilm model formulations that provide new insights at both the macroscale and microscale. The two case studies deal with

- 1) the influence of small levels of floccular biomass in a granular sludge combined nitrification-anammox reactor on macroscale N removal efficiency, optimal dissolved oxygen (DO) conditions, and microscale microbial population and activity distribution; and
- 2) the influence of microbial diversity on biofilm development and microscale microbial population dynamics in a nitrifying biofilm, considering competition between 10 ammonium-oxidizing species and 10 nitrite-oxidizing species.

BIOFILM MODELS

General model features

Two 1-dimensional multispecies biofilm models were developed in Aquasim (Reichert *et al.* 1995). The modelled biofilm reactors were operated under similar conditions (Table). Both case studies concern biological nitrogen removal processes. The first one considers completely autotrophic nitrogen removal through partial nitrification and anammox in a granular sludge reactor. The second case study concerns conventional ammonium oxidation to nitrate in a flat biofilm. The general stoichiometric matrix and kinetics for both case studies are based on Ni *et al.* (2009), Volcke *et al.* (2010) and on Vannecke *et al.* (2014), respectively.

Table 1. Influent characteristics and reactor operating conditions.

	Case study 1	Case study 2
Temperature (°C)	30	30
pH	7.5	7.5
Nitrogen loading rate (kg N.m ⁻³ .d ⁻¹)	0.5	0.9
Initial biofilm thickness (μm)	10	1
Steady state biofilm thickness (μm)	750	1000
Biofilm porosity	80%	80%
Influent NH ₄ ⁺ (g N.m ⁻³)	300	250
Influent sCOD (gCOD.m ⁻³)	10	0
Reactor volume (m ³)	400	2e-003

Case study 1: Modeling heterogeneity in aggregate structure

To assess the importance of small levels of flocs in putatively granular sludge combined nitrification-anammox reactors, two multispecies biofilm models were developed in Aquasim. The first model included only granular biomass in a continuous flow bioreactor, while the second model structure included both granular and floccular biomass. Two primary properties differentiated these two aggregate fractions: 1) biomass distribution was assumed to be heterogeneous in granules, as is

standard in biofilm models, and homogeneous in flocs due to flocculation and deflocculation; and 2) granules were mass transfer (diffusion) limited, while flocs did not exhibit mass transfer limitations. Both models included growth and decay (death-regeneration) of ammonium-oxidizing organisms (AOO), nitrite-oxidizing organisms (NOO), ordinary heterotrophic organisms (OHO) under both aerobic and denitrifying conditions, and anammox (AMO). OHO grew on organics arising from biomass decay or from exogenous organic carbon. In both model structures, granules were considered to be symmetrical spherical biofilms with a rigid biofilm matrix and negligible external mass transfer limitations. Solids detached from biofilm (granule) surfaces into the bulk phase were homogeneously distributed and potentially active before being removed proportionally to the effluent flow. In the model structure considering both floccular and granular biomass, flocs were modeled by implementing a bifurcation from the effluent to the inlet, thus recycling part of the biomass detached from the granule surface:

$$Load_{X,Rec} = Q_{in} * \left(1 + \alpha - \frac{\theta_H}{SRT}\right) * X$$

where $Load_{X,Rec}$ is the loading of particulate (floccular) material in the recycle, Q_{in} the influent flow rate, α the recycle ratio (here = 0.1), θ_H is the hydraulic retention time (0.5d), SRT the sludge residence time (40d) and X is the floccular biomass concentration in the reactor. The SRT was held constant by wasting a portion of the floccular biomass from the recycle.

Case study 2: Modeling multispecies competition

To model microbial competition between nitrifying species performing the same function in the biofilm, and to verify the importance of various microbial parameters in determining the competition outcome, a two-step nitrification biofilm model including the growth and endogenous respiration of 10 ammonium-oxidizing species (AOO) and 10 nitrite-oxidizing species (NOO) was used. Possible ranges of values for maximum growth rate (μ_{max}), yield (Y), affinity for the nitrogen substrate (K_{NH}^{AOO} and K_{NO2}^{NOO}) and the affinity for oxygen (K_{O2}^{AOO} and K_{O2}^{NOO}) were determined based on an extensive literature study. For each considered microbial parameter, a normal bimodal distribution was constructed as in Ramirez *et al.* (2009). The eight bimodal distributions were each typified by two means ($\mu_1 = 0.6 \times k$; $\mu_2 = 1.4 \times k$) and standard deviations of $\sigma_{1,2} = 0.125 \times k$, with k the average value of the range of values found in literature for the corresponding parameter. Ten species per type were then constructed by picking 10 random numbers from each bimodal distribution. Parameters employed in the final model are given in Table 2. The endogenous respiration rate for each species was assumed to be 5% of its corresponding maximum growth rate. The initial concentration of each AOO and NOO species was equal for all species of the same type (AOO: 7000 g COD.m⁻³ and NOO: 2333 g COD.m⁻³). As heterotrophic growth on biomass decay products can be neglected (Mozumder *et al.* 2013), and the influent did not contain an organic carbon source, heterotrophic growth was not considered in this model. The initial concentration of ammonium in the bulk liquid was set equal to the influent ammonium concentration (250 g N.m⁻³) while the initial concentrations of nitrite and nitrate were negligible (1 g N.m⁻³). The bulk liquid oxygen concentration was kept constant at 3 g O₂.m⁻³ during the simulations. The simulations were run during a sufficient amount of time to assure steady state reactor conditions, both at micro- and macroscale.

Table 2. Microbial parameters characterizing the AOO and NOO species included in Case study 2.

RESULTS AND DISCUSSION

Case study 1: Impact of coexistence of flocs and granules: considering multiple aggregate fractions

For both granular sludge combined-nitrification anammox model structures (granules alone, and combined granular and floccular biomass), the maximum N removal efficiency achieved was about 95% (Fig. 1A). In both reactors at DO <0.1mg/l, the low oxygen concentration limited AOO activity and thus hampered the N removal process, and for DO >0.5mg/l, the increasing bulk DO concentration gradually inhibited AMO and improved the conditions for the NOO growth. However, the addition of small levels (~5% of total biomass) of flocs changes the predicted overall reactor performance in two critical ways. Firstly, the maximum N removal efficiency was achieved at lower DO with flocs. Secondly, the N removal peak was narrower, suggesting that small levels of floccular material may decrease process robustness to bulk oxygen changes in granular sludge reactors.

In addition to impacting overall N removal performance, the addition of flocs also exerted a substantial influence on microscale segregation of microbial processes and activities, as illustrated by NH₄⁺, NO₂⁻, and NO₃⁻ fluxes into granules under a variety of bulk DO conditions in the presence and absence of flocs (Fig. 1B-D). The addition of 5% floccular material reduced NH₄⁺ flux into granules by half with no impact on overall NH₄⁺ removal, indicating partial conversion of NH₄⁺ to NO₂⁻ in the bulk liquid (Fig. 1B). NO₂⁻ flux to the granules was correspondingly increased (Fig. 1C). Above DO=0.5mg/L, AMO activity is minimal in the presence and absence of flocs, and all NH₄⁺ is converted to NO₃⁻ (Fig. 1D). These patterns in NH₄⁺, NO₂⁻, and NO₃⁻ fluxes into granules indicate that even small levels of flocs can lead to significant task segregation between biomass fractions, with AOO activity concentrated in floccular material and Ax activity concentrated in granular biofilms.

Figure 6. A: Nitrogen removal efficiency at steady state in granular sludge reactors with and without flocs with respect to bulk oxygen concentration. B-D: Ammonia, nitrite and nitrate fluxes into granules in a granular sludge reactor with and without flocs. N surface load: 0.45 gN/m²/d, COD surface load: 0.015 gCOD/m²/d.

Flux patterns were paralleled by segregation in microbial population distributions (Fig. 2). AOO predominate in flocs, resulting in relatively AMO-rich granules. Similarly, OHO populations are concentrated in the floccular fraction under low DO conditions when both biomass fractions are included. In the combined granular and floccular sludge reactor, NOO started to grow at DO=0.25mg/l in the bulk and accounted up to about 30% of the total biomass in the granules at DO=0.3mg/l (Figure 2, right). In the exclusively granular sludge reactor, NOO reached a similar fraction only at DO=0.5mg/l (Figure 2, left). These patterns in population and activity segregation can be explained in part by the lack of diffusive mass transfer limitation in floccular biomass, such that organisms in this fraction were directly exposed to oxygen.

A study focused on organotrophic anammox activity in MBBR and granular sludge combined nitrification-anammox reactors by Winkler *et al.* (2012) offers an initial experimental assessment of such activity and population differences between floccular and biofilm aggregate fractions. Winkler documented substantially higher aerobic activity (AOO, NOO, and heterotrophs) in the floccular compared to biofilm fraction in the MBBR via oxygen uptake rate measurements (the granular sludge biomass was not subjected this analysis), in qualitative agreement with our model. Furthermore, the Winkler *et al.* remarked on the dominance in the floccular fraction of both reactors of AOO via FISH analyses.

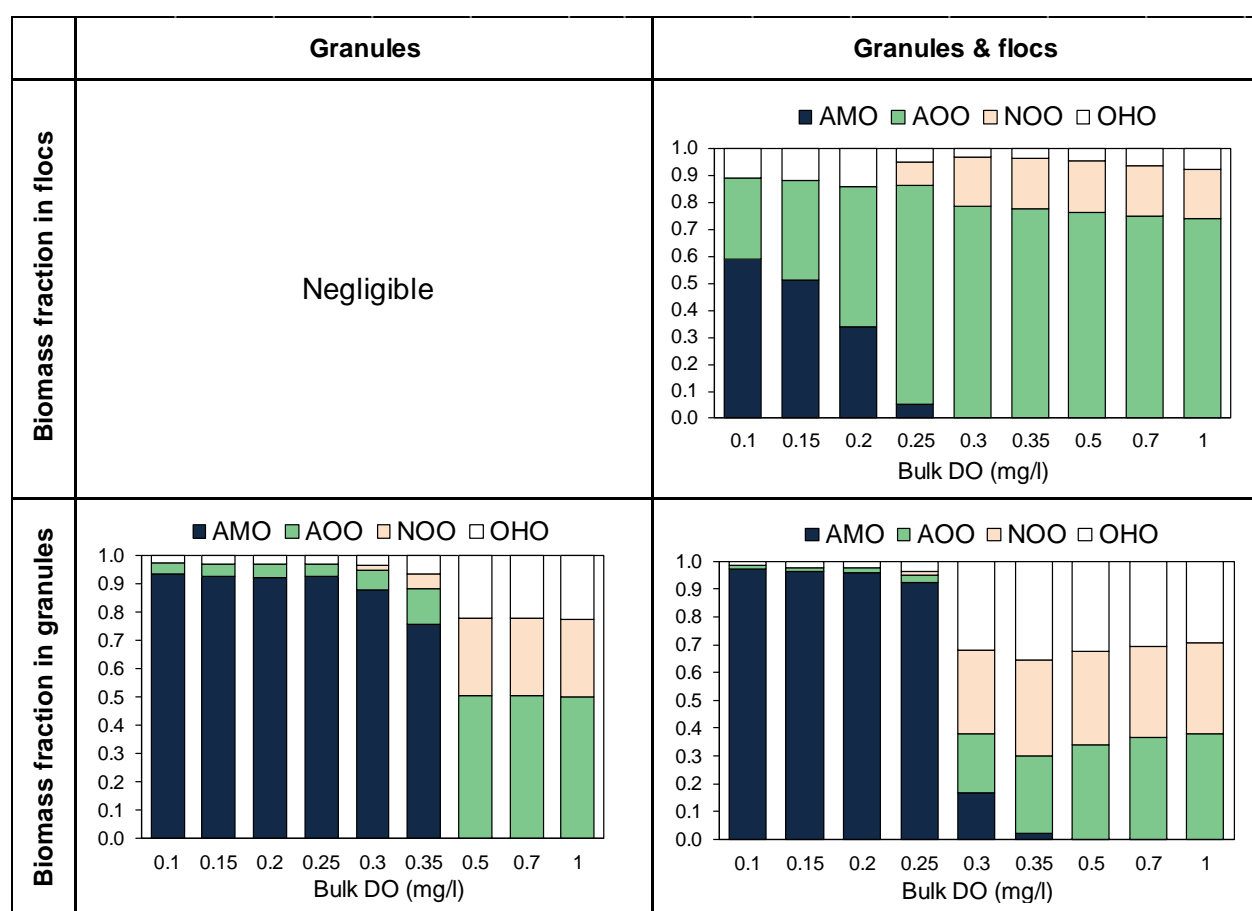

Figure 27. Steady state active biomass partitioning between flocs (5% total biomass, above) and granules (below) in a granular sludge reactor (left) and in a mixed granules-flocs reactor (right) for different bulk oxygen concentrations. N surface load: 0.45 gN/m²/d, COD surface load: 0.015 gCOD/m²/d (COD:N=0.1:3).

Volcke *et al.* (2012) assessed the influence of a non-uniform granule size distribution on granular nitrification-anammox reactor macroscale and microscale characteristics, and concluded that size distribution influences microscale solute transport due to increased relative abundance of AOO in smaller granules and AMO in larger granules. Interestingly, our model indicated a similar segregation of microbial populations and activities due to the inclusion of a second biomass fraction without mass transport limitations (flocs), with AMO concentrated in (uniform size distribution) granules and AOO predominating in floccular biomass.

Taken together, our results indicate that even small levels of floccular biomass in biofilm reactors can have important implications for reactor performance and optimization under certain operating conditions and for segregation of linked microbial processes. This suggests that the

common practice of neglecting small levels of heterogeneity in aggregate structure (e.g. small levels of flocs in granular sludge reactors) in biofilm models may lead to erroneous patterns or results at the microscale, and also for macroscale performance in some cases.

Case study 2: Modeling microbial competition in biofilm reactors: considering multiple taxa in a single functional group

Using the two-step nitrification biofilm model implementing the growth and endogenous respiration of 10 AOO and 10 NOO species, it was observed that the macroscopic reactor behavior, in terms of nitrifying performance, was already at steady state within 10 days after start-up (Fig. 3A). At first, nitrite accumulated to a maximum concentration of $185 \text{ g NO}_2^- \cdot \text{N} \cdot \text{m}^{-3}$ on day 1, but was completely converted after four days. At steady state, ammonium was almost completely converted to nitrate, resulting in a nitrate effluent concentration of $241 \text{ g NO}_3^- \cdot \text{N} \cdot \text{m}^{-3}$.

Figure 3. Bulk liquid concentration of nitrogen components (A) and the biofilm thickness (B) in function of time. Mind the different scale and units (days versus years) of the x-axis in both figures.

In contrast to the macroscopic reactor behavior, the steady state biofilm thickness of 1 mm was only reached after about 2.5 years (Fig. 3B), indicating that constant reactor performance not necessarily implies that the steady state biofilm thickness is already reached. The biofilm thickness increased linearly due to the formation of active biomass by microbial growth and the formation of inert particulate components by endogenous respiration. Inert particulate components made up more than 90% of the total particulate mass in the biofilm at steady state.

The steady state conditions of the microbial community were only reached after about 12 years (Table 2). A major microbial community shift was even observed after 5 years of operation. Initially, all AOO species made up 7.5% and all NOO species 2.5% of the total particulate matter mass (100 g COD) in the biofilm. Due to microbial competition, the initial fraction of each species evolved in time to its steady state value. In the AOO community, species AOO1 became dominant. In the NOO community, NOO6 remained dominant for about 7 years. However, after 5 years, species NOO2, which was virtually absent in the biofilm for 3 years, reappeared in the biofilm. This species became dominant after 8 years and remained the dominant NOO species at steady state. At steady state, 3 dominant species coexisted in the biofilm: AOO1, NOO6 and NOO2. All the others species could be considered absent and not contributing to the microbial conversions. However, it is assumed that when the operation conditions change, these species could re-emerge when the new conditions are favorable for them, as their concentrations were negligible, but nonzero.

Table 3. Evolution of the percentage of the total particulate matter (100 g COD) made up by each species in the biofilm through time. Percentages of individual AOO and NOO species are visualized by color codes from 0% (white) to 25% (black).

The steady state substrate gradients are displayed in Fig. 4. In this study, ammonium and nitrite were especially limiting, as the concentrations prevailing in the biofilm of these substrates were much lower than the affinity constants considered. Indeed, species with a rather high affinity for ammonium (AOO1) and nitrite (NOO2 and NOO6) were selected.

From the biomass concentration profile (Fig. 4D), it is observed that at steady state, NOO6 remained present in a small concentration at the surface of the biofilm while NOO2 had the highest concentration 83 μm below the surface of the biofilm. The coexistence of two genetically and morphologically different populations of NOO with different distribution patterns in a biofilm was already observed experimentally by Schramm *et al.* (1998). When coexistence of species performing the same function is observed, a distinction is typically made between slow growing species with a high substrate affinity (K-strategists) and fast growing species with a low substrate affinity (r-strategists). The r- and K-selection strategy (Andrews & Harris 1986) was already used previously to explain experimentally observed population shifts and microbial coexistence in nitrifying biofilms (Schramm *et al.* 2000; Volcke *et al.* 2008; Terada *et al.* 2010; Almstrand *et al.*

2013). In the NOO community considered in this study, NOO6 was an r-strategist with a relatively high growth rate (high μ_{\max}^{NOO6}) and NOO2 was a K-strategist with a relatively high affinity for nitrite (low $K_{\text{NO2}}^{\text{NOO2}}$). The r-strategist NOO6 was able to survive close to the surface due to the higher substrate concentrations prevailing there, in combination with its high maximum growth rate. As a K-strategist, NOO2 was able to cope with the limiting substrate concentrations deeper in the biofilm. Considering the evolution of the NOO community in time, it was observed that the r-strategist NOO6 was able to cope rapidly with the prevailing conditions and grew at a high rate due to its relatively high maximum growth rate. After 8 years, the slow growing K-strategist NOO2 became dominant over NOO6 due to its higher affinity for nitrite. It can thus be concluded that the r- and K-selection strategy not only can be used here to explain the steady state microbial distribution profile but also the development of the microbial community composition over time.

Figure 4. Steady state concentration profiles for ammonium (A), nitrite (B), oxygen (C) and particulate matter (D) in function of the position of the biofilm (0 μm = bottom, 1000 μm = surface of the biofilm). Mind the different scale of the y-axis of the substrate concentration profiles.

By using a multispecies nitrification biofilm model, the individual role of various microbial characteristics on the microbial population dynamics was demonstrated. The coexistence of several species of the same type, in this case several types of nitrite-oxidizers, may be explained based on their difference in maximum growth rate and affinity for the limiting substrate. It was shown that the biomass distribution profiles at steady state of the coexisting NOO reflected the ecological niches created by the substrate gradients. Furthermore, it was concluded that constant macroscopic reactor performance not necessary reflects steady state conditions on the microscale. Significantly more time is needed for the biofilm and the microbial community to reach steady state compared to the macroscopic reactor behavior.

CONCLUSIONS & OUTLOOK

We highlight above two instances in which additional model complexity is included beyond the conventional formulation for numerical 1-dimensional biofilm models. In Case study 1, our model suggests that even low levels of flocs can have a significant impact on process performance, optimal operating ranges, and microbial population and activity distributions in combined nitrification-anammox granular sludge reactors. The implication is that a better characterization of size distribution, mass transfer properties, and microbial population segregation of microbial aggregates – including flocs and granules- could improve operation of these reactors and contribute to better understanding of unexpected reactor behaviors. In Case study 2, it was shown that multispecies models are a useful tool to investigate the individual influence of various microbial characteristics on microbial population dynamics, and that coexistence of several species performing the same function is linked to the ecological niches created by the substrate concentration gradients in the biofilm. Nitrifying biofilm models including the growth of several species performing the same function not only demonstrate that a constant macroscopic reactor

behavior may be hiding major microbial community shifts, but can also be used to investigate major microbial population shifts resulting in a different nitrifying performance (Vannecke *et al.* 2014).

Additional model complexity considered here had a substantial impact on macroscale outputs in some specific conditions, and on microscale outputs (namely, spatial distribution of dissolved and particulate components) under all conditions. It is likely a general rule that increased complexity will be more useful when the focus is on understanding fundamental microscale outputs. When the focus is on macroscale outputs (e.g. substrate removal rates, optimal bulk conditions), this complexity is clearly not always necessary. However, under specific conditions, additional model features can be critically informative for bulk reactor behavior prediction or understanding. Based on the results presented here, we suggest that two instances where additional biofilm model complexity may be warranted are 1) assessment of performance under dynamic process conditions; and 2) characterization of processes with a balance between aerobic and anoxic metabolisms.

Ample future work is warranted to delineate implications of both heterogeneity in mesoscale aggregate structure and of microbial diversity to biofilm models. Regarding the former, evaluating the combined influence of granule size distribution with small levels of floccular material in both granular nitrification-anammox reactors and in other biofilm systems, particularly those that involve cross-feeding between multiple functional groups, is a logical next step. In addition, the model presented here evaluated only two aggregate fractions (flocs and granules), whereas in reality there appears to be a continuum of structures between the two. For example, granules in some systems have been observed embedded in floccular sludge (Innerebner *et al.* 2007), thus potentially increasing locally the connections between a couple of aggregates and leading to more or less active flocs. In addition, Arrojo *et al.* (2006) demonstrated experimentally that aggregate size distribution varied over time when the mixing changed in the reactor. This suggests that the relative abundance of granules and flocs is probably not constant, and that flocs might become granules at some point and vice versa, which supports the presence of different types of flocs in reactors. Future modeling efforts are warranted to test the implicit assumption here that we can safely neglect these additional structural complexities under all relevant conditions when evaluating macroscale outputs, and to assess their influence on microscale microbial distribution and solute exchange.

From the standpoint of microbial diversity, further simulation studies based on multispecies nitrification biofilm models are required to investigate the individual role of various microbial characteristics and operation conditions on microbial competition. In the near term, a worthwhile future goal would be to assess the influence of both multiple taxa within the same functional group and heterogeneity in mesoscale aggregate architecture. In addition, there is increasing interest in explicitly incorporating our rapidly expanding understanding of microbial community structure and dynamics via molecular tools into predictive process models. Seshan *et al.* (2014) present an excellent example of this via a support vector regression model using microbial community diversity indices derived from DNA fingerprinting (T-RFLP) to predict reactor removal performance for COD, ammonia, nitrate, and 3-chloroaniline. Wastewater treatment modelers would also be well served by adapting emerging techniques in this direction in biogeochemical modeling. For example, Reed *et al.* (2014) provide a gene-based framework for incorporating environmental genomics data into a model of nitrogen cycling in the Arabian Sea oxygen minimum zone. A similar approach may be possible in bioprocess modeling to refine our understanding of the role of microbial diversity and community dynamics on both microscale and macroscale outputs in biofilm reactors.

Abstract

Observed (extant) K_s is strongly influenced by diffusion. This paper argues that diffusion can be used to describe bacterial kinetic effects that are sometimes attributed to “K-strategists” and in fact the physics of the system is the dominant mechanism affecting the apparent (extant) K_s ; not biological selection, in real treatment systems. The authors use the “porter-diffusion” model to make their case.

Keywords

K_s , Monod, diffusion, strategists, half-saturation

BACKGROUND

It is commonly held that populations of bacteria can be subdivided into “ μ -strategists” (also termed “r-strategists”) that thrive in conditions of high substrate concentrations, and “K-strategists” that somehow predominate under low substrate conditions. This paper offers the opinion – backed by measurements and plausible theory – that in some cases, observations attributed to different “strategist” populations can, more simply, be attributed to diffusion effects due to a boundary layer thickness and/or substrate concentration levels. In other words, different kinetic rates can be described adequately using the physical phenomenon of diffusion without reverting to the somewhat subjective approach of selecting different kinetic parameters in order to match different observed removal rates for the same biomass types under different substrate conditions.

K_s is a function of Maximum Rate

Over the past several years, several researchers have shown that half-saturation coefficients (K_s) in many biological treatment systems are not constant but in fact are functions of the maximum removal rates. Wilson et al. (2012) showed that the K_s for acetic acid in anaerobic systems was a linear function of the maximum removal rate. Shaw et al. (2013) showed that the extant K_s for nitrate in denitrification is a function of the maximum denitrification rate. Further, they showed that the apparent *extant* K_{NO_3} value can be described by using a diffusion model with a very small intrinsic K_{NO_3} .

Figure 1 shows data from Shaw et al. (2013), Wilson et al. (2012) and data from two other wastewater treatment systems. Despite the systems being very different and for different substrates, all 4 show a strong correlation between K_s and the maximum substrate removal rate.

Figure 1: K_s as a function of r_{max} for 4 different biological systems: (a) nitrate limit for denitrification in an activated sludge system (Shaw 2013); (b) nitrate limit in an MBBR; (c) mesophilic anaerobic digestion (Wilson 2012); (d) DO limit for nitrification in activated sludge. Note, maximum rates shown with respect to biomass growth in cases (a), (b) and (c) but with respect to dissolved oxygen for case (d).

Many researchers have used the concept of “strategists” to explain the apparently different kinetics including substrate affinity under different operating conditions. For example, Wett *et al.* (2011) used the concept of “ μ -strategists” to explain different overall rates and growth kinetics that had to be used in a model to match overall observed performance when adjusting mixed liquor recycle rates (Figure 2).

Figure 2: Graph from Wett *et al.* (2011) showing the Model Fraction of “ μ strategists” Based on Internal Mixed Liquor Recycle

In their discussions of nitrite modelling, Sin *et al* (2010) used higher K_{DO} values for ammonia oxidizing bacteria (AOB) and nitrite oxidizing bacteria (NOB) to model sidestream treatment (non-substrate limited conditions) than the rest of the plant. Other researchers have used the μ vs K strategist concept to explain observed differences between high rate and low rate systems for methylotrophs (e.g. Purtschert and Gujer, 1999) and anaerobic digestion (Wett *et al.*, 2012). Though these systems are for different types of biological treatment, they use the common approach of shifting kinetic parameters – especially K_S – for low substrate conditions from those used for high substrate conditions.

EXPLAINING K_S USING THE PORTER-DIFFUSION CONCEPT

The Monod equation that is used to describe biological kinetics is empirical and does not have a mechanistic basis. It does have the same form as the Michaelis-Menten equation that is used to describe enzyme kinetics and does have a mechanistic basis. Researchers in the field of natural aquatic systems have developed a mechanistic model using a “porter-diffusion” concept that couples enzyme kinetics (Michaelis-Menten) with a diffusion model for a spherical cell. A conceptual sketch of the model, first presented by Pasciak and Gavis (1974) and refined further by several authors (Armstrong, 2008; Aksnes *et al.*, 2011; Fiksen *et al.*, 2013) is shown in Figure 3. Substrate in the bulk liquid (S_∞) passes through a boundary layer where the transport is governed by diffusion until it reaches the cell wall at a concentration S_0 . At this point, a porter enzyme transports the substrate into the cell using Michaelis-Menten kinetics. Figure 3 shows a curve in blue to represent a high bulk liquid concentration of S and a red curve to show a low concentration for S_∞ , demonstrating that, although the overall rate is higher with a higher bulk liquid concentration, diffusion limitations are more pronounced (i.e. greater curvature).

Figure 3: Conceptual sketch of the porter-diffusion model for an individual spherical cell with radius r_0 . The blue line shows the decrease in substrate concentration through the boundary layer by diffusion from an initially high substrate concentration (S_∞) in the bulk liquid, to a lower concentration at the cell surface (S_0). At the surface the substrate is then transferred into the cell (S_i) by a porter enzyme (E). The red line shows a similar transport but for an initially lower substrate concentration (S_∞) in the bulk liquid.

The solution to the porter-diffusion model is a quadratic equation. However, Armstrong (2008), Aksnes et al. (2011) and Fiksen et al. (2013) show that it can also be approximated to a Monod (or Michaelis-Menten) type of equation such as Equation 1 (nomenclature based on Fiksen et al (2013).

Equation 9

$$V = V_{max} \frac{S_{\infty}}{K_0 + V_{max}(4\pi r_0 D)^{-1} + S_{\infty}}$$

Where:

- V is the substrate uptake rate per cell (mols cell⁻¹ s⁻¹)
- V_{max} is the maximum uptake rate per cell (mols cell⁻¹ s⁻¹)
- S_{∞} is the bulk liquid concentration (mols m⁻³)
- K_0 is the Michealis-Menten half-saturation coefficient with S_0 as the reference concentration (mol m⁻³)
- r_0 is the cell radius (m)
- D is the diffusivity of the substrate (m² s⁻¹)

Comparing Equation 1 to the Monod equation, an expression can be given to the extant (observed) half-saturation coefficient, K_S .

Equation 10

$$K_S = K_0 + V_{max}(4\pi r_0 D)^{-1}$$

In this expression, the extant half-saturation coefficient, K_S , is made up of two parts summed. The first part is K_0 which is the Michaelis-Menten half-saturation coefficient, or the *intrinsic* half-saturation coefficient. The second part of the expression incorporates the observed effect of diffusion on the extant K_S and is a function of the maximum substrate removal rate, cell radius and diffusivity. The fact that K_S is proportional to the maximum substrate removal rate, matches the observations of the four wastewater treatment systems shown in Figure 1.

Armstrong (2008) proposed modifications to Equation 2 to include a shape factor, Φ , to account for diffusion to non-spherical cells and a dimensionless Sherwood number, Sh , to account for convective mass transport compared to molecular or diffusive mass transport, resulting in Equation 3 as shown.

Equation 11

$$K_S = K_0 + V_{max}(4\pi r_0 D \Phi Sh)^{-1}$$

Finally, the V_{max} in Equation 3 is expressed as the rate per cell. In order to use rates based on overall cell volume or mass, V_{max} has to be multiplied by the cell volume. Assuming the cell is a sphere with volume $4/3\pi r^3$, equation 3 then becomes Equation 4, where R_{max} is a volumetric rate.

Equation 12

$$K_S = K_0 + R_{max} r_0^2 (3D \Phi Sh)^{-1}$$

Equation 4 was fitted to the data for each of the four different systems shown in Figure 1, and the results are shown in Figure 4. In each case, the “cell radius”, r_0 , was adjusted until the model line gave a reasonable fit to the data; K_0 was assumed to be 0; diffusivity was selected based on substrate; the shape factor was assumed to be 1; Sh was assumed to be 1.0 for cases (a), (b), and (d) but was adjusted for case (c). The final point is discussed further below. Table 1 is a summary of the parameters used for each case.

Figure 4: Porter-diffusion model (dotted) and simple linear regression (solid) for the 4 different biological systems shown in Figure 1: (a) nitrate limit for denitrification in an activated sludge system (Shaw 2013); (b) nitrate limit in an MBBR; (c) mesophilic anaerobic digestion (Wilson 2012); (d) DO limit for nitrification in activated sludge.

TABLE 1: Porter-diffusion model parameters used in Figure 4

System		K_0	ϕ	D	Sh	r_0
		gm^{-3}	-	m^2d^{-1}	-	μm
(a)	Denite AS	0	1	1.47E-04	1.0	400
(b)	Denite MBBR	0	1	1.47E-04	1.0	600
(c)	MAD	0	1	8.64E-05	0.001	1000
(d)	Nitrification	0	1	1.73E-04	1.0	250

The following observations are made from Figure 4 and Table 1:

1. The porter-diffusion model was developed for individual cells, whereas the systems shown in Figure 4 contain most of the biomass within flocs or biofilms. However the logic applied to developing the cellular model can be extended to a larger grouping of cells within a floc or biofilm, with r_0 a representative diffusive distance to give the equivalent effect.
2. In cases (a), (b), and (d) it was possible to select a value for r_0 that is within the realms of a plausible dimension for an equivalent floc size or biofilm thickness. No other parameters had to be adjusted.
3. In case (c), r_0 was adjusted up to a maximum of 1000 μ m but the model line did not match the data by several orders of magnitude. Sh was then adjusted to match the data better. A lower Sh may indicate that diffusion is severely restricted in this system.
4. In all systems, the linear line fit did not have a positive intercept on the Y-axis which would be necessary to provide an estimate for K_0 . The inference from this is that K_0 is insignificant (near zero) in comparison to mass transfer effects for these particular systems.

In the derivation of Equation 1, Fiksen et al. (2013) show that $V_{max} = nh^{-1}$, where n is the number of porter sites and h is the handling time for each site. All of the systems analyzed in this paper have a relatively high concentration of biomass or low food to microorganism ratio (F/M) and hence the number of porter sites is not limiting. This may explain why K_0 (porter effect) is not significant for these systems, but diffusion dominates the formulation of K_S .

Significance of the Porter-Diffusion Model

In Equation 4, K_S is proportional to r^2 , D^{-1} and Sh^{-1} . On first glance, K_S being proportional to Sh^{-1} seems logical because when diffusion controls (over convection), K_S will be larger (low affinity). Strictly speaking, however, the modification proposed by Armstrong (2008) relating K_S to Sh is valid only for single cells, and may not hold for flocs because there is little or no convection inside the flocs. This is similar to pore diffusion in carbon adsorption where advection is zero. Assuming that convection is zero inside the flocs, then diffusion always controls. K_S is proportional to D^{-1} and therefore at high diffusivity, K_S is low and vice versa. When r_0 (indicative of diffusion distance) is small, the inter-cell tubes are smaller both in diameter and length reducing the impact of diffusion.

In practical terms, Equation 4 can be used to give a reasonable first estimate of K_S depending on the overall maximum rate (R_{max} , measured or modelled), floc size (r_0 , measured or used as a calibration parameter), and diffusivity (D = physical constant, dependent on substrate and temperature). If this estimate does not match observations, Φ (shape factor) and/or Sh can be used as adjustment factors to provide a better fit. This equation can be coupled with the approach outlined in Shaw et al. (2013) to provide an estimate for K_S that can be incorporated into a process simulator to provide a better model fit for a wider range of substrate concentrations than the typical current approach of assuming a fixed K_S .

A final observation from fitting data to the porter-diffusion model is that K_0 was near zero for all of the modelled systems in Figure 4. It is posited that this is due to the systems all having a relatively low F/M and hence an abundance of porter sites. It is plausible that high F/M systems would exhibit a greater influence from the lower number of porters and hence K_0 would be higher for these systems. A practical consequence of this is that K_S should not be estimated from high F/M tests and then applied to low F/M systems. Ideally, K_S should be estimated using tests carried out at a similar F/M to that of the modelled or real-world system.

A NEW PARADIGM

As noted in the paper by Shaw *et al.* (2013) and as explained by the porter-diffusion model discussed in this paper, at low substrate concentrations diffusion becomes more important and can be used to explain the reduction in observed kinetic rates, rather than adjusting kinetic parameters to fit data. This reduction in rate will cause a shift in biomass populations that appear to be due to “K-strategists” but in fact may be caused by diffusion and other physical effects. Another way to view this is that the apparent “K-strategists” gain their advantage by somehow exploiting an ability to overcome diffusion limitations, such as growing in filamentous form outside of the floc which shortens diffusion distances.

Figure 5 shows a comparison of processes types and the importance of diffusion effects versus maximum rates. For systems operating at or near maximum rates the impact of K_S is not significant and diffusion is not important. However, for treatment processes where substrate concentrations are low it is important to consider shifting to variable extant K_S values or explicitly modelling the effects of diffusion. Additionally it is important to consider diffusion effects or variable extant K_S for systems where biomass is moved from high rate to low rate systems such as the case when waste activated sludge from a high-rate, sidestream treatment facility is used to bioaugment a mainstream system (e.g. Wett, 2011).

Variable K_S is an important consideration wherever low substrate concentrations are important such as facilities with low effluent limits, systems with competing organisms (e.g. anammox vs NOBs in deammonification, Stinson *et al.* 2013) or models dependent on transitional species (e.g. NO_2 for models of N_2O emissions, Guo *et al.* 2012).

Abstract

The accumulation of the denitrification intermediates in wastewater treatment can be highly undesirable, since both nitrite and NO are known to be toxic to bacteria, and N₂O is a potent greenhouse gas and an ozone depleting substance. The four steps in denitrification could exert influence on each other through electron competition, leading to denitrification intermediates accumulation. To date, two distinct concepts for the modelling of the four-step denitrification process have been proposed, with one of them adopting the “directly coupling” and the other adopting the “indirectly coupling” approach in linking the carbon oxidation and nitrogen oxides reduction processes. In this study, these two models are examined and compared based on their ability to describe the experimental denitrification dynamics reported in literature. The modelling results show that the “indirectly coupling approach” could predict all the data from the three cases studied, while the “directly coupling approach” was able to reproduce two of the three datasets. The results suggest that separating the kinetics of carbon oxidation from the nitrogen oxides reduction is advantageous in modelling the electron competition in denitrification.

Keywords

denitrification; modelling; electron competition; nitrous oxide; nitrate; nitrite

INTRODUCTION

Denitrification is an important part of the global nitrogen cycle. Nitrate reduction consists of four consecutive reduction steps, with nitrite (NO₂⁻), nitric oxide (NO) and nitrous oxide (N₂O) as three obligatory intermediates (Zumft 1997). Each reduction step is catalysed by one or more specific reductase enzymes, namely nitrate reductase (Nar), nitrite reductase (Nir), NO reductase (Nor) and N₂O reductase (Nos). In the wastewater treatment process, denitrification is a key process to remove the nitrogen pollutants from wastewater. Tremendous efforts have been made to optimise the performance of this process, including avoiding the accumulation of reaction intermediates.

The accumulation of the denitrification intermediates can be highly undesirable. For example, nitrite and NO are known to be toxic to bacteria (Schulthess R. V. 1995, Tan *et al.* 2008), while N₂O is a potent greenhouse gas with a 300-fold stronger radiative force than carbon dioxide, and is also a primary ozone depleting substance in the 21 century (IPCC 2007, Ravishankara *et al.* 2009). Previous work clearly demonstrated that the four denitrification steps could exert influence on each other through electron competition, leading to denitrification intermediates accumulation (Pan *et al.* 2013a, Schalk-Otte *et al.* 2000). The fundamental cell physiology responsible for the electron competition phenomenon is that all denitrifying enzymes require electrons from a common source, the ubiquinol pool of the respiratory electron transport chain (Richardson *et al.* 2009).

Mathematical modelling has been widely applied to predict nitrogen removal during wastewater treatment (Henze *et al.* 2000). Previous modelling efforts have primarily focussed on the prediction of the removal of nitrate, and in some case nitrite as well. However, it is increasingly recognised that NO and N₂O accumulation should also be modelled, especially due to their potent and vicious influence on atmosphere. This can be achieved through modelling denitrification as a four-step process that use nitrate, nitrite, nitric oxide, and nitrous oxide, respectively, as the terminal electron acceptor (Hiatt and Grady 2008, Schulthess and Gujer 1996, Vonschulthess *et al.* 1994). With each step being modelled with individual, reaction-specific kinetics, the accumulation of nitrite, NO and N₂O can be, theoretically, predicted.

To date, two distinct concepts have been proposed in the development of multi-step denitrification models, with their structure schemes shown in Figure 1.

Model A: the “direct coupling approach” (Hiatt and Grady 2008), with which the carbon oxidation and nitrogen reduction processes are directly coupled in the model. This type of model describes each of the four steps as a separate and independent oxidation-reduction reaction (Figure 1a), with the kinetics of each step modelled according to the reduction reaction kinetics.

Model B: the “indirect coupling approach” (Pan *et al.* 2013b), with which the carbon oxidation and nitrogen reduction processes are indirectly coupled. Electron carriers are introduced as a new component in this model to link carbon oxidation to nitrogen oxides reduction (Figure 1b). In this way, the reactions can be regulated by both the reduction and the oxidation processes.

Figure 1. Simplified reaction schemes used in the two 4-step denitrification models evaluated in this study: *Model A* - Using the “direct coupling approach” to model the carbon oxidation and nitrogen reduction processes during denitrification; *Model B* - Using the “indirect coupling approach” to model the carbon oxidation and nitrogen reduction processes during denitrification.

It is of importance to know the prediction ability of these two different types of models, by conducting parallel comparison with existing data reported for different cultures and under different conditions. However, such comparison has not been done to date. Therefore, the aim of this work is to reveal how the structures of the two models presented in Figure 1 would affect their ability to reproduce experimental data reported in literature. Three distinctive denitrifying cultures were used

in this examination, which included one pure culture (*Paracoccus denitrijkans* (N.C.1.B. 8944)) and two mixed denitrifying cultures fed with acetate and methanol, respectively. In particular, their ability in predicting electron competition during denitrification is assessed. The findings are expected to provide guidance to both future experimental studies and modelling practice aimed to get better understanding of denitrification.

MATERIALS AND METHODS

Mathematical models for denitrification

The kinetic and stoichiometric matrices describing the nitrogen reduction and the carbon oxidation processes for the two mathematical models are presented in Table 1. Nomenclature for all state variables used slightly differs from the original publications. We employ the following symbols for concentration: heterotrophic biomass (X), nitrate (S_{NO_3}), nitrite (S_{NO_2}), nitric oxide (S_{NO}), nitrous oxide (S_{N_2O}), readily biodegradable carbon source (S_s), reduced form of electron carriers (S_{Mred}), oxidized form of electron carriers (S_{Mox}). Other processes involved in denitrification, such as death and lysis of heterotrophs, hydrolysis of particulate organic nitrogen are included in both models with standard ASM kinetic expressions and parameter values taken from published literature (Hiatt and Grady 2008, Ni *et al.* 2011, Schulthess and Gujer 1996). Table 2 listed the definitions, values and units of the parameters used in the two models.

As show in Table 1, in Model A, the reduction of a nitrogen oxide compound (e.g. nitrate) and the oxidation of organic carbon are “directly coupled” in a single oxidation-reduction reaction with a stoichiometric relationship obtained through electron balance. However, in Model B, the carbon oxidation process (R_1) is decoupled from the nitrogen reduction processes (R_2 to R_5). Electron carriers (S_{Mred} and S_{Mox}) are introduced as a new component in this model to link carbon oxidation and nitrogen oxides reduction.

Testing the predictive abilities of the models

Experimental data from three cases (KuČEra *et al.* 1983, McMurray 2008, Pan *et al.* 2012) concerning denitrification dynamics were used for testing the predictive abilities of the two mathematical models.

Case 1: The nitrogen conversion dynamics by a pure denitrifying culture of *Paracoccus denitrijkans* (N.C.1.B. 8944) were measured in two batch tests by KuČEra *et al.* (1983). In the first batch test, nitrate was added to a concentration of 14 mg N/L at the beginning of the tests, followed by nitrite addition to around 5 mg N/L at 0.5 hour. In the second batch test, the nitrate reduction rate was measured under the following condition: 1) with only NO_3^- being present; 2) with NO_2^- being present simultaneously with NO_3^- ; 3) with N_2O being present with NO_3^- ; 4) with NO_2^- & N_2O & antimycin (an inhibitor for nitrite and N_2O reduction) being present with NO_3^- . Glucose was used as the carbon source and was in excess throughout all the tests. They found that the extent of electron flow to nitrate depends on the activity of electron flows to nitrite and N_2O . By quantitatively evaluating the extent of electron flows, they revealed that the nitrate, nitrite and N_2O reductases competed for a constant limited flow of redox equivalents supplied from dehydrogenases, although the external carbon source (glucose) was in excess.

Case 2: McMurray (2008) investigated denitrification dynamics by a full-scale activated sludge fed with acetate. In a batch test, nitrate, nitrite were added at the beginning of the test, to initial

concentrations around 5.2 mg N/L, 8.9 mg N/L, respectively. Acetate was also added at the same time, and was present in excess during the entire experiment. The conversion of nitrate, nitrite and acetate was monitored throughout the test, along with the production rate of nitrogen gas (N₂).

Case 3: By studying a enriched denitrifying culture fed with methanol, Pan *et al.* (2013a) carried out extensive investigations to study electron competition during denitrification. Four batch tests were chosen in this paper to evaluate the two types of models, which include 1) nitrate being added as the sole externally-supplied electron acceptor; 2) nitrite being added as the sole externally-supplied electron acceptor; 3) N₂O being added as the sole externally-supplied electron acceptor; 4) nitrate, nitrite and N₂O being added simultaneously. The initial concentration of the nitrogen compounds were between 30 and 50 mg N/L. Methanol was in excess in all these four tests, with its initial concentration at approximately 300 mg N/L.

Parameter estimation were performed with AQUASIM for aquatic systems (Reichert *et al.* 1995). Not all the parameters were identifiable from the experimental data; however, some of the parameters have been extensively studied and well established in previous studies (Hiatt and Grady 2008, Pan *et al.* 2013b). Therefore, literature values were adopted for these parameters (see Table 2). Only parameters specific for each model ($\eta_{g1}, \eta_{g2}, \eta_{g4}$ for Model A and $r_{COD,max}, K_{Mred,1}, K_{Mred,2}$ and $K_{Mred,4}$ for Model B) were calibrated in this modelling practice, with their values presented in Table 2 as well.

RESULTS

Evaluation of the Mathematical Models: Case 1

In the first case, the two denitrification models in Figure 1 were evaluated based on their ability to capture the nitrogen conversion by a pure culture of *Paracoccus denitrificans* (N.C.1.B. 8944), reported in Kučera *et al.* (1983). The influence of nitrite and N₂O on nitrate reduction was extensively investigated in this study. The experimental data along with the model predictions are presented in Figure 2.

In the first batch test, after nitrite was added externally at 0.5 hour, the nitrate reduction rate was significantly lowered (Figure 2 (a) & (b), phases 1 & 2). However, when nitrite depleted, the activity of nitrate reductase recovered to its original level (Figure 2 (a) & (b), phase 3). Model B was able to reproduce both the nitrate and nitrite profiles (Figure 2b). In contrast, Model A failed to predict the dynamic nitrate profile although the nitrite profile was correctly reproduced (Figure 2a).

The results from the second batch are shown in Figure 2c and 2d. With the initial nitrate reduction rate, measured with nitrate as the sole externally-supplied electron acceptor, being accounted as 100%, the nitrate reduction rate reduced to 32% after the nitrite addition. The value lowered even further to 6% after the addition of N₂O. However, when N₂O, nitrite and antimycin (a chemical which inhibits nitrite and N₂O reduction) were added together, the nitrate reduction rate increased to 233%. Model A completely failed to predict the experimentally observed variations in the nitrate reduction rate after the addition of nitrite, N₂O and antimycin (Figure 2c). The results clearly indicate that Model A is not able to reflect the influence of nitrite and N₂O on nitrate reduction. On the contrary, as shown in Figure 2d, Model B successfully captured the influence of nitrite, N₂O and antimycin on nitrate reduction, with 38% of nitrate reduction activity left after nitrite addition (in comparison to the 32% experimentally observed), 7% left after N₂O addition (in comparison the experimental data of 6%). With the inhibition of nitrite and N₂O reduction using antimycin, the

model also correctly predicted the substantial increase (240% vs. the experimentally observed 233%) in the nitrate reduction rate (Figure 2d).

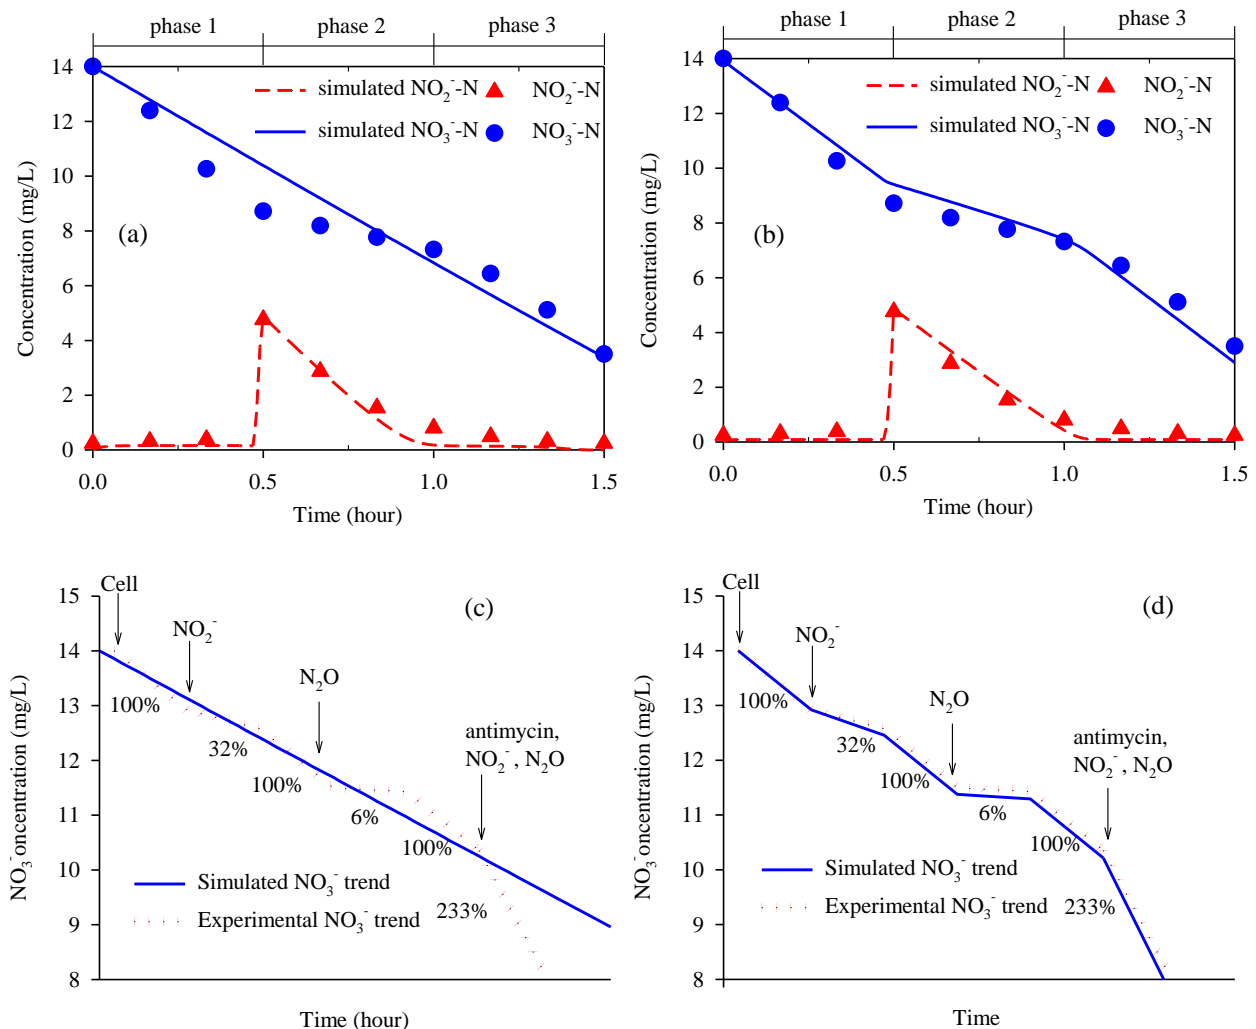

Figure 2: Experimental results and model predictions for Case 1 (KuČera *et al.* 1983). (a) & (c) – Evaluation of Model A; (b) & (d) – Evaluation of Model B.

Evaluation of the Mathematical Models: Case 2

In the second case, the denitrification dynamics by a full-scale activated sludge fed with acetate was studied by McMurray (2008). The experimental data along with the model predictions are presented in Figure 3. While not shown in the figure, no N_2O accumulation was observed during the entire experiment. Both models predicted negligible N_2O .

Figure 3: Experimental results and model predictions in Case 2 (McMurray 2008): (a1), (b1) & (c1) - Evaluation of Model A; (a2), (b2) & (c2) - Evaluation of Model B

Nitrite accumulated during nitrate reduction, and declined after the depletion of nitrate (Figure 3 (a1) & (a2)). COD was consumed during nitrate and nitrite reduction (Figure 3 (b1) & (b2)). The N_2 production was around 22 mg N/hour when both nitrate and nitrite were present, and increased to around 28 mg N/hour when only nitrite was present.

Model A roughly captured the trend of nitrate and nitrite reduction (Figure 3 (a1)), and the trend of acetate (Figure 3 (b1)). However, the fit between the model predictions and experimental data was relatively poor. The consequence of the poor fit can be clearly seen from the incorrect prediction of the N_2 production rate (Figure 3 (c1)). In comparison, Model B successfully reproduced all the data observed including the N_2 data (Figure (a2), (b2) & (c2)).

Evaluation of the Mathematical Models: Case 3

In the third case, the two denitrification models in Figure 1 were evaluated based on their ability to capture the nitrogen conversions by an enriched denitrifying culture fed with methanol as the carbon source (Pan *et al.* 2013a). The experimental data points along with the model predictions are presented in Figure 4.

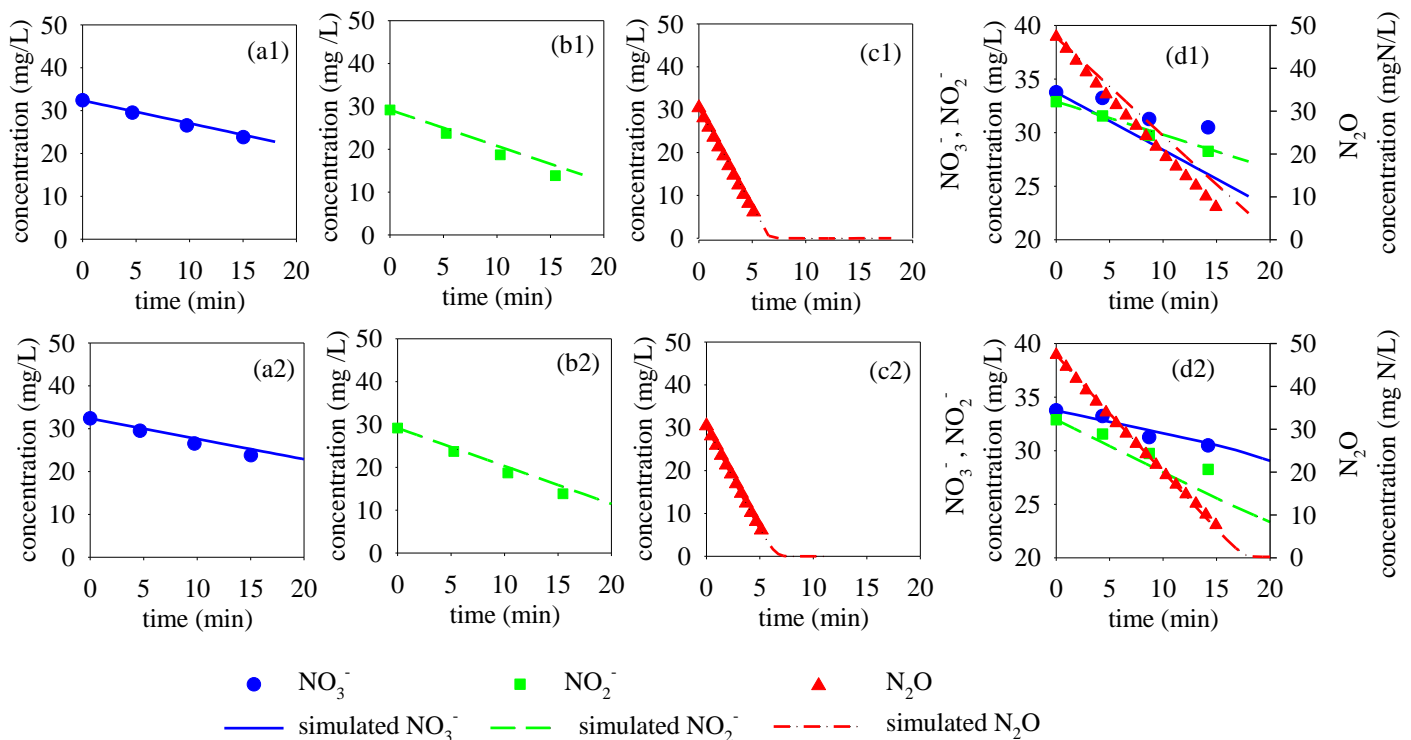

Figure 4: Experimental results and model predictions Case 3(Pan *et al.* 2013a): (a1) & (b1) & (c1) & (d1) - Evaluation of Model A; (a2) & (b2) & (c2) & (d2) - Evaluation of Model B

In the tests when only one nitrogen oxide specie was added (Figure 4 (a1) to (c1) and (a2) to (c2)), the nitrate, nitrite and N_2O reduction rate was 45, 74 and 370 mg N/(gVSS \times h), respectively. However, when nitrate, nitrite and N_2O were added simultaneously, the reduction rate of all the nitrogen oxides decreased, valued at 19, 39 and 256 mg N/(gVSS \times h), respectively (Figure 4 (d1) and (d2)).

Generally, both Model A and Model B were able reproduce the nitrate, nitrite and N_2O profiles in Figure 4 (a1) to (c1) and Figure 4 (a2) to (c2). However, Model A failed to reproduce the experimental results in Figure (d1). The predicted nitrate reduction rate is significantly higher than the predicted nitrite reduction rate, which is opposite to the experimental observation. In addition, the predicted N_2O reduction rate is significantly lower than the experimentally observed N_2O reduction rate. In comparison, Model B reproduced all experimental data reasonably well despite a slight mismatch between the model-predicted and experimentally observed nitrite data (Figure 4 (d2)).

DISCUSSION

In this work, the two types of 4-step denitrification models were evaluated for their ability to predict denitrification dynamics in three cases. One common feature for all three cases is that interactions between the reduction of two or three nitrogen compounds during denitrification were observed (i.e. nitrate & nitrite & N_2O in Case 1 and Case 3; nitrate & nitrite in Case 2). Model B was able to describe the experimental data in all the three cases, while Model A failed to reproduce the experimental data in any of the three cases.

The question arising herein is why the two models performed differently. The answer to this question lies in their consideration of the electron competition process during denitrification. All

the denitrifying enzymes derive their electrons from a common electron supply source, the ubiquinol pool of the respiratory electron transport chain (Richardson *et al.* 2009). The electron competition among the nitrogen reduction steps could happen if the electron supply rate becoming the rate limiting process during denitrification, leading to dynamic changes in the electron allocation and hence the nitrogen conversions. A closer examination of the experiment results of the three cases studied reveals that the electron competition process played a key role in determining the denitrification dynamics in all the cases studied. Below, we will comment on Case 1 in detail to illustrate the differences between the two models. Case 2 and Case 3 will be briefly discussed, further highlighting the key features of the two models.

For Case 1, electron supply was the rate limiting process in all the batch tests. This is evident from the fact the nitrate reduction rate increased by around 233% when both nitrite and N₂O reduction was inhibited by antimycin (Figure 2d). Herein, the experimental results revealed that nitrate reductase did not achieve its maximum turnover rate even when only nitrate was added, due to the fact that the reduction of the continuously produced downstream denitrification intermediates (nitrite, NO, N₂O) were deriving their electrons from the same electron source. Similarly, the reason for the decline of the nitrate reduction rate with nitrite or N₂O addition (Figure 2d) was due to the electron competition between the different denitrification steps. In Model B, by modeling the carbon oxidation process (II-R₁) and the nitrogen reduction processes (II-R₂ to II-R₅) separately, the model was able to predict both the electron supply rate and the electron consumption rate. The electron supply rate was reflected by II-R₁, while the electron consumption rate was reflected by II-R₂ to II-R₅. The relative ability of each denitrification step to compete for electrons was reflected by the calibration of $k_{Mred,1}$, $k_{Mred,2}$, $k_{Mred,3}$, $k_{Mred,4}$ in Model B. Therefore, the model predicts that the electron flow to nitrate reduction (II-R₂) was affected by the electron flows to nitrite (II-R₃) and N₂O (II-R₅). When nitrite reduction (II-R₃) and N₂O reduction (II-R₅) were stopped, nitrate reduction (II-R₂) received more electrons and thus a higher reduction rate was achieved. When external nitrite or nitrous oxide were added, the overall rate of nitrite reduction (II-R₃) or N₂O reduction (II-R₅) increased due to higher substrate concentrations, leading to a smaller electron flow to nitrate reduction (II-R₂). In comparison, in Model A, the carbon oxidation process is not modeled independently, but directly lumped into the four nitrogen reduction steps (I-R₁ to I-R₄). Therefore, the structure of Model A is intrinsically unable to distinguish the electron flow regulation between the carbon oxidation and the four-step nitrogen reduction processes. Thus, a constant nitrate reduction rate was predicted by Model A when all the tests were used to calibrate the relevant parameters. This constant nitrate reduction rate is essentially a compromise of the model to simulate the nitrate dynamics observed in all the tests in Case 1. One possible argument might be that by adding an inhibition terms to describe nitrite and N₂O inhibition on nitrate reduction (e.g. $(\frac{K_{NO2}}{K_{NO2} + S_{NO2}})(\frac{K_{N2O}}{K_{N2O} + S_{N2O}})$ in I-R₁, with K_{NO2} and K_{N2O} defined as nitrite inhibition and N₂O inhibition coefficient on nitrate reduction), Model A may be able to predict the nitrate reduction dynamics presented in Figure 2. This is proven to be infeasible. Even such terms are added, the 233% nitrate reduction rate achieved after the addition of antimycin & nitrite & N₂O would still not be predicted.

For Case 2, the nitrogen production rate, which essentially reflected the turnover rate of the nitrite reductase since there was no accumulation of NO or N₂O, increased after nitrate depletion (Figure 3 (c1), (c2)). This phenomenon indicates that there was electron competition between nitrate reduction and nitrite reduction when both of them were present. The competition was relaxed after the depletion of nitrate, resulting in a higher nitrite reduction rate (nitrogen production rate). Again, Model B captured the two distinctive nitrite reduction rates through regulating the electron flow to

II-R₂ to II-R₅. Model A failed to do so since the nitrite reduction rate was determined by I-R₂, and the depletion of nitrate could not exert any influence to the nitrite reduction rate predicted by I-R₂.

For Case 3, the decline of the reduction rates of nitrate, nitrite and N₂O when all of them were added was due to electron competition (Figure 4 (d1) & (d2)). Model B captured this trend through calibrating the relatively ability of the three steps to compete for electrons, reflected by $k_{Mred,1}$, $k_{Mred,2}$, $k_{Mred,4}$. The prediction by Model A accelerated the nitrate reduction rate (I-R₁) and reduced the N₂O reduction rate to give its best fit of all the batches. It is worth to note that, unlike Case 1 in which the carbon oxidation process was rate limiting in all the cases, nitrate or nitrite reduction in Case 3 was rate limiting by the turnover rate of nitrate reductase or nitrite reductase rather than by the electron supply rate (Pan *et al.* 2013a) (Figure 4 (a1) & (a2), (b1) & (b2)). Thus, the electron competition process did not play a key role in determining the denitrification dynamics when only nitrate or nitrite was present.

To date, the presence of denitrification intermediates during wastewater treatment has been widely reported. The ability of models to predict electron competition during the denitrification process enables the model to predict denitrification intermediates. It has been revealed by this work that Model B could give satisfactory prediction of the dynamics of the intermediates during denitrification. Further investigation should be made by upgrading the current ASM models widely used by wastewater treatment plants by incorporating the concept of the “*indirect coupling approach*”.

CONCLUSIONS

In this work, two distinct mathematical model structures were compared for their ability to predict nitrogen conversion dynamics in one pure culture and two mixed culture studies. It was demonstrated that the model based on the indirect coupling of the carbon oxidation and nitrogen oxides reduction processes was able to describe the experimental data in all three cases studied, while the ASM model, directly couples the carbon oxidation and nitrogen oxides reduction processes, failed to describe the experimental data. The results suggest that the ‘indirect coupling’ approach is advantageous over the ‘direct coupling’ approach in describing the electron competition between the four steps of denitrification and in predicting the accumulation of denitrification intermediates.

ACKNOWLEDGMENT

Abstract

In this study five activated sludge models including N₂O emission were compared to four different long-term process data sets. Different production pathways and kinetics were considered for N₂O production by ammonium oxidising bacteria (AOB). Satisfying calibration could be obtained but none of the models based on a unique pathway of AOB were able to describe all the N₂O data obtained in the different systems with similar parameter set. The dependence of pathways with nitrite (or FNA) concentration is confirmed by this confrontation of models and experiences. These results suggest that efforts should be deployed to create a model in which the two main N₂O pathways active in AOBs are represented together.

Keywords

Calibration, modelling; N₂O, NO, nitrification, denitrification, wastewater treatment

INTRODUCTION

N₂O is a powerful greenhouse gas that can be emitted from wastewater treatment plants (WWTP). The emission varies with the design and operation of a WWTP. Experimental campaigns demonstrated that the fraction of influent nitrogen load emitted as N₂O shows high temporal and spatial variability in a range 0.01 % to more than 10% (Kampschreur *et al.*, 2009; Ahn *et al.*, 2010). Both denitrification and nitrification processes can produce N₂O. However, recent measurement campaigns have conclusively shown that ammonium oxidising bacteria (AOB) in most cases contribute significantly more to N₂O production than heterotrophic denitrification (Daelman *et al.*, 2013; Guo *et al.*, 2013a; Wunderlin *et al.*, 2012), whereas heterotrophic denitrification may be important in removal of the produced N₂O (Guo and Vanrolleghem, 2014a).

In order to evaluate the influence of process configuration and operation on the N₂O emission a significant effort in mathematical modelling has been recently developed. For dynamic modelling of N₂O production, new model components have been proposed to enhance the currently commonly used nitrification and denitrification models to include various reaction intermediates such as nitrous oxide (N₂O), nitric oxide (NO) and hydroxylamine (NH₂OH).

Concerning heterotrophic denitrification N₂O and NO are known to be intermediary compounds. These compounds were included in the ASM_N model proposed by Hiatt and Grady (2008) considering four successive steps in denitrification. The accumulation rate of NO and N₂O depends on the respective ratio between rates of successive steps. More recently Pan *et al.* (2013) also proposed to consider the electron transport and the competition between the different electron acceptors.

The mechanisms responsible for N₂O production by AOB are more controversial. The two widely accepted mechanisms are the AOB denitrification pathway, through which AOB produce N₂O via NO by reducing nitrite (Chandran *et al.*, 2011), and the hydroxylamine-related pathway. In this second mechanism, incomplete oxidation of hydroxylamine could form NO or NOH (nitroxyl radical) as intermediates for N₂O production (Stein, 2011; Law *et al.*, 2012). Several mathematical models have been proposed based on these hypothesised pathways (Ni *et al.*, 2011, Ni *et al.*, 2013a, Ni *et al.*, 2013b; Mampaey *et al.*, 2013). Ni *et al.* (2013a) evaluated four different models by calibrating these models with data reported in literature, obtained in batch experiments with activated sludge samples. As none of the models tested could reproduce all results, Ni *et al.*, 2013a suggested that a regulation between the two main pathways probably occurs, and called for more work to further identify the specific conditions under which each of the models would be applicable, and to also develop a unified model by integrating various pathways. One issue related to model calibration with batch experiments is that the sludge history may impact the physiological state of the sludge, potentially leading to transient behaviour due to metabolic regulation, especially after a sudden change from biomass cultivation conditions to the batch condition. For this reason models confronting to long term operational data measured *in situ* is necessary.

In the last years, measurement campaigns have been performed by many research groups including the authors' groups. The objective of this study is to evaluate the calibration of different models with the collected continuous long-term data from different systems to reveal the performance of these models under various process conditions. This could shed light on the conditions under which each of the models would be suitable, and would also facilitate the development of a unified model by combining different pathways.

METHODS

Experimental data

As detailed in Table 1, four different continuous biological systems were considered in this study: a UCT process (University of Cape Town), an oxidation ditch, two sequencing batch reactors (SBR). Three of them were full-scale processes treating real domestic wastewater, whereas one was a lab-scale pilot treating high strength wastewater. The N₂O concentration in the off-gas was monitored using online continuous Infra-Red spectroscopy for three of these systems (UCT and SBRs). In the oxidation ditch dissolved N₂O was measured in liquid samples using gas chromatography (GC) at different times and in different zones. In addition NO concentration in the off-gas was also collected in the SBR(1) by means of an IR analyser. In the different systems daily average N₂O emission factors varied from 0.12 to 5% (gN-N₂O/gTN removed), the highest emission being obtained with the SBR process working at the highest loading rate (0.267 kgN/m³/d) with the highest nitrite variation (0-50mgN/L). More details concerning each system and measurement campaigns can be found in dedicated articles and communications (Ni *et al.*, 2013b; Guo and Vanrolleghem, 2014b; Pocquet *et al.*, 2013).

Mathematical models

In this study mathematical models based on ASM framework (Hiatt and Grady, 2008) were used with additional modification for considering production of NO and N₂O by AOB. As nitrification was supposed to be the main contributor to N₂O emission and because of the different possible pathways involved in, different AOB models were compared. The reaction stoichiometry and kinetics of five N₂O models related to AOB are summarized in Table 2.

Two models were based on the AOB denitrification pathway: namely the Ni et al. (2011) model which does include NH_2OH as an intermediate in ammonium oxidation (model A), and the Mampaey et al. (2013) model, which does not (model B). Another key difference is the influence of oxygen: model A includes DO inhibition whereas oxygen is a substrate in the model B. The third model was based on the hydroxylamine incomplete oxidation pathway (model C). In this last model NO is considered as an intermediary compound during the oxidation of NH_2OH into nitrite (Ni et al., 2013a, Ni et al., 2013b). N_2O is then produced by reduction of NO with the same reaction as in model A. Note that a modification has been made in model C compared to the initial model of Ni et al. (2013b): as growth was considered in two processes originally, here biomass production was removed from process 3 in order to use the conventional value for the growth yield (Y_{AOB}). Consequently the value of the new maximal rate $\mu_{\text{AOB,HAO},2}$ is here calculated as $\mu_{\text{AOB,HAO},1}/Y_{\text{AOB}}$.

Two modifications of the original AOB denitrification models (A and B) have also been considered (Pocquet et al., 2013; Guo and Vanrolleghem, 2014b) (model A1 and B1). In the model A1 the oxygen inhibition function on AOB reduction pathway was not considered. In addition free ammonia (FA) and free nitrous acid (FNA) were considered as the substrate for AOB reaction rates, in order to consider the effect of variation of pH. In the model B1, oxygen limitation and inhibition was considered as a Haldane function in both the kinetics of NO_2^- reduction and NO reduction (Guo and Vanrolleghem, 2014a, Guo and Vanrolleghem, 2014b). Inhibition by FNA and FA were also considered in models A1 and B.

The gas liquid transfers for oxygen, NO and N_2O were also included. The transfer coefficients (K_{La}) for both NO and N_2O were calculated with measured oxygen transfer coefficient and respective diffusivity ratio (Ye et al., 2014). Simulations were performed using AQUASIM software (Reichert, 1998) and WEST (Vanhooren et al., 2003).

Parameters calibration

Calibration was performed in two different steps considering first the major rates and components (ammonia, nitrate, nitrite) and secondly the N_2O and NO data. Our approach has been to use typical parameter values reported in literature (Hiatt and Grady, 2008) for most of heterotrophic and autotrophic processes whenever possible. Parameter estimation was first realised manually and in a second time, for sensitive parameters, automatic minimisation of the mean square root error was used. The results of the sensitivity analysis on N_2O and NO for parameters involved in the AOB models are presented in the table 3. Parameters influencing ammonium, nitrite, nitrate as well as NO and N_2O were first calibrated during the first step (ex: $\mu_{\text{AOB,AMO}}$, μ_{AOB} , $K_{\text{NH}_4,\text{AOB}}$). Secondly the parameters influencing only and mostly the N_2O emission and NO emission were adapted. In this second phase the reduction factor η_{AOB} as well as affinity constants (ex: $K_{\text{NO}_2,\text{AOB}}$) were focused upon due to their high influence (table 3). The NO emission is also very sensitive to the parameter $K_{\text{NO},\text{AOB}}$ which was estimated with the NO measurements performed on the system SBR(1).

RESULTS

SBR(1)

The models were examined with the data collected from the SBR(1) operated at a high ammonia load (0.25 to 1.10 $\text{kgN/m}^3\cdot\text{d}$) with transient nitrite accumulation. This process was operated during more than six months treating wastewater with high ammonium concentration (500 mgN.L^{-1}). Cycles were composed of five phases: feeding, aerobic period, anoxic period with secondary COD feeding, settling, withdraw. The system was controlled for nitrification over nitrite by controlling the aerobic period time. Very low nitrate

concentrations were observed in the reactor and more than 97% of the ammonia was converted to nitrite during the aerobic period. Different volumetric exchange ratios and various anoxic times were imposed in order to modify the ammonium concentration as well as the nitrite concentration in the reactor. Heterotrophic denitrification was performed during the anoxic period with a suitable COD:N ratio by means of organic influent feeding. N_2O and NO peaks were only observed during the aerobic period whereas no production was observed during the anoxic phase. The models were calibrated on a series of data (5 cycles) and model predictions were also validated with other cycles collected at different times in contrasted conditions. Figure 1 shows examples of simulated and experimental data (NH_4^+ , NO_2^- , DO, NO and N_2O) during the aerobic periods. Oxygen varied from 2 to 6 $\text{mg O}_2 \text{ L}^{-1}$, initial ammonium from 10 to 40 mg N L^{-1} , and final nitrite ranged from 30 to 135 mg N L^{-1} .

For all models the predicted profiles of ammonium, nitrite and DO match the observed experimental trends. The four models based on nitrite denitrification (A, A1, B, B1) also describe the observed N_2O peak well. In contrast, the last model (C) could not predict the variation of N_2O peaks for the different cycles, with high discrepancies at high nitrite concentrations. In those conditions with relatively high DO, simulations indicate that N_2O was mainly related to AOB processes with an insignificant contribution of heterotrophic denitrification.

The order of magnitude of NO peaks was correctly predicted with the four models based on AOB denitrification whereas model C could not predict the NO peaks variations. Based on simultaneous monitoring of N_2O and NO an accurate calibration of the K_{NO} value was possible in this work. However despite this calibration effort model C was unable to predict the experimentally observed change in the NO to N_2O ratio (table A1). Finally, the best predictions for NO and N_2O were observed with model A1, B and B1. This could be explained by a better description of the pH effect on the kinetics through the use of FA and FNA in their formulation. Corrections made on the oxygen effect (inhibition) could also impact the simulation. But in the data used the oxygen concentration was relatively high and the constant for oxygen inhibition was not really identifiable. It should be pointed out that this system has high transient nitrite accumulation and the data indicates a clear correlation between FNA and the N_2O production rate. It was possible to predict this phenomenon with AOB denitrification models but not with the $\text{NH}_2\text{OH}/\text{NO}$ model (model C).

Figure 2 compares the predicted and experimental emission factor (EF) for N_2O and NO for 11 different cycles (calibration and validation). This result confirms that models A1, B and B1 show the best prediction of N_2O and NO emissions, model A also being relatively good. The predictions of NO fluctuations are less accurate than for N_2O but the ratio between both gases is relatively well predicted by the models based on the AOB denitrification pathway (Table 5). Model C based on $\text{NH}_2\text{OH}/\text{NO}$ pathway could not predict the experimental data as it is unable to predict the effect of nitrite accumulation on N_2O and NO production. This leads to an underestimation of N_2O at high FNA concentration whereas NO emission is overestimated.

Oxidation ditch

The AOB denitrification models (Models A and B) and the $\text{NH}_2\text{OH}/\text{NO}$ model (Model C) were examined with the experimentally observed continuous N_2O data from the full-scale oxidation ditch (OD) plant with surface aerators. The OD system receives domestic wastewater at approximately 4 mega liter (ML) per day. The plant consists of primary clarifier and an activated sludge system. After primary sedimentation, wastewater is introduced into the activated sludge unit, which is an oxidation ditch with a working volume of 8750 m^3 . The average hydraulic retention time (HRT) in the oxidation ditch is approximately 48 h. The

mixed liquor from the oxidation ditch flows into a secondary settler. The solids retention time (SRT) is approximately 10 d.

The models were calibrated using the extensive monitoring data from the three-day intensive sampling campaigns at the three different locations (OD4, OD5 and OD2) of the ditch. Figure 3 shows the simulated and experimental data (NH_4^+ , NO_2^- , NO_3^- and N_2O) at the three locations along the ditch. For the three models the predicted profiles of ammonium, nitrite and nitrate match the observed experimental trends. However, the results indicated that Model A could not predict the N_2O data. Indeed, Model A predicted a dependency of N_2O production on DO that is opposite to that observed at the OD plant (Figure 3A-F). The kinetic structure of Model B ensures that the N_2O production rate is dependent on oxygen availability, resulting in a N_2O dynamic trend similar to that shown by the experimental data (Figure 3G-L). In order to reasonably predict the N_2O production rate when nitrite accumulation in the OD system is very low (<0.67 mg-N/L), a relatively high anoxic reduction factor had to be employed due to the fact that the N_2O production rate is dependent on nitrite concentrations in Model B. In contrast, Model C achieved a good fit between the model-predicted and measured N_2O data. It is important to note that the OD system has low nitrite accumulation. The N_2O emissions occurred mainly during aerobic zones (OD4) with high ammonium concentrations but low nitrite accumulation. The NH_2OH pathway of Model C captures all these trends.

SBR(2)

Models A, B and C were also evaluated with the experimentally observed continuous cycling N_2O data from the full-scale SBR plant (SBR2). The average daily flow of the plant is 120 ML. The plant is commissioned with a primary sedimentation tank followed by secondary treatment. The biological nutrient removal component of the plant comprises a circular tank that is evenly quartered into four basins. Each basin operates as a separate SBR. At the time of this study, each SBR cycle consisted of the following phases in sequence: 90 min continuous feeding and aeration, 35 min settling and 55 min decanting. The average exchange volume per cycle in each SBR was approximately 5 ML. Each SBR had a working volume of 28 ML, and hence the average HRT was 17 h. The total airflow to the three SBRs was fixed at $45000 \text{ m}^3 \text{ h}^{-1}$ throughout the aeration phase with equal distribution among the three reactors. The SRT was maintained at 19 days.

The models were calibrated using the monitoring data collected from SBR2 during the three-cycle continuous intensive sampling campaign. Figure 4 shows the simulated and experimental data (effluent NH_4^+ , NO_2^- , NO_3^- and N_2O) during the three cycles. Again, for the three models the predicted profiles of ammonium, nitrite and nitrate match the observed experimental trends. Model A predicted an opposite N_2O trend to that observed. Models B and C achieved a good fit between the model-predicted and measured N_2O data. Similar to the OD system, SBR2 also has low nitrite accumulation. In SBR2, N_2O emissions occurred mainly during aerated periods. The N_2O production rate increased with the increase of DO concentration during the cycles of SBR2. Model C captures all these trends in general.

UCT process

The Eindhoven WWTP, in the Netherlands, has a capacity of 750,000 PE. It treats wastewater using a University Cape Town (UCT) process which consists of three rings. The inner ring is an anaerobic tank, the middle ring is an anoxic tank and the outer ring is a partially aerated tank. The outer ring is equipped with two aeration packages. The summer aeration package is open all year round, but the winter aeration package is turned on occasionally under certain conditions, e.g. under rain events.

Model A1, Model B1 and Model C were implemented to this plant and their parameters were calibrated based on a 1-month measurement campaign. Figure 5 compares the simulated NH_4^+ , NO_3^- and DO concentrations with the on-line sensor data near the outlet of the summer aeration package. Figure 6 compares the simulation and the measurement data of N_2O emissions at three different locations along the summer aeration package. The conclusion is that all models can be calibrated to the same level of fit. They have similar performance and can follow the dynamic variations in the measurement data.

There was a rain event encountered on August 25th - 26th. All models showed better simulation performance under dry-weather conditions than wet-weather conditions (Figure 5). Results show that there was less N_2O emission under wet-weather conditions compared to dry-weather conditions (Figure 6).

DISCUSSION

Capabilities of the models and comparison of parameter sets

The data monitored on the four continuous systems considered in this study confirm that the N_2O emission factors varied very significantly from 0.1 to 5.2% of the nitrogen removed. Data and simulations also confirmed that major N_2O productions were related to nitrification. For instance, N_2O emission were negligible in SBR(1) during anoxic period (even if nitrogen gas was injected) whereas 0.5 to 5% of nitrogen was converted into N_2O during aerobic nitrification depending on the FNA concentration (DO from 2 to 6 ppm). In OD the overall N_2O emission factor over a full month was 0.52% of the nitrogen load to the plant, with over 90% contribution from the aeration zone (DO of over 5 ppm), 8% contribution from the DO zone at 1 ppm, and less than 2% contribution from DO zone at 0.05 ppm. Similarly, the N_2O emission factor of the SBR2 over the month is around 1.0-1.5 % of the nitrogen load, with N_2O emissions occurring mainly during aerated periods. In the UCT process the average contribution of each species to the N_2O production has been quantified with the model B1. N_2O is produced through the AOB pathway but is consumed by heterotrophic denitrification. Finally, the total N_2O production by AOB is 291.83% of the net production while the heterotrophs contribute by -191.83% (Guo and Vanrolleghem, 2014b). Hence these results clearly confirm the need of a good prediction for AOB-related N_2O production as well as heterotrophic denitrification by N_2O .

The modelling results indicate that all five models can correctly describe the ammonium, nitrite and nitrate measurements. However none of these models was able to accurately predict all measured N_2O data sets. On the one hand this confirms the first conclusion made by Ni *et al.* (2013a) in their previous evaluation with batch data. On the other hand, new information (summarized below) is provided by this comparison on long-term data. Table 6 summarizes the models' capabilities for the different case-studies.

Satisfying predictions were observed with AOB denitrification models for the SBR(1) in which the nitrite concentration varied significantly, the best results being obtained with models based on FNA instead of total nitrite (A1, B, B1). At the contrary it was not possible to predict the data with model C based on hydroxylamine incomplete oxidation as the effect of nitrite (or FNA) was not considered in this model. In addition, NO emissions were also predicted more accurately with the AOB denitrification model. For the UCT and SBR(2) processes in which nitrite did not accumulate, the simulations with model C were in agreement with the observations whereas a model based on AOB denitrification (model A) failed. Finally, for the UCT process models A1, B1 and C gave similar trends after an important calibration effort.

On figure 7, the FNA influence on simulated NO production rate is represented for two models (A1 and B1) calibrated on the SBR(1) and UCT processes. It should be pointed out that the N₂O production rate is correlated to this rate as NO is the precursor for N₂O in these models. In the system with low nitrite concentration (UCT), a high value for η_{AOB} (0.3-0.5) and a low value for $K_{\text{HNO}_2, \text{AOB}}$ (10^{-5} - 10^{-6}) are obtained in order to satisfy the observed NO and N₂O emission data. With these parameter values the N₂O production rate is poorly influenced by the nitrite concentration except at very low concentrations. In comparison a lower value for η_{AOB} (0.1-0.2) and a higher value for $K_{\text{HNO}_2, \text{AOB}}$ ($2 \cdot 10^{-3}$) were obtained with the calibration on the SBR(1) process. In that case the variation of FNA concentration influences the NO and N₂O production rates significantly. On the one hand these large variations of parameters from one system to another could possibly be explained by adaptation of enzymatic activity (NirK). This would mean that the calibration realised at low nitrite concentrations is not valuable in a system with high nitrite accumulation (and vice-versa). On the other hand another explanation is that the second pathway based on hydroxylamine incomplete oxidation is also present next to the denitrification pathway. For this reason a model which would consider both pathways would be useful as it would probably be able to predict a larger range of experimental conditions with the same parameter set.

Relation between FNA concentration and AOB pathways

From the models comparison it can be concluded that the AOB denitrification models (especially A1, B, B1) were able to describe the process with high nitrite variation whereas the NH₂OH/NO model (C) fits well with the data collected on low loaded systems with low nitrite accumulation. In addition, Models B and C could both predict the trend of the N₂O production dependency on DO at high DO level. These observations may help the future development of a unified model involving both the AOB denitrification and the NH₂OH pathways. Considering the model structures, only the models based on AOB denitrification correlate the N₂O production rate to nitrite, whereas the NH₂OH oxidation models correlate the N₂O production to the ammonium uptake rate.

The maximal nitrite concentration in the OD and SBR(2) are respectively around 0.67 ppm and 1.53 ppm, with pH close to 7.1. It corresponds to 0.16 and 0.32 $\mu\text{gN-FNA/L}$ respectively at 15°C. It was also observed in SBR(1) that below a concentration around 0.5 $\mu\text{gN-FNA/L}$ the production of N₂O decreases very significantly. It could be concluded that this value could be the limit under which the AOB denitrification processes become less significant compare to the hydroxylamine oxidation pathway. On the other hand, in the UCT process the maximal nitrite was only 0.11 mgN/L and the model A1, B1 and C were able to predict the observed trends.

These results are in accordance with the results of the quantification of N₂O origin during nitrification based on isotopes signature (Toyoda et al., 2011; Wunderlin et al., 2013; Rathnayake et al., 2013). Wunderlin et al. (2013) demonstrated that the nitrite reduction pathway was the major mechanism responsible for N₂O production during batch feeding with ammonium and nitrite. In contrast the hydroxylamine oxidation pathways became the major process as soon as hydroxylamine accumulated or was injected. The contribution of N₂O reduction was also observed to increase with the nitrite accumulation over time (Wunderlin et al., 2013; Rathnayake et al., 2013).

CONCLUSIONS

The continuous long-term data sets collected from four different full-scale wastewater treatment plants and the calibration results obtained for five different model structures compiled in this paper lead to the conclusion that neither of the proposed models presented so

far in literature were capable to properly describe all observations. More specifically none of the models were able to describe with similar parameter set the data obtained in systems with high and low nitrite concentration.

This is consistent with the conclusions drawn from a previous exercise based on short-term laboratory scale data and the suggestion is that efforts should be deployed to create a model in which the two main N_2O pathways active in AOBs are represented and their interaction described by their dependence on the reactor conditions.

INTRODUCTION

Benchmarking WWTP/WRRF control strategies has turned out to be a very successful vehicle for development of consolidated models of whole facilities (Gernaey et al., 2014). Over the last year, a comprehensive think tank of researchers involved in this development has put together a wish list of future developments in WWTP/WRRF modelling. They want these ideas to be exposed to the modelling community gathered at WWTmod2014. Starting from a summary ongoing work on extending the Benchmark Simulation Model No.2 (BSM2) and the wish to extend the current BSM2 to include phosphorus aspects, the think tank presents this abstract to outline the options lying ahead. The lecture will present arguments for choosing among the identified modelling options, in order to get informed feedback from the WWTmod2014 audience and define a roadmap for future modelling efforts. It is believed that this way of guiding the combined (voluntary) efforts of model development will be beneficial to the WWTP/WRRF modelling community at large.

The developments in the benchmarking area this paper will discuss relate to:

- G. Greenhouse gases (GHG): Next to methane and CO₂ that are intrinsically part of the plant-wide benchmark simulation model, recent work has focused significantly on N₂O emissions, leading to considerable extensions to the details of the N-removal sub-model of the BSM2;
- P. Phosphorus: P-removal has been a focus of WWTP/WRRF design and operation, but its inclusion in whole plant models is lagging behind that of N-removal, due to the difficulties in modelling the precipitation processes that P is involved in, especially in the sludge train.

- S. Sulphur: This element is receiving increased attention not only because of its role as a competitor for P and the related impact on P-complexation and release, but also because new processes in seawater-based systems (e.g. the SANI-process) take advantage of sulphur as a reactive element. Efforts to control H₂S emissions and induced corrosion in sewer systems will benefit from such S-focused modelling efforts as well.
- X. Micropollutants: Recent interest in micropollutants has led to a diversity of model developments that would benefit from consensus-building and inclusion in the benchmark simulation platform. The diversity of micropollutants remains a challenge, but consensus can probably be found regarding models of the overall fate-determining mechanisms (sorption, biodegradation, volatilization, hydrolysis, photolysis ...).

With these four themes combined, the name to be given to this extension of the plant-wide Benchmark Simulation Model No.2 coincidentally turns out to be BSM2-GPS-X, a nice wink to one of the important WWTP/WRRF simulators.

To reach this goal, the following topics will have to be addressed: 1) new evaluation criteria; 2) new chemical and biochemical processes that should be taken into account; 3) new components involved in these processes that thus need to be modelled; 4) new influent wastewater characteristics; 5) modifications to the original BSM2 physical plant layout and new unit process models; 6) model integration; and, 7) new control handles and opportunities. These are shortly presented below.

The intention at the WWTmod2014 seminar is to select a number of the more clear-cut topics developed below, and get the opinion from the audience by presenting them with a clear choice and a way to directly provide feedback (colored cards or a SurveyMonkey on-line voting system).

DISCUSSION TOPICS

1. New evaluation criteria

With the ambition to use benchmark simulation models to evaluate the control and monitoring performance of WWTP/WRRFs that go beyond what could be achieved with BSM1/2 (COD/N-removal) a new set of evaluation criteria needs to be put forth:

- ✓ Is the approach for GHG-emission evaluation appropriate (Flores-Alsina et al., 2014)?
- ✓ P-related criteria should be added, such as its contribution to the effluent quality index.
- ✓ Given the interest in nutrient recovery, should evaluation criteria be developed that highlight production of (high quality) recovered nutrients from WWTPs/WRRFs?
- ✓ Should sulphur compounds be considered in performance evaluation and in what way?
- ✓ Do we consider ecotoxicity to evaluate micropollutant removal (Clouzot et al., 2013)?

2. New chemical and biochemical transformations

Upgrading the BSM WWTP with the GPS-X related transformations inevitably leads to a wide range of processes that need to be added. The level of complexity remains an open question though:

- ✓ GHG-modelling has matured significantly over the last two years, but finalization is still required (e.g. Ni et al., 2013);
- ✓ In GHG-models temperature dependency of reaction kinetics has been modelled using the Ratkowsky equation instead of Arrhenius, enabling to model decreasing rates at high temperatures. Is this to be applied to all kinetics?
- ✓ Is ASM2d still adequate for modelling enhanced biological P-removal or do we need modifications, e.g. electron acceptor dependent decay, denitrification by specific

substrates with special kinetics (methanol, glycerol, methane, ...), role of the ions Mg^{2+} , Ca^{2+} , K^{+} ;

- ✓ Is it important to model the behaviour of PAO's when they enter the anaerobic digester with a consequent P-release, VFA uptake, storage? How must ADM1 be upgraded to account for phosphorus and treatment of Bio-P sludge? Is ADM1 the proper model (Ikumi et al., 2011)?
- ✓ Is it important to include anoxic-aerobic digestion of Bio-P wastage sludge with lime or Mg dosing for P-precipitation (to achieve low N and P dewatering liquors) for sludge treatment and how must ASM2/2d be modified to also model this (Vogts and Ekama, 2012)?
- ✓ Which precipitation reactions to model and which numerical approach to use?
- ✓ How will the physico-chemical model look like (precipitation, acid-base reactions, pH, ion-pairing, ion activity, etc.) in terms of level of detail, equation structure and solver requirements, etc. (Batstone et al., 2012);
- ✓ If S-containing components are considered important for P-modelling (e.g. competition for iron), which of the (bio)chemical S-related oxido-reduction processes need to be included and how is the competition with methanogens to be modelled?
- ✓ Do the traditional micropollutant fate models (volatilization, sorption, photolysis, biodegradation) that only require standard chemical properties (Henry coefficients, Kow, ...) suffice or are dedicated models necessary for each micropollutant (Clouzot et al., 2013)?

3. New components

If the above list of processes is all considered important, a wide range of new components will have to be added to the current set of components considered in the next generation of BSM models:

- ✓ Inert inorganic suspended solids need to be added for proper TSS accounting;
- ✓ P-related components (phosphate, PAO's, poly-P, PHA) and the components related to precipitation and PAO hydrolysis (calcium, magnesium, potassium, iron, struvite, K-struvite, newberyite, calcium phosphate, iron phosphate, iron hydroxide, calcite, magnesite);
- ✓ S-related components (sulphate, sulphite, sulphur, H_2S , poly-S, iron and other sulphides);
- ✓ A multitude of micropollutants (and their transformation products);
- ✓ Components related to GHG emissions (methane, CO_2 , NO, N_2O , NH_2OH).

4. New influent wastewater characteristics

Evidently, when the set of state variables is extended, the inputs to the system will have to be extended too, including methane (G), phosphorus (P), sulphur (S), micropollutants (X). Are colloids important for the proposed configuration? Multiple approaches could be proposed:

- ✓ Can we just use correlations with the traditional wastewater components in the influent files used so far (using TSS, COD and N-fractions as independent variables to correlate with)?
- ✓ Do we need to develop new influent generation models that include, for instance, methane formation in the sewer (Guisasola et al., 2009), micropollutant release patterns (De Keyser et al., 2010), sulphur conversions, etc.?
- ✓ Do we need to provide detailed information on influent pH-dynamics and acid-base / ion composition to support the physico-chemical model that is required?

5. New physical layout and unit process models

The suggested layout of the BSM2-GPS-X WWTP is shown in Figure 1. The activated sludge section has been modified by including an anaerobic section for Bio-P removal. The actual volumes are still open for discussion and will be obtained through application of standard design guidelines, just as for BSM2 (Gernaey *et al.*, 2014). Some proposals have been made to extend the layout that this paper will put to the floor for feedback:

- ✓ Should we include a P-recovery unit process in the sludge train and how do we model it? Evidently, including such a process in the layout would attract a lot of attention to the BSM work, and in principle the physico-chemical model contains the necessary processes, but is there a “typical” P-recovery process that industry would accept as being representative?
- ✓ Sludge reject water treatment was already tried out in the BSM2 process layout (Volcke *et al.*, 2006). Is it time to make this an integral part of a whole plant model?
- ✓ Should we also model the pumping station, screens and grit chamber so as to really model all processes within the fence? A storage tank prior to the digester could allow for more control options and the addition of external organic material input to the system.
- ✓ The primary clarifier is receiving increased attention due to its potential role in separating organics for energy recovery by anaerobic digestion (Flores-Alsina *et al.*, 2014). Should chemical enhancing of primary treatment (CEPT) be added to the BSMs (Tik *et al.*, 2013)?
- ✓ Is a “fermenter” that generates VFA’s out of primary sludge a unit process to be included in the whole plant configuration to be studied in the future? It certainly would provide an interesting possibility for control.
- ✓ Should the secondary settler model be upgraded to include compression and dispersion and to make its numerical solution consistent (Bürger *et al.*, 2011)?
- ✓ Is it now time to explicitly consider the reactions in the secondary clarifier, in particular denitrification, and how would that best be done (fully reactive settler, separate reactor, etc. (Gernaey *et al.*, 2006))? Must the same hold for thickeners and storage tanks?
- ✓ Should we add effluent polishing systems for nutrients (denitrifying filters) and TSS (disk filters) and can consensus on a representative technology and appropriate models be found?

Figure 1. Plant layout of the proposed BSM2-GPS-X. Some questions remain to be answered.

6. Model integration

So far, BSMs have used interfaces to integrate the submodels. As complexity increases, the following questions can be asked:

- ✓ Do we stick to the approach with submodels with individual component sets and mass continuity interfaces to connect them or do we move towards the plant-wide modelling concept or the Supermodel approach (Grau *et al.*, 2009)?
- ✓ If we stick to interfaces, do we extend the existing ad hoc interface or do we rigorously apply the continuity-based-interfacing-of-models (CBIM) approach (Vanrolleghem *et al.*, 2005)?

7. New sensors and control handles

Control of WWTP/WRRFs will require a new set of sensor models to measure, for example, phosphate concentrations. Also, more control handles will become available compared to BSM2.

- ✓ Models for P-analysers and nitrite measurement devices need to be established;
- ✓ Will off-gas analysis (methane, H₂S, O₂, N₂O, CO₂...) break through and how will we model these measuring systems with gas sample preparation?
- ✓ Models for actuators needed for CEPT may have to be developed, given their particularities;
- ✓ Which sensors and control handles can be modelled for nutrient recovery systems? For instance one could imagine on-line particle size distribution measurement combined with seeding as a control handle for struvite formation.

CONCLUSION

This contribution intends to allow the control benchmarking community to get feedback from the wastewater modelling community regarding the requirements for the next generation benchmark simulation model. Given the many spin-offs that the benchmark modelling efforts have generated for the wastewater modelling community at large (Gernaey *et al.*, 2013), it is believed that streamlining the work that is planned to occur in this benchmarking framework should be guided by the specialists in the discipline.

Efforts have and will be deployed to make the interaction with the audience as efficient as possible by presenting only a selected number of key topics presented above and providing clear choices that can be answered during the time allocated for the presentation.

Abstract

Population Balance Models (PBMs) represent a powerful modelling framework for the description of the dynamics of properties that are characterised by statistical distributions. This has been demonstrated in many chemical engineering applications. Modelling efforts of several current and future unit processes in WWTPs could potentially benefit from this framework, especially when distributed dynamics have a significant impact on the overall unit process performance. In these cases, current models that rely on average properties cannot sufficiently capture the true behaviour. Examples are bubble size, floc size, crystal size or granule size,... PBMs can be used to provide new insights that can be embedded in our current models to improve their predictive capability. This paper provides an overview of current applications and the future potential of PBMs in the field of WWT modelling, introducing new insights and knowledge from other scientific disciplines.

Keywords

bubble size, distributed properties, floc size, granule size, heterogeneity, PBM, product specifications, quality by design

INTRODUCTION TO POPULATION BALANCE MODELS (PBM)

Many natural systems consist of populations of individual entities (e.g. flocs, bubbles, granules, crystals, bacterial cells) with specific properties (e.g. size, composition, density, activity). The individual entities interact with their environment (e.g. dissolved chemical precipitation, oxygen transfer from air bubble to liquid phase, shear-induced breakup) or with one another (e.g. aggregation, coalescence). Typically, these interactions are a function of one or more properties, which may vary within a population of entities. In this context, we can refer to this variation as “distributed properties” as they can be represented by a distribution instead of a scalar (i.e. one single value). A simple example of the use of a distribution would be to characterize the variation in floc size in an activated sludge system. This distributed feature implies that the behaviour of distinct entities can be significantly different, and can deviate substantially from ‘average’ non-distributed behaviour.

Current modelling frameworks usually assume non-distributed scalar properties (e.g. using a single particle size or bubble size), implying that all individuals behave in exactly the same way. In some cases, this is sufficient, but in others this assumption is too strict and will lead to predictions that deviate significantly from the real system. The required level of detail is clearly governed by the modelling objective. Yet, few researchers and design engineers in WWT are aware of alternative modelling approaches that can account for the impact of these distributed properties on unit process performance.

A framework to achieve distributed behaviour by considering distributed population properties already exists and is called Population Balance Models (PBMs). PBMs have been

extensively used in chemical engineering for a myriad of applications (Ramkrishna, 2000; Marchisio, 2012). The governing equation in its most general form is given as

$$\frac{\partial f_1(x,t)}{\partial t} + \frac{\partial}{\partial x}(\dot{X}(x,t)f_1(x,t)) = h(x,t) \quad \text{Eq. 1}$$

where x is the internal coordinate (i.e. the distributed property), $f_1(x,t)$ is the number density function (i.e. the distribution of the distributed property), $\dot{X}(x,t)$ is the continuous growth term of x and $h(x,t)$ is the PBM reaction term (through discrete events). Table 1 provides some examples in regard to wastewater treatment applications.

Table 1 – Some examples of wastewater treatment processes and related internal coordinates (x), number density functions ($f_1(x,t)$) and continuous ($\dot{X}(x,t)$) and discrete ($h(x,t)$) governing mechanisms

Process	X	$f_1(x,t)$	$\dot{X}(x,t)$	$h(x,t)$
(De)floculation*	Floc size	Floc size distribution	Microbial growth	Aggregation, breakage
	Size/Density**	Size/Density distribution	-	Aggregation
Coalescence	Bubble size	Bubble size distribution	-	Coalescence
Granulation	Granule size	Granule size distribution	Microbial growth	Granulation
Crystallization	Crystal size	Crystal size distribution	Crystal growth	Aggregation, breakup
Bio P-removal	Poly-P	Poly-P distribution	Poly-P storage, release	Cell division, cell birth
PHB production	PHB	PHB distribution	PHB storage, release	Cell division, cell birth
Growth	μ_{\max}	μ_{\max} distribution	Growth rate gradient	Cell division, cell birth
Affinity	K _x	K _x distribution	Affinity gradient	Cell division, cell birth

*Note that this mechanism is driving the settling processes in primary and secondary sedimentation

**In this case a 2D PBM is obtained

The first term on the left hand side of Eq. 1 represents the accumulation term. Distribution dynamics that can be described are either governed by continuous processes (e.g. biomass growth, crystal growth, particle drying – represented by the second term on the left hand side of Eq. 1) or discrete processes (e.g. aggregation, breakage, coalescence, granulation – represented by the term on the right hand side). The latter term usually consists of a birth and a death term, where the birth rate describes the rate at which particles of property x are being formed and the death rate describes the rate at which they are being removed. In crystallisation, a nucleation term needs to be added in the smallest size class mimicking the nucleus that is formed in an oversaturated solution.

The internal coordinate x can be either a scalar (i.e. a single independent variable) or a vector resulting in a 1 dimensional or multi-dimensional PBM, respectively. The use of multi-dimensional PBMs means that the distribution of one or more material properties can be described. It should be noted that formulating and solving multidimensional PBMs is a challenging task.

The nature of the resulting equation depends on the presence of the $\dot{X}(x,t)$ and $h(x,t)$ terms. If only the former is present, a partial differential equation (PDE) is obtained for which solution methods are available. The latter term usually contains integral terms expressing the interactions between members of the distribution, turning the equation into an integro-partial differential equation. Several numerical methods have been reported in the literature to solve this type of equations (Ramkrishna, 2000).

Applications of PBMs to wastewater treatment processes are rather scarce. The first application was introduced by Fukushi *et al.* (1995), where a PBM model was used for modelling the dissolved air flotation process in water and wastewater treatment. The authors described the attachment process of bubbles to flocs during the flocculation process in a turbulent flow. Gujer (2002) investigated the impact of lumped average cell composition versus distributed composition in the context of ASM2 and ASM3 and concluded that this indeed had a significant impact. Schuler (2005) demonstrated that lumped state (= averaged) assumptions in EBPR system performance models produced large errors due to the difference in individual residence times of organisms in different zones. This was found to be related to process hydraulics (Schuler, 2006) and to impact the endogenous respiration as the latter was found to be more important when distributed models were applied (Schuler and Jassby, 2007). Finally, several PBM references can be found in the field of activated sludge flocculation ranging from very simple formulations (Parker *et al.*, 1972) to more elaborate ones (Biggs *et al.*, 2003; Nopens *et al.*, 2002) and papers focussing on experimental validation (Nopens *et al.*, 2005) and model structure analysis (Nopens *et al.*, 2007; Torfs *et al.*, 2012).

PBMs can serve the purpose of building process understanding. The result of such a detailed modelling exercise can be included in next generation simplified WWTP models that go beyond the currently used paradigms (i.e. ASM using averaged biomass behaviour combined with residence time distribution models and oversimplified aeration and settling models). Hence, PBM models should not be considered as replacement of current WWTP models, but as enhancement tools to improve the future quality of their unit process predictions. This paper intends to outline the potential of PBMs in the field of wastewater treatment through several examples of different WWTP unit processes.

APPLICATIONS OF PBMS IN THE FIELD OF WWT

Improved flocculation to better exploit primary and secondary settling

The current settling models are either based on removal efficiencies or settling velocities correlated with particle concentration. Settler models are still receiving attention as there is still room for improvement in their use (e.g. storage function during wet weather) and operation. This is especially true for primary settlers as they can be an important asset for energy recovery through the maximisation of the primary sludge that is sent to the anaerobic digester. Their behaviour has not been widely studied thus far (Bachis *et al.*, 2014). Moreover, the primary treatment process is often chemically enhanced (CEPT) which creates an optimal dosage problem. As particle concentrations are low in primary settlers, the settling regime is not hindered but rather discrete, i.e. Stokian, and a function of particle size, shape and density, leading to a wide distribution of settling velocities as evidenced by Bachis *et al.* (2014). The discrete settling assumption is also true for the zone just above the sludge blanket of a secondary settler. In discrete settling, settling velocities are directly related to size, shape and density and, hence, the particle size distribution (PSD). The PSD depends on the original flocculation state as well as on actions undertaken to improve the flocculation state (e.g. turbulent shear, coagulant). Note that the flocculation state also depends on the particle's history (e.g. a sludge can have the same PSD, but it can react very different if the floc strength is different caused by a different flocculation history).

Flocculation of particles is probably the most straightforward application of PBMs. Since biological growth occurs on a much longer time scale compared to aggregation and breakage

it can be ignored when studying short-term flocculation behaviour of activated sludge. The PBM reaction term is then defined as

$$h(x,t) = B(x)_{agg} - D(x)_{agg} + B(x)_{break} - D(x)_{break} \quad \text{Eq. 2}$$

in which the birth (B) and death (D) terms occur for both aggregation and breakage as shown in Figure 1. Through these different mechanisms flocs of any size can be formed or removed. Furthermore, it becomes clear that aggregation is a particle-particle interaction process, whereas shear-induced breakage is not. The rates of all these processes are, hence, governed by the number of flocs present (N) as well as an aggregation rate (β), an aggregation efficiency (α) and a breakage rate (S) and distribution of resulting particles (the so-called daughter size distribution). Aggregation and breakage rates are in their turn a function of the mechanisms that drive the aggregation or breakup. Traditionally, shear and polymer addition are accounted for which is likely sufficient for the application in the context of primary and secondary settling. More details on these rates and their dependencies on shear and flocculant addition can be found elsewhere (Nopens *et al.*, 2002; Nopens *et al.*, 2005). An example of a model prediction along with measured size distribution during a batch sludge flocculation process is shown in Fig. 2.

Fig. 1 – Illustration of mechanisms involved in flocculation (after Nopens *et al.*, 2002)

Fig. 2 – Example of a PBM model prediction of a batch sludge flocculation process (time unit = seconds; unit on size axis = μm^3) after Torfs *et al.*, 2012)

Flocculation usually takes place in the process units prior to the actual settling tank as well as in the settling tanks (if conditions are good). Flocculation models as described above can be used for both. Currently, the flocculation process in primary and secondary clarifiers is not studied in detail and its effects are incorporated using rules of thumb. However, understanding the contribution of flocculation would improve their design and operation which can significantly improve the settling performance and control. Indeed, being able to predict and control the size distribution of a population of particles arriving to either the primary or secondary settler would be a useful input to settler models that can handle a distribution of settling velocities, calculated from the size distribution derived with the PBM (Bachis *et al.*, 2014).

In a secondary settler, exposure of flocs to elevated shear during transport from the bioreactor to the centre well of the settler will induce reflocculation and impact the floc size distribution and the floc strength. An appropriate application of PBM for settler induced flocculation would specify size as the internal coordinate.

In primary settler applications, the availability of particle settling velocity distributions as the internal coordinate of the suspended solids has generated a more accurate prediction of the load to the secondary treatment model, reduced the need for calibration (Bachis *et al.*, 2012, 2014), and produced more accurate and optimal control of chemical dosage that lead to cost savings. In addition to particle size, particle density can be included as a second internal coordinate when density varies significantly with floc size. This additional internal coordinate can be accomplished using a 2D PBM approach but comes with an increased computational and parameter estimation cost since the rate expressions need to be extended to include density, which will require a detailed investigation of the process. Another interesting route for further research is the coupling of PBMs to computational fluid dynamics models as the latter can predict local shear which then serves as input for the PBM model. Research that couples PBM with CFD in WWT has been reported already (Griborio *et al.*, 2006; Gong *et al.*, 2011), but needs further attention. Here, again, it should be clear that coupling a 1D PBM to a CFD model is a challenging task, typically resulting in models which need very long simulation times. One strategy to reduce the computational burden is to reduce the PBM model before coupling it to a CFD model (Mortier *et al.*, 2013).

More accurate aeration modelling for better design and energy optimisation

For a long time, $k_L a$ -based models have been used to capture mass transfer between the gas and adjacent phases during aeration. More recently, models taking air flow rate as input were proposed. Despite the inclusion of somewhat more complexity and the resulting improved model performance, the variability of the α "fudging factor" in space could still not be entirely related to process variables such as sludge concentration and sludge age, i.e. a lot of unexplained variance remains. Moreover, α was shown to vary spatially in a reactor (Rosso *et al.*, 2011). This spatial variation introduces a significant amount of uncertainty in the model prediction when a single α value is used, resulting in locally different dissolved oxygen concentrations and, hence, aerobic process rates.

To date, a key assumption in all aeration models is assigning a single average bubble size. This assumption is not very apparent, but resides in the gas-liquid interface surface area (a) of $K_L a$ and is hidden in the α value in oxygen transfer efficiency (OTE) based models. This constant bubble size assumption is unrealistic and can be very restrictive for the model since the bubble's interfacial area drives the oxygen transfer process. In reality, bubble size is spatially distributed (Fig. 3, left) from the point of injection to the top of a reactor due to the process of coalescence leading to a significantly different bubble size distribution near the reactor top. Another factor that plays a role here is the fact that there are pressure differences

when moving from the bottom to the top of the reactor, and these will also influence bubble size. Increased viscosity (due to the presence of sludge) further promotes coalescence compared to clean water (Fig. 4) (Fabiyyi and Novak, 2008; Ratkovich *et al.*, 2013). A PBM using bubble size as the internal coordinate and including coalescence as a PBM reaction process can significantly improve the local prediction of oxygen mass transfer (and hence α) as well as improve the design of aeration systems to maximize the oxygen transfer (in combination with Computational Fluid Dynamics - CFD). It should be noted that the current work in CFD linked to aeration also uses a fixed bubble size (Fayolle *et al.*, 2007). The use of PBMs in aeration systems with suspended solids has not been widely studied in WWT. PBMs applied to bubble columns are widespread in fermentation systems and the chemical engineering literature (Wang, 2011; Dhanasekharan *et al.*, 2005; Sanyal *et al.*, 2005) and can serve as solid examples of improved benefits to these process models.

Fig. 3 – Illustration of variability in bubble size as measured with a high speed camera

Fig.4 - Impact of viscosity on bubble coalescence

Typical mechanisms taking place in bubble breakup and coalescence are shown in Fig. 5. The kernels used in a PBM describing bubble breakup and coalescence are very similar as those used in a flocculation PBM.

Fig. 5 - Bubble breakup and coalescence due to different mechanisms (after Wang, 2011).

Floc and granule size: distributed kinetics

Despite the fact that the size of agglomerates, be it flocs or granules, can play an important role in biological activity (e.g. different microbial consortia at different locations in the agglomerate), the simulation of such a microenvironment within a macro-scale fluid transport environment has hardly been performed. Recently, Volcke *et al.* (2012) demonstrated the significant impact of granule size distribution on the performance of an Anammox-based granular sludge reactor. The authors used a fixed size distribution for this analysis. It is clear that size distribution can be impacted by shear and, hence, will further influence the system behaviour. The absence of size and size dynamics in the currently used models indicates that the activity loss caused by particle size (causing transport limitation due to stratification, e.g. Vangsgaard *et al.*, 2012) cannot be predicted by current models. Again, when experimental data are confronted with these models, other degrees of freedom (i.e. parameters or input variables) will be calibrated for inappropriate reasons.

Sobremisana *et al.* (2011) demonstrated that including floc size can result in significantly deviating reactor performance since kinetics can be quite different depending on reactor location and the size of the biological floc. The authors used an integrated PBM-CFD approach to simulate the carbon and nitrogen removal process at both the reactor scale and internal floc scale. The effect of size was introduced by means of an effectiveness factor (i.e. ratio of rate with and without diffusional resistance) based on floc size for all different processes. For a simple baffled reactor the treatment performance deviated by 13% for COD, 10% for NH_4 and 56% for NO_3 compared to the same simulation not accounting for influence of size. However, further validation is required.

Knowledge arising from this can be useful to (partially) decouple affinity constants in kinetic rate expressions and reduce their requirement for calibration. Understanding the interaction between size and reaction kinetics can inform researchers and engineers on how to better design and operate these processes (e.g. avoid or promote certain shear zones and account for imposed shear of mixing and aeration intensities). Moreover, it will reduce the need to adjust parameters unnecessarily to improve the model fit.

Apart from size heterogeneity, incomplete mixing can lead to spatial heterogeneous concentrations in biomass and substrates that ultimately result in locally different kinetics. Integrating the effects of spatial variations in macroscale mixing as well as the biomass and substrate concentration is another avenue for further model development. Lencastre Fernandes *et al.* (2013) demonstrated the effect of this heterogeneity for a budding yeast population using a multi-scale modelling approach that included PBM. A similar approach could be used for WWT modelling, and could be helpful in developing an improved understanding of

biomass population dynamics. A complicating factor for the WWT compared to a yeast fermentation is that multiple species have to be considered to model the WWT appropriately.

Models including floc size and local heterogeneities could also be helpful in developing technologies to select between wanted and unwanted microbial communities, which is a recently developing topic in view of mainstream Anammox application. Microbial selection can be done on a physical basis (size) or through selection by creating favourable growth conditions for the targeted microbial consortium (Al-Omari *et al.*, 2014).

Precipitation/crystallisation for better quality marketable products

WWTPs are transforming into WRRFs (Water Resource Recovery Facilities) leading to new modelling challenges (Vanrolleghem, 2013). One important aspect in product recovery, driving their market value, will be the specifications of the recovered material. These comprise both composition and size. Crystallisation has been extensively modelled in the field of chemical engineering and pharmaceutical engineering to produce crystals with tailor-made specs (e.g. Aamir *et al.*, 2009, Nagy and Braatz, 2012). A PBM with crystal size as an internal coordinate and inclusion of nucleation (function of supersaturation) and crystal growth can be used as a first approximation. If needed, more internal coordinates can be added to deal with composition or crystal shape (e.g. 2-D compared to 1-D, Samad *et al.*, 2011). Additional phenomena such as agglomeration and breakage can be added. Interestingly, describing crystallisation with a PBM also allows describing phenomena such as size-dependent crystal growth (Samad *et al.*, 2011).

The use of a PBM modelling framework is widely accepted when studying crystallization processes. However, in a WRRF context the PBM framework has not really been used thus far, with the exception of a recent manuscript by Galbraith and Schneider (2014) where a discretized PBM was used to describe the chemical precipitation of phosphorus. The most important discussion points, when implementing a PBM, are usually related to the model assumptions (which phenomena should be included?), and to the selection of the kinetic expressions for each phenomenon that is included in the PBM. The main phenomena are nucleation, crystal growth and dissolution (= negative growth), agglomeration and breakage. However, it happens frequently that the PBM only considers growth and nucleation (Fujiwara *et al.*, 2005). Another important variable that needs to be included in these models is the super-saturation, which will vary as a function of temperature and is usually represented as a polynomial describing the super-saturation curve as a function of temperature.

CONCLUSIONS

Many processes in WWTPs are governed by population dynamics of materials characterised by variation in property dynamics. These potential complexities in system behaviour are lost or significantly suppressed when only average behaviour is characterized or simulated. Population Balance Models can deal with these process complexities and have already demonstrated their benefits in the field of (bio)chemical engineering. The majority of the models in WWT modelling that need more rigour are physical-chemical processes. Hence, more than ever we need to look over the fence and integrate available (bio)chemical engineering knowledge into WWTP models. Some examples are described in this paper, but potentially many more applications of PBM in WWT exist and can be exploited. The intention of this paper is to make WWT modellers aware of this framework and its potential applications, challenges, and pitfalls.

Abstract

Characterisation and modelling of primary settlers have been neglected pretty much to date. However, whole plant and resource recovery modelling require primary settler model development, as current models lack detail. This paper focuses on the improved modelling and experimental characterisation of primary settlers. First, a new modelling concept based on particle settling velocity distribution is proposed which is then applied for the development of an improved primary settler model as well as for its characterisation under addition of chemicals (Chemically Enhanced Primary Treatment, CEPT). Second, another basic primary settler model, developed for control under chemicals addition, is presented. Third, the variation of the COD fractionation produced by primary settling is investigated, showing that typical wastewater ratios are modified by primary treatment. The latter provides a further argument for more detailed primary settler models in view of whole plant modelling as they clearly impact the downstream processes.

Keywords

Primary clarification model, particle settling velocity distribution, CEPT, ASM fractionation.

INTRODUCTION

The role of primary settling in wastewater treatment has often been neglected and very few efforts have been made for its optimisation and modelling (Lessard and Beck, 1988; Gernaey *et al.*, 2001; Ribes *et al.*, 2002). It has been neglected either because primary settling is not considered very influential for modelling purposes, or because the simple models proposed earlier were considered sufficiently robust to describe the primary settling tanks (PSTs) behaviour (Otterpohl and Freund, 1992). In many modelling case studies, the boundaries of the wastewater treatment plant (WWTP) are defined from the primary effluent onwards, i.e. using the primary effluent as model input, hereby keeping the primary settler out of the modelling scope. However, a better understanding and modelling of the processes taking place in PST result in a more accurate description of the primary effluent characterisation and sludge wastage. As such, it results in improved operation of the subsequent treatment phases, i.e. water and sludge treatment.

Improved primary settler models are also essential ingredients of whole WWTP descriptions. In this respect, Choubert *et al.* (2013) stated that based on combined expertise of modellers (Phillips *et al.* 2009) and sensitivity analysis (Petersen *et al.* 2002) profound effects of wastewater characterisation on modelling outputs (Henze *et al.* 2000) have been shown:

- Sludge production is influenced by the estimated inert particulate COD.
- Oxygen demand is influenced by the estimated total biodegradable COD.
- Anoxic denitrification rate and anaerobic phosphorus release are influenced by the estimated readily biodegradable COD.

- Effluent COD is influenced by the estimated inert soluble COD.

The importance of providing reliable wastewater characterisation, enabling the link with the industry-standard activated sludge models (ASM) (Henze *et al.*, 2000), was also highlighted. Hence, the function of PSTs under the ASM framework should be reconsidered since the impact of primary treatment on wastewater fractionation may be significant.

In this context, the simulation study of Flores-Alsina *et al.* (2014) illustrated the considerable advantages given by the enhancement of the TSS removal in a PST on final effluent quality and operational costs. This enhancement can be obtained by addition of chemicals (combined or not with lamellar settling) in the primary treatment, which may increase TSS removal efficiency up to 90% (Tchobanoglous *et al.*, 2003).

Chemically enhanced primary treatment (CEPT) by addition of coagulants/flocculants, which is often operated under wet weather conditions, may be also pursued for maximising the organic material directed to biogas production and other resource recovery. It thus becomes directly involved in the design of the energy self-sufficient WWTP. CEPT can be applied to achieve many different objectives in wastewater treatment facilities: to increase the TSS removal performance of PST in primary only plants; to reduce organic loading rates thereby reducing demand on aerobic biological treatment facilities; lastly, it can permit increased hydraulic loading rates to existing PST, thus favouring plants that receive high wet weather flows. The first most significant application of CEPT was in the 1960s by Canadian and U.S. engineers to address eutrophication of the Great Lakes through chemical precipitation of phosphorus. Galil and Rebhun (1990) showed that the reduction in organic load using CEPT significantly reduced aeration tank volume in the downstream activated sludge process. More recently, in the U.S., with increased emphasis on CSO and SSO controls, agencies are seeking for inexpensive and compact solutions to manage wet weather flows, other than just increasing secondary treatment hydraulics and process capacity. CEPT has been extensively evaluated because of the minimal investment in new infrastructure. Indeed, hydraulic capacities of existing primary settlers can be increased by a factor of up to three, which is often sufficient to manage peak wet weather flows. Bench-scale (Melcer *et al.*, 2005, 2009) and pilot-scale (Melcer *et al.*, 2012; Newman *et al.*, 2013) demonstrations of wet weather treatment using CEPT have been conducted. These have led to the application of CEPT at full scale.

Most of the existing settling models make use of a unique settling velocity for all the particles, even though the particles are heterogeneous and the assumption of a single settling velocity is a too simplistic approach. Introducing the concept of particle settling velocity distribution (PSVD) in the model provides a better description of the behaviour of the particles in the PST. Moreover, even though little literature exists on the topic, a few studies have highlighted that a link exists between particle physical properties and particle biodegradation properties (Chebbo and Bachoc, 1992; Hvitved-Jacobsen *et al.*, 1998; Morgenroth *et al.*, 2002), emphasizing the need to focus more on how primary settler models and subsequent biological reaction models have to be complementary. Hence, models of an adequate complexity need to be developed for a more accurate description of the PST behaviour and the chemical/biological phenomena that may affect particles, their settling velocity and, as a consequence, their removal. Indeed, the efficiency of the PST directly influences the performance of the subsequent treatment units in WWTPs, since during settling organic matter and suspended solids of the influent, as well as pollutants associated with them, are removed. Not only does this determine the load to the downstream treatment steps,

it is also critical in the evaluation of the benefits that the sludge treatment train will be able to accomplish (energy and nutrient recovery).

This work presents different ongoing developments related to the improved modelling and experimental characterisation of primary settlers. The paper is organised in four sections: (1) a new primary settling model based on particle settling velocity distribution (PSVD) is first proposed; (2) it is briefly illustrated how PSVD can also be used to characterise and model a CEPT process; (3) a simple primary settling model for CEPT is presented and (4) ASM fractionation in primary settlers is discussed.

PSVD FOR PRIMARY SETTLER MODEL DEVELOPMENT

A new dynamic primary settler model, based on the PSVD approach and inspired by the work of Maruéjols *et al.* (2012) on retention tanks, was initially presented by Bachis *et al.* (2012). This model allows improved predictions in terms of effluent TSS compared to previous primary settling models. It was shown that by creating a number of particle classes that cover the settling velocity distribution, a vertical gradient of the concentration of each of the particle classes and the pollutants associated to them can be calculated.

The ViCAs (Vitesses de Chute en Assainissement) batch settling protocol developed by Chebbo and Gromaire (2009) is an excellent method to feed this type of PSVD-model, as it allows to experimentally determine the fraction of the different settling velocity classes, each characterised by a distinct settling velocity V_s . A ViCAs experiment consists in filling a settling column ($H=60$ cm, $\varnothing=7$ cm) with a homogenized suspension. Solids settled during predefined time intervals are recovered at the bottom of the column and weighed for TSS. From the time evolution of the cumulated mass of particles settled since the beginning of the experiment one can calculate the distribution of settling velocities.

The PSVD model was implemented on the modelling and simulation environment WEST (mikebydhi.com). To describe the vertical gradient of particle class concentrations the settler is divided into a number of layers and a mass balance is calculated around each layer for each of the classes. Five particle classes with different (constant) settling velocities make up the core of the model.

Influent TSS fractionation into particle classes

Each particle class is assigned a fraction of the influent TSS. Given the dynamics of the wastewater composition, this assignment is, however, not constant. To assign the fraction of influent TSS to the classes, advantage is taken from the observation from multiple ViCAs experiments that the ViCAs curves are located higher for low TSS concentration and lower for high TSS. This means that high TSS samples contain a larger fraction of rapidly settling particles. Therefore, the assignment is made by interpolating the PSVD curve between two boundary curves (continuous lines on Figure 1). These are the boundaries delimiting the zone where most of the observed influent PSVD curves for the particular plant under study were located (results not shown). The upper limit of this zone is the ViCAs representing low influent TSS concentrations, while the lower limit is given for high influent TSS concentrations. The assignment for a sample with a certain TSS concentration is performed as follows: for a certain settling velocity (on the x-axis), the two corresponding limiting TSS fractions are determined (y-axis) and a linear interpolation is made between them from the influent TSS-value. Thus, the observed relation between PSVD and TSS concentration is used to define the fraction of each class of the influent TSS. The settling velocities characterising

each class were calculated as the geometrical mean of the settling velocity boundaries of the class.

Figure 1 Fractionation of the ViCAs zone into 5 classes and upper and lower limits of the zone where most of the PSVD curves observed for the case study were found. Settling velocities characterising each class were calculated as the geometrical mean of the settling velocity boundaries of the class

Primary settler data

The performance of the five classes PSVD model was evaluated through the simulation of the data from the Eastern wastewater treatment plant of Québec City (Canada). Two series of data were available: one was the TSS 24h-evolution of the influent and effluent collected at the full-scale primary settlers during a sampling campaign conducted in 2010 (three days under dry weather flow conditions); the other data set contained online TSS values measured by turbidity sensors on a pilot-scale primary settler (2013) (one day under dry weather flow conditions).

The PSTs of the Eastern WWTP of Québec City are lamellar settlers, with a total surface of 27,000 m², treating a mean flow rate of 236,600 m³/d during dry weather conditions. The 5 m³ pilot-scale PST was installed in the same WWTP and it received the influent from the full-scale PSTs, treating a mean flow rate of 192 m³/d.

Evaluation of the model performance

Model parameters were estimated by fitting the model to the data sets. The goodness-of-fit of the model was statistically evaluated through the calculation of the chi-squared criterion (weighted least squares). The assumption of independent and normally distributed measurement errors is made.

$$\chi^2(\theta) = \sum_{i=1}^n \left(\frac{1}{\sigma_i} (y_i - \hat{y}_i(\theta)) \right)^2$$

where y_i is the observed value; $\hat{y}_i(\theta)$ is the simulated value for the parameter set θ ; σ_i is the standard measurement error of the observation y_i and n represents the number of data points to which the model was fitted. The computed χ^2 is then compared to tabulated values of the chi-

squared distribution for $n-1-n_\theta$ degrees of freedom (n_θ stands for the number of estimated parameters), to decide whether the model is justified by the data or not (Gujer, 2008).

Calibration results

The parameters estimated during the calibration consisted on the location of the five settling velocity class boundaries (see Figure 1, lower limit not visible). During the calibration of the model different settling velocities and, consequently, different sets of fractions were tested until a good model fit to the measured effluent TSS time series was achieved. Two of the four full-day data sets were used for the calibration, visibly resulting in a good fit for the effluent TSS concentrations (Figure 2). The calculated χ^2 for the two events is respectively 11 (Figure 2a) and 34 (Figure 2b). For 18 degrees of freedom ($n=24$ and $n_\theta=5$) the observed χ^2 is in 99% of the cases smaller than the critical value 34.8. This means that the model is justified by the data, especially for the first simulation. The PSVD model's V_s values and limit TSS fractions resulting from the calibration are given in Table 1.

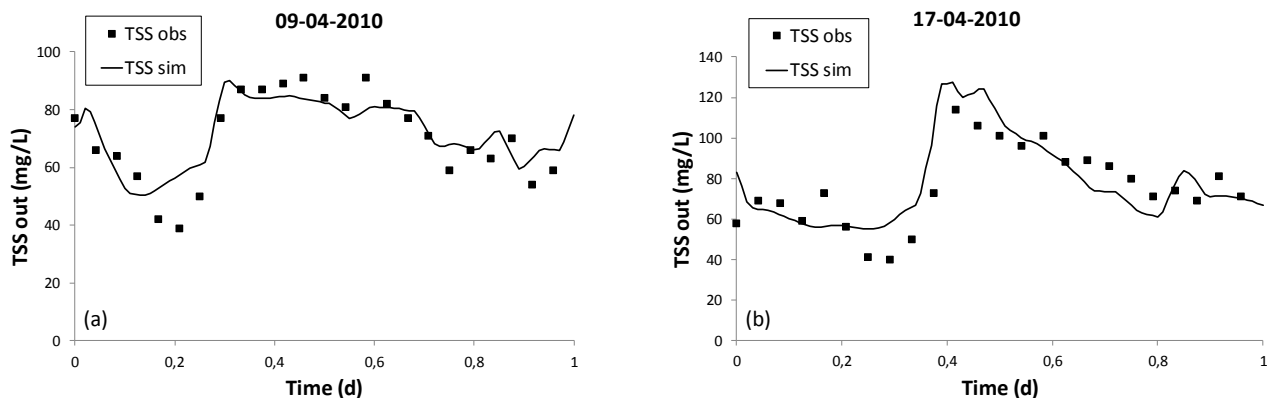

Figure 2 Model fit for effluent TSS concentrations during the calibration phase.

Table 1. Settling velocity (V_s) and boundary TSS fractions (F) associated to each of the 5 classes in the PSVD model and settling velocities used in the primary settling model from Lessard and Beck (1988).

	Class 1	Class 2	Class3	Class 4	Class 5
Class-characterising V_s (m/h)	0.06	0.70	1.91	5.48	13.36
F (high TSS-low TSS) (%)	32-51	22-19	20-15	18-11	8-4
	Dry weather		Wet weather		Return liquors
V_s Lessard&Beck (1988) (m/h)	1		2		10

Validation results

The remaining two full-day data sets were used to validate the model. One of the data sets was collected at the full-scale PST, the other was the data set with on-line turbidity data collected at the pilot primary settler treating the same wastewater.

Full-scale PST. The TSS concentrations were simulated quite well (Figure 3a). The χ^2 -test resulted in an acceptable value (23) since in 90% of the cases the sum of squares is smaller than 26.

Pilot-scale PST. The pilot-scale PST was modelled in the same way as the full-scale PST, with adjusted dimensions. The PSVD-model was fed with influent TSS data obtained through a linear correlation from NTU data provided by the turbidity sensor located at the inlet of the pilot-scale PST. The PSVD-model parameters estimated above were applied as such. Figure 3b confronts the simulated effluent TSS concentrations with the observations from the turbidity sensor located at the effluent of the pilot-scale PST. Even if it failed the χ^2 -test, it can be stated that, given the difference in configuration of the settler, a remarkably good fit is obtained.

Figure 3 Model fit for effluent TSS concentrations during the validation phase of the full-scale PST (a) and the pilot-scale PST simulated with the same PSVD model and model parameters (b).

Further tests of the model were conducted by applying it to simulate TSS concentrations obtained from a 10-day sampling campaign at the Norwich (UK) treatment plant (Lessard and Beck, 1988). Supernatant liquors from the sludge treatment were returned to the primary inlet two or three times a day. Return of supernatant sludge liquors and storm sewage to the influent stream affected the wastewater composition, producing peaks of TSS concentrations that were reproduced in the effluent as well. Therefore, Lessard and Beck distinguished in their model three different streams: crude sewage, storm sewage and crude sewage with return liquors and attributed different settling velocities to them (1, 2 and 10 m/h respectively) (Table 1). Hence, in their work the unique settling velocity of their model had to be changed each time one of the three mentioned events occurred (Figure 4a). When applying the dynamic PSVD model no such changes are needed as it just needs the observed influent TSS concentrations. It is not only capable of taking into account these sudden changes, but also proves to better simulate the data (Figure 4b), especially with regard to the time delay of the peaks. Please note the remarkable finding that the ViCAs curves obtained in Québec City could be applied as such to the Norwich treatment plant with excellent predictive capabilities. The only calibration performed was the estimation of the class settling velocity boundaries.

In conclusion, a new dynamic primary settler model based on particle classes has been developed, showing to be effective in predicting effluent TSS concentration and providing increased accuracy in simulating the TSS dynamics at the outlet of a primary settler compared to existing dynamic settling models. The approach of taking into account the PSVD of the

particles in the influent provides a type of primary settler model with very good prediction power for different sewages and weather conditions.

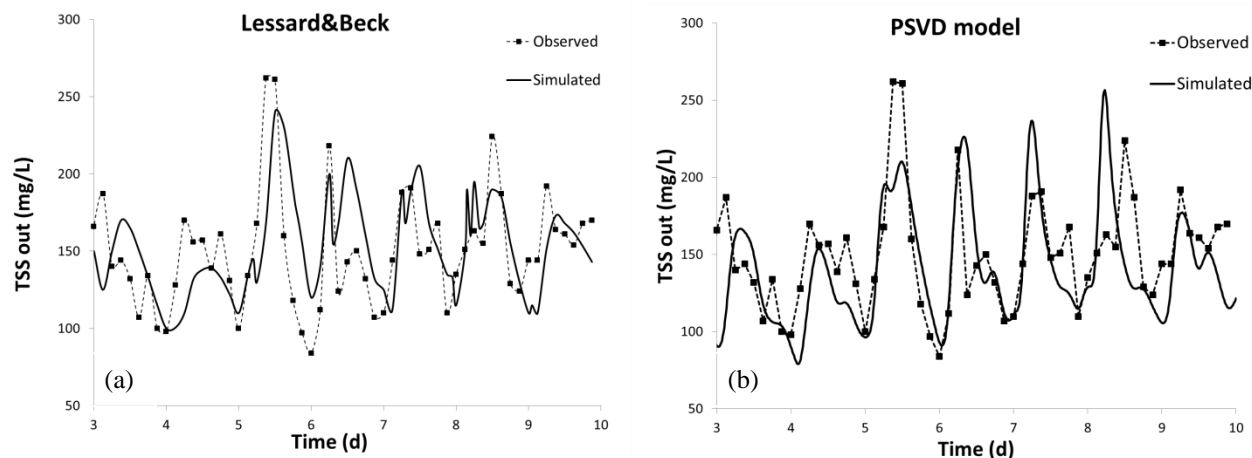

Figure 4 Model fit for effluent TSS concentrations in (a) the Lessard&Beck model and (b) the PSVD model.

PSVD FOR CEPT MODELLING

The effect of CEPT on the PSVD can also be characterised by means of ViCAs tests. To illustrate this, samples taken at the inlet of the pilot-scale PST after addition of coagulants/flocculants were subjected to the ViCAs test. Figure 5a illustrates that the inlet PSVD after chemical addition is shifted towards higher settling velocities and outside the typical reference zone of the primary settler influent without CEPT (Maruéjols *et al.*, 2011). The effect is more pronounced for slow settling particles, which is the logical consequence of the aggregation of the particles produced by the addition of chemicals, making them grow in size and increase in settling velocity.

This experimental approach may thus be very well suited to model the effect of the addition of coagulation/flocculation chemicals on primary settling. Indeed, the curve with the appropriate PSVD (with or without chemical addition) may be used directly as input to the model, fractionating the TSS in the appropriate better settling fractions. Applying the model using the PSVD with chemical addition results in a significantly better TSS removal, as illustrated with the simulation of CEPT applied to the same influent situation (Figure 5b). Further confirmations are under study.

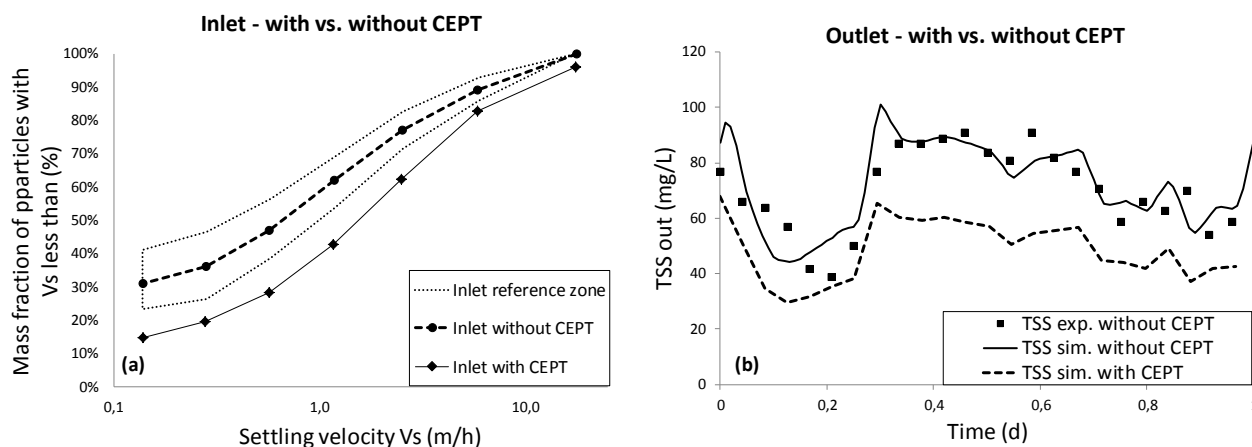

Figure 5 (a) Comparison of PSVD observed at the PST inlet during operation without CEPT and with CEPT. The reference zone illustrates typical PSVD observed at the PST inlet in Québec City, Canada, without CEPT (Maruéjols *et al.*, 2011). (b) PSVD model fit for effluent TSS concentrations without CEPT and simulation with CEPT.

SIMPLIFIED CEPT MODEL

As an alternative to the relatively complex PSVD model, a simple model for chemically enhanced primary settlers was developed by Tik *et al.* (2013) with the dedicated objective of having a model that can be used for the development of a controller for chemical addition. Without the need for ViCAs characterisation, the effect of alum addition was modelled by varying two settling characteristics in the settling velocity function: the overall particle settling velocity (V_0) (Figure 6a) and the fraction of non-settleable suspended solids (f_{ns}) (Figure 6b). The proposed model allows the primary settlers' outlet concentration of TSS to be properly simulated during an experiment of full-scale alum addition with step concentration changes (Figure 6c) and seems sufficiently robust to satisfactorily describe dry weather conditions as well as wet weather conditions. Further validation on other case studies is required to confirm the usefulness of the model for this type of control development and tuning studies.

Figure 6 Dependency of (a) the non-settleable fraction of TSS (f_{ns}) and (b) settling velocity, V_0 , on alum concentration (C_{alum}); (c) experimental (inlet and outlet) and simulated (outlet) TSS concentrations of a full-scale experiment in Québec City, Canada, on August 25th, 2011. The flow rate was approximately constant at 9,300 m³/h (Tik *et al.*, 2013).

With this model Tik *et al.* (2013) developed a successful control loop using effluent turbidity measurements that could reduce alum addition by 30% compared to a constant alum addition and yielding the same performance in terms of maximum TSS concentration in the primary effluent.

ASM FRACTIONATION IN PRIMARY TREATMENT

Primary treatment removes particles from the wastewater and as such changes its composition. These changes can be expressed in terms of several calculated ratios of traditional pollutant characteristics (Table 2). Fractionation of wastewater is thus affected by primary settling, thus impacting the subsequent treatment processes (Kristensen *et al.* 1992, Pasztor *et al.* 2009).

For the correct model-based evaluation of a WWTP in which ASMs are used to describe the subsequent bioreactor models, a proper prediction of the primary effluent into the ASM input fractions is required. However, the effect of the PST on these fractions is frequently overlooked or oversimplified (the fractions in the PST are assumed to remain constant under all conditions). Note that the models described above only focus on TSS removal prediction and do not consider variations in fractionation in the primary settler.

Table 2. Differences in typical ratios of traditional wastewater characteristics of raw influent and primary effluent of municipal wastewater treatment (redrafted after Rieger *et al.*, 2012) and comparison with Québec City ratios.

		Ratio	Unit	n ¹⁾	mean	Std% ²⁾		n	Mean	Std%

¹⁾ number of answers; ²⁾ standard deviation in %

Therefore, to better describe the subsequent biological treatment by providing a good fractionation, primary settling was also studied from an ASM point of view, taking inlet and outlet samples from primary settlers at three different WWTPs (Eindhoven, Roeselare and Québec City). The samples were analysed in terms of COD fractions into four components: the readily biodegradable COD, S_B ; the slowly biodegradable COD, XC_B ; the inert soluble COD, S_U ; the inert particulate COD, $X_{U,Inf}$ (notation from Corominas *et al.*, 2010). For the Québec City samples, these fractions were determined by combining a respirometric protocol together with total (COD) and soluble (sCOD) COD analysis and ultimate BOD (UBOD) measurements (Petersen *et al.*, 2003). S_B directly resulted from the respirometric test on the wastewater sample, while XC_B , S_U and $X_{U,Inf}$ were calculated as follows: $XC_B = UBOD - S_B$; $S_U = sCOD - S_B$; $X_{U,Inf} = COD - sCOD - XC_B$. For the WWTPs of Eindhoven and Roeselare both a respirometric evaluation and the STOWA method (Roeleveld and van Loosdrecht, 2002) were applied. The two protocols resulted in different COD fractions for the same wastewater sample. Nevertheless, both showed that primary treatment has a significant impact on the ASM1 fractions. Primary treatment yielded a significant variation of the particulates ratio ($XC_B/X_{U,Inf}$) (on average 1.9 to 1.2 for the Eindhoven, 1.1 to 0.5 for the Roeselare and 1.5 to 1.8 for the Québec City experiments), while, as expected, the soluble ratio (S_U/S_B) was not affected by the primary settler (Figure 7).

Figure 7 Evolution of COD fractions before and after a PST at three WWTPs: Eindhoven (The Netherlands), Roeselare (Belgium) (both by the STOWA protocol) and Québec City (respirometric protocol).

In the Québec WWTP a more detailed analysis was conducted. The wastewater samples could be classified into two types: a low loaded one (sampled at nighttime) and a heavily loaded one (sampled at daytime). According to this classification, by comparing inlet and outlet samples different trends in the aforementioned ratios were noticed: the particulate ratio ($X_{CB}/X_{U,Inf}$) systematically decreases for daytime samples, but increases for wastewaters collected at nighttime. Moreover, some work was also conducted on samples collected after addition of chemicals. It was found that both the particulate and the soluble ratios tend to increase, i.e. the primary effluent contains relatively more biodegradable material than the influent.

These first results, although requiring further investigation, show that primary treatment has a significant impact on the ASM1 fractions. Therefore, the influence of the PST on the wastewater characterisation cannot be neglected and a proper COD fractionation into model variables can significantly improve simulation results. For instance, by applying the PSVD model concept to the mass balances of the ASM fractions in the primary settler model, i.e. having five classes for each of the ASM fractions, it will be possible to make them settle at different velocities, allowing the observed increase in ratios to be predicted properly. This will result in an appropriate fractionation at the primary settler effluent.

CONCLUSIONS

All studies presented in this contribution focus on primary settlers. The authors believe that PSTs need to be properly modelled and characterised in view of whole plant and resource recovery modelling. A new experimental and modelling approach, based on Particle Settling Velocity Distributions (PSVD), is proposed, and was shown to successfully predict TSS effluent concentrations on the basis of influent TSS time series and a number of ViCAs characterisation experiments. Simulation results under calibration and validation of the model were presented. It is illustrated that this approach can also be used to characterise primary influent under addition of chemicals, representing a potentially useful tool for the modelling of PSTs under CEPT. In addition, a simpler settler model, in view of controller development for CEPT, was presented as an alternative to the particle classes-based model. Finally, wastewater fractionation results obtained for the influent and the effluent of PSTs have shown, for the first time, that the primary settler produces a significant change in the wastewater composition ratios and, as a consequence, in the ASM fractionation of the wastewater. Hence, it can be anticipated that a more detailed primary settler model with explicit consideration of ASM fractions may be needed to properly feed the subsequent bioreactor models of a whole plant and resource recovery model.

ACKNOWLEDGEMENT

The authors would like to acknowledge the whole primEAU team for its contribution. Funding for this work comes from the Natural Sciences and Engineering Research Council of Canada (NSERC/CRSNG), John Meunier and Québec City. Peter Vanrolleghem holds the Canada Research Chair on Water Quality Modelling. The authors also want to acknowledge Aquafin N.V. and Water board the Dommel for giving the opportunity to and assisting in the set-up of the sampling, testing and modelling.

Abstract

The objective of this work was to assess the impact of filamentous bacteria on the settling velocity and rheological behaviour of activated sludge. We then identified the relevant settling and rheological model parameters to account for the impact of filamentous bulking on the prediction of sludge mixing and transport in secondary settling tanks by a computational fluid dynamics (CFD) model. We identified the relevant settling velocity and rheology model parameters influenced by the filamentous bacteria content of activated sludge. The hindered, transient, and settling parameters of the settling velocity model proposed in our previous study were estimated using measurements from batch settling tests with a novel column setup. Additionally, the rheological measurements from experiments with a rotational viscometer were used to calibrate the Herschel-Bulkley rheology model including the rheology correlations with the sludge concentration obtained in our previous study. Both settling and rheological tests were performed with sludge samples collected biweekly from the Lundtofte wastewater treatment plant in a four-month measurement campaign. Quantitative fluorescent in-situ hybridisation (qFISH) analysis was carried out on the sludge samples to quantify the volume fraction of filamentous bacteria. Based on the correlations of settling and rheological model parameter values with the volume fraction of filamentous bacteria, we identify the significant impact of filamentous bacteria on the hindered settling of activated sludge. However, no significant impact on the transient and compression settling model parameters was observed. This study also finds that microbial filaments residing inside the microbial flocs can significantly alter the rheological behaviour of activated sludge. A two-dimensional, axi-symmetrical CFD was used to assess the impact of calibration scenarios for settling and rheology under low and high abundance of filamentous bacteria on the CFD predictions. Results obtained suggest that the influence of filamentous bulking on the settling and rheology of activated sludge can affect the solids distribution and transport in the SSTs.

INTRODUCTION

Secondary settling tanks (SSTs) are located after the biological reactors in wastewater treatment plants (WWTPs) to separate the treated water from the microbial mass by means of

gravity sedimentation. The clarification and thickening performance of SSTs depend on their hydraulic features as well as the settleability of activated sludge. A malfunctioning SST with a poor quality effluent in terms of suspended solids and insufficiently thickened sludge for recycling to the reactors, impacts the sludge retention time (SRT) in the system, and potentially deteriorates the performance efficiency of the biological processes. Moreover, SSTs are the hydraulic bottlenecks of WWTPs. The efficiency of SSTs can limit the maximum flow rate entering the WWTPs under wet-weather conditions.

A common operational problem in SSTs is the poor settling of activated sludge resulting from the excessive growth of filamentous bacteria, which prevents the formation of well-settling sludge (Wanner, 1994). Activated sludge flocs have a very heterogeneous structure, which consists of a variety of microorganisms as well as organic and inorganic particles and dead cells surrounded by extracellular polymeric substances (Wilén *et al.*, 2008). The operational and seasonal variations in activated sludge units, such as dissolved oxygen concentration, nutrient deficiency and substrate limiting conditions, influence the structure of the growing flocs in bioreactors (Comas *et al.*, 2008). However, the exact cause of filamentous bulking can be very diverse (Jenkins *et al.*, 1993), and is not fully understood (Mielczarek *et al.*, 2012). A common approach to identify filamentous bulking is to detect and quantify the content of filamentous bacteria in activated sludge samples by performing quantitative fluorescent *in-situ* hybridisation (qFISH) analysis (Nielsen *et al.*, 2009).

In WWTP modelling, conventionally, the influence of filamentous bulking is accounted for by modifying the hindered settling parameters in the settling velocity formulation in the SST models (Ekama *et al.*, 1997). Several studies have shown the relation between the morphology of bulking sludge and settling parameters (Grijpspeerdt and Verstraete, 1997; Jin *et al.*, 2003; Wilén *et al.*, 2008). However, the question arises whether filamentous bulking can also affect the transient and compression settling as well as the rheology of activated sludge and how these effects influence the sludge distribution in the SSTs.

Computational Fluid Dynamic (CFD) models have been used to predict the internal flow and solids transport in SSTs (Deininger *et al.*, 1998; Lakehal *et al.*, 1999; De Clercq, 2003; Weiss *et al.*, 2007). CFD models are computationally heavy, and they are thus mainly used for the purpose of design of new SSTs, or optimization and trouble shooting of existing SSTs. However, validated CFD models can replace expensive field experiments to calibrate and validate one-dimensional models (De Clercq, 2003; Plósz *et al.*, 2007). The non-Newtonian behaviour of activated sludge as well as its hindered and compression settling behaviour have significant impacts on the overall solids transport in the SSTs (Ekama *et al.*, 1997). Thus, the accurate CFD prediction of hydrodynamics and solids distribution in the tank requires inclusion of optimized setting and rheology models.

In this study, we used a validated two-dimensional, axi-symmetrical CFD model with settling velocity and rheology models developed in our previous study (Ramin *et al.*, 2014) to simulate the sludge distribution in the SST at Lundtofte WWTP. Additionally, we used the long-term settling and rheological measurements, as well as qFISH analysis performed by Wágner *et al.* (2014) on the sludge samples from Lundtofte WWTP.

The main objectives of this study are (i) to assess the impact of filamentous bacteria on hindered, transient and compression settling as well as the rheological behaviour of activated sludge based on the measurements with activated sludge of varying filamentous bacteria abundance, (ii) to identify the relevant settling and rheological model parameters, and finally

(iii) to investigate how the effect of filamentous bulking on the model parameters can influence the prediction of sludge mixing and transport in SSTs by the CFD model.

MATERIAL AND METHODS

Laboratory experiments

In this section, the settling and rheology experiments, as well as qFISH analysis (Fig. 1) performed by Wágner *et al.* (2014) are briefly described.

Figure 1. The laboratory set-ups for the settling (a), rheology (b), and qFISH (c) experiments performed by Wágner *et al.* (2014) .

Sampling. Activated sludge samples were collected biweekly for four months from the combined recycle flow at Lundtofte WWTP (Lyngby, Denmark). The samples were used on the same day of collection for settling experiments, and some were stored in 4 °C for rheology experiments on the next day. The concentration of sampled sludge was determined using method 2540 D of Standard Methods (APHA, 1995). Additionally, some sludge was pre-treated and fixed with 4 % paraformaldehyde to preserve its initial state, and then stored at -20 °C until the qFISH analysis.

Settling tests. Settling tests were performed using the newly developed settling column set-up (Ramin *et al.*, 2014), consisting of a large settling column (diameter = 20 cm, Height = 80 cm) with a total suspended solids (TSS) sensor (Solitax®, Hach Lange, Germany) installed at the bottom of the settling column (Fig. 1a). Prior to each settling test, the sludge sample was diluted with the SST effluent in the settling column and homogenized with coarse-bubble aeration. During each 60-minute settling test, the evolution of sludge blanket height (*SBH*) and the sludge concentration at the bottom (X_b) were recorder. Next, the settled sludge was re-homogenized and diluted to a lower concentration. Overall, the settling tests were performed at sludge concentration in the range 1.5–4.5 g/l.

Rheology measurements. The rheological experiments were performed using a standard rotational rheometer (TA Instruments AR2000, USA) with a conical single-gap cylindrical geometry (Fig. 1b). The experiments were performed on sludge samples diluted with SST effluent over the concentration range of 5–12.8 g/l under shear-stress controlled conditions to obtain shear rates in the range of 0.001–250 s⁻¹. The shear stress was applied from high to low values to minimize the sludge settling problem in the sample during the tests.

FISH analysis. The qFISH procedure was conducted using 1 μ l of fixed sample taken from the activated sludge used in the settling and rheological experiments. The total amount of bacteria and the specific filamentous bacteria were targeted with two different fluorescently-labelled probes (MPA mix: MPA 645, MPA 223, MPA 60). A confocal laser scanning microscope (LEICA SP5®, Leica, Germany) was used to assess the samples with 20x magnification and 2x zoom (Fig. 1c). 15-20 randomly chosen images were taken using the confocal microscope (Nielsen *et al.*, 2009). The images were analysed using the *daime* (digital image analysis in microbial ecology) software (Daims *et al.*, 2006). We note that, in the study of Wágner *et al.* (2014), the two dominant microbial species namely *Chloroflexi spp.* (CFX) and *Microthrix parvicella* (MPA) were identified in the activated sludge samples. In the present paper, we only present results obtained on the impact of the MPA volume fraction on the settling and rheological behaviour of activated sludge. For further information on the study, readers are kindly referred to Wágner *et al.* (2014).

Numerical modelling

Description of the SST. The SST under study is part of the Lundtofte WWTP (Lyngby, Denmark). It is a circular centre-feed conical tank with a diameter of 24.5 m and an average depth of 4 m.

CFD simulations of the SST. The CFD simulations of the SST was executed in OpenFOAM CFD toolbox (OpenCFD, 2012) and using the settlingFoam solver (Brennan, 2001). The physics of the solver is based on the average Eulerian two-phase flow combined with the modified k- ϵ model, accounting for density stratification. To predict the distribution of solids, a convection-diffusion equation derived from the continuity equation for the solid phase (drift flux model) is coupled with the momentum and turbulence equations in the solver.

To reduce the computation effort, the flow in the SST is assumed to be axi-symmetric, and only a radial segment of the tank is considered for CFD modelling. The geometry is discretised with around 6000 polyhedral grids in depth and radial directions (Fig. 2). The imposed boundary conditions are as follows. The water-surface is modelled as a symmetry-plane, i.e. normal gradients to the surface are zero. The inclined bottom is considered as a frictionless boundary to simulate the effect of an ideal scraper facilitating the sludge flow to the hopper by overcoming the wall stress, as proposed by Deininger *et al.* (1998). The rest of the walls were considered as no-slip with standard wall-functions to approximate the mean velocity near the wall.

Figure 2. The 2-D axi-symmetric mesh with about 6000 polyhedral grids generated in STAR-CCM+® and implemented in OpenFOAM for CFD simulations of the circular SST at Lundtofte WWTP.

THE SETTLING VELOCITY AND RHEOLOGICAL MODEL

The settling velocity model

The settling velocity model developed by Ramin *et al.* (2014) accounts for hindered, transient and compression settling regimes that are typically observed in the activated sludge batch settling tests. This model was developed based on an evaluation of state-of-the-art settling velocity models with measurements from the simple, novel batch settling experimental set-up explained in the previous section.

The widely used double-exponential hindered settling velocity model developed by Takács *et al.* (1991) and the mechanistic compression settling velocity model based on phenomenological sedimentation-consolidation theory (Bürger, 2000; Kinnear, 2002; De Clercq, 2006) with the empirical effective solids stress formulation developed by De Clercq *et al.* (2008) were evaluated based on their predictions of the *SBH* and X_b measurements. To evaluate these settling velocity models, the different models were implemented in a dynamic 1-D model of the settling column, developed based on a modified form of the 1-D SST model by Plósz *et al.* (2007), i.e. using a discretisation level of 60 layers and the numerical fluxes treated with the Godunov scheme (Bürger *et al.*, 2011). The differential mass conservation equation is

$$\frac{\partial X}{\partial t} - \frac{\partial(v_s X)}{\partial z} = 0 \quad (1)$$

where X is the sludge concentration, t denotes time, v_s is the settling velocity model, and z is the depth in the column. We note that using the compression formulation in Eq. 1 yields a second order partial differential equation.

Results obtained by Ramin *et al.* (2014) show that, using Takács hindered settling velocity model with the hindered parameter (v_0 , and r_H , Vesilind, 1968) estimated directly from the *SBH* measurements the predictions were shown to diverge from the *SBH* and X_b measurements during the transient and compression regime. Furthermore, including the mechanistic compression settling velocity model with the effective solids stress formulation of De Clercq *et al.* (2008) was shown to over-predict the X_b data when it was calibrated to the *SBH* data only. Consequently, a new power formulation for the effective solids stress was developed to improve the predictions of X_b . Finally, by applying an exponential transition formulation in the compression zone, the best prediction of X_b data could be achieved. The formulation of the settling velocity model is

$$v_s = \begin{cases} v_0 e^{-r_H \cdot X} - v_0 e^{-r_p \cdot X} & X < X_c \\ v_{0,t} e^{-r_t X} \left(1 - \frac{\rho_s}{(\rho_s - \rho_f) g X} \left(\frac{X - X_c}{C_1}\right)^{c_2} \frac{dX}{dz}\right) & X \geq X_c \end{cases} \quad (2)$$

where v_0 is the maximum settling velocity; r_H and r_P are the hindered and low concentration indices, respectively; $v_{0,t}$ and r_t are the transient settling parameters; C_1 and C_2 are parameters in the compression settling model; ρ_s and ρ_f are the sludge and water density, respectively; g denotes the gravity constant; C_1 and C_2 are compression parameters; and X_C is the threshold compression concentration. Fig. 3 illustrates the prediction of the sludge profile in the settling column by simultaneously calibrating it to the SBH and X_b measurements using the adaptive Markov Chain Monte Carlo (MCMC) Bayesian global optimization method $DREAM_{(ZS)}$ (Laloy and Vrugt, 2012). Using the $DREAM_{(ZS)}$ optimization algorithm, the prediction uncertainty of the settling velocity model for the estimated parameters can be obtained from the posterior parameter distributions. Fig. 4 shows the prediction accuracy of the settling velocity model for the measurements with sludge samples taken from two WWTPs in Denmark, Lundtofte (PE= 135.000, SRT = 31 d) and Lynetten (PE= 750.000, SRT = 29 d).

Figure 3. Prediction of the settling velocity model (Ramin et al., 2014) calibrated to the SBH and X_b measurements by implementing it in a 1-D settling column model (with 60 layers discretization). The lines correspond to the simulated evolution of sludge concentration in each layer.

Figure 4. Predictive uncertainty (95% confidence intervals of the model prediction due to parameter uncertainty) of the settling velocity model calibrated to the measurements with the Lundtofte and Lynetten WWTP sludge using the DREAM_(ZS) optimization algorithm.

The Rheological model

The rheological measurements can very accurately described with the yield-pseudoplastic type Herschel-Bulkley rheology model (e.g., Ratkovich *et al.*, 2013):

$$\eta = \frac{\tau_0}{\gamma} + K\gamma^{n-1} \quad (3)$$

where η is the apparent viscosity, τ_0 is the yield stress, γ is the shear rate, K is the consistency index, and n is the flow behaviour index. Fig. 5 shows the predictions of the Herschel-Bulkley model for one set of measurements with different sludge concentrations. A constraint of maximum viscosity was set for the Herschel-Bulkley model for the shear rates of below 0.01s^{-1} to avoid unrealistic prediction of apparent viscosity values at very low shear rate conditions.

Figure 5. An example on the prediction of activated sludge apparent viscosity with the Herschel-Bulkley model (Eq. 3), shown for one set of the rheological measurements (out of eight) with different sludge concentrations.

The estimated parameters of the Herschel-Bulkley model (τ_0 , K , and n) were correlated to the sludge concentration with the correlations presented in our previous study (Ramin *et al.*, 2014), e.g. for yield stress, the following power formulation was used:

$$\tau_0 = AX^B \quad (4)$$

where A and B are the yield stress correlation parameters.

RESULTS

Impact of filamentous bulking on settling

Hindered settling. Fig. 6a illustrates the relation between the ratio of hindered settling parameters (v_0/r_H) estimated from the settling measurement sets, and the volume fraction of *Microthrix parvicella* (MPA) filamentous bacteria. The decreasing trend of v_0/r_H with increasing filament volume fraction (i.e. development of filamentous bulking sludge) is in line with conventional theory (Ekama *et al.*, 1997).

Figure 6. Correlation of the ratio between the hindered settling parameters with the volume fraction of MPA filamentous bacteria in the activated sludge (a), and dependency of the compression settling parameter on the initial sludge concentration in each settling test (b). The hindered parameters were estimated for the eight measurement sets (one outlier), and the compression settling parameter were estimated for each settling test (3 to 4 tests for each measurement set).

Transient and compression settling. We further assessed the influence of filamentous bacteria on the transient and compression settling processes, characterised by parameters r_t and C_2 , respectively (Eq. 2). No clear relation between these parameters and the volume fraction of filamentous bacteria was observed (data shown by Wágner et al., 2014). The estimated values of r_t were obtained in a narrow range (0.6–1.0 l/g) regardless of the sludge concentration and the filamentous bacteria content. On the other hand, the estimated values of C_2 were scattered in a wider range (0.1–0.8, dimensionless). The dependency of C_2 on the sludge concentration is further investigated in Fig. 3b, showing C_2 as a function of the initial sludge concentration in the settling column tests.

Based on Fig. 3b, no effective correlation between C_2 and X or distinct tendencies under bulking and no-bulking conditions (defined based on the MPA volume fraction – cut-off value: 1.5%) can be observed. The 95% confidence interval (defined by the dashed lines in Fig. 4) shows a relatively high uncertainty in estimating the value of C_2 based on the initial sludge concentration of the settling tests. For the CFD model (Ramin et al., 2014), the value of C_2 is determined based on the SST feed concentration (3 g/l). Therefore, later in this paper it is investigated if the variability of C_2 parameter values (see Fig. 3b) causes any significant variation in the CFD simulation results of an SST.

Impact of filamentous bulking on rheology

We investigated how the rheological behaviour of activated sludge is influenced by the presence of filamentous bacteria. The Herschel-Bulkley rheology model (Eq. 3) was calibrated to the eight rheology measurement sets (each set includes measurements with four to five different sludge concentrations). The estimated rheology parameters (τ_0 , K , and n) were then correlated to the volume fraction of MPA filamentous bacteria in the sludge. Among the

three parameters, only the estimated yield stress values showed a higher degree of association with the volume fraction of MPA (see Fig. 7a). No significant influence on the behaviour index (n) and consistency index (K) was observed (data not shown). Fig. 7a shows a decreasing tendency in the value of yield stress with the increase in MPA volume fraction at high sludge concentrations (only the concentration range of 7.5–9.5 g/l is shown here).

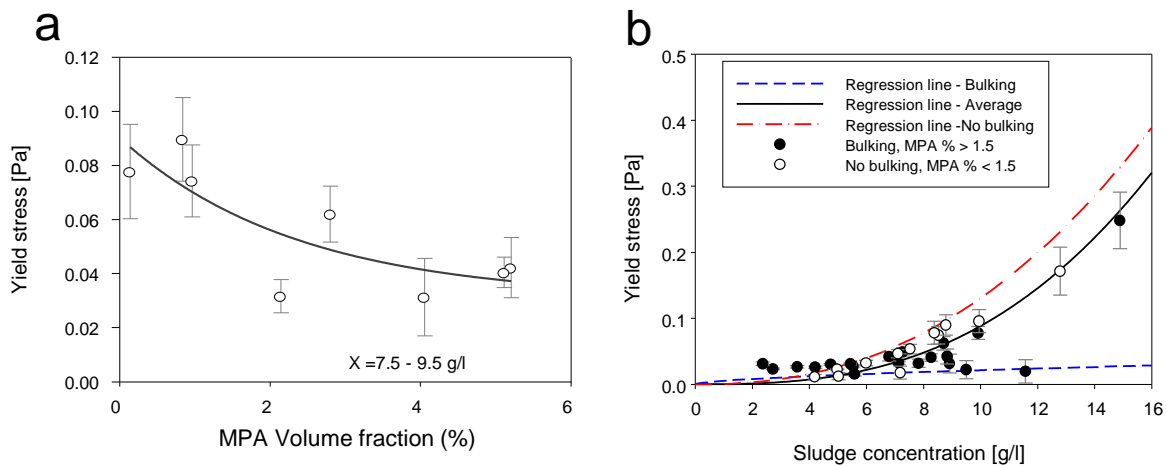

Figure 7. Dependency of yield stress of activated sludge on (a) the MPA filamentous bacteria (MPA) volume fraction for the concentration range of 7.5–9.5 g/l.

The reasoning behind the correlations shown in Fig. 7a can be explained as follows. The increase in the content of MPA filament, residing inside the flocs as the backbone of the flocs, influences the bulkiness of the flocs. As stated by Eshtiaghi *et al.* (2013), the increase of sludge water content can decrease the sludge viscosity. Since MPA resides in the floc, a high abundance of this filament can result in high bound water content, which would explain the observed decrease of yield stress. These results suggest that the filaments residing in the flocs mixture can impact the rheology of activated sludge.

Based on Fig. 7b, the estimated yield stress values shows an overall dependency on the sludge concentration (solid line in Fig. 7b), which confirms the proposed correlation (Eq. 4) in our previous study. However, the values are more scattered with the increase in the sludge concentration. Consequently, two power formulations are fitted to the lower and upper data points to determine the interval of the estimated yield stress values (the two dash lines in Fig. 7b). Based on Fig. 7b, good settling (or no bulking) condition, characterised with low MPA filament presence (<1.5 %) can increase the yield stress, which then corresponds to values closer to the upper curve (dashed-dotted line in Fig. 7b). On the other hand, bulking conditions (MPA volume fraction > 1.5 %) can decrease yield stress, which corresponds to values closer to the lower curve (dashed line in Fig. 7b).

CFD simulations

Based on the above observations, it is investigated here how the influence of filaments filamentous organisms can impact on the hindered settling and yield stress of sludge, and thus the sludge distribution and hydrodynamics in the SST can influence the using CFD scenario simulations. Moreover the influence of uncertainty in estimating the compression parameter (C_2) on the variation of the CFD simulation results is assessed. Table 1 summarizes the CFD simulation cases and includes only the values of the parameters under investigation that were

obtained from Figures 6a, 6b and 7b. In the first case, the impact of C_2 is assessed by keeping the hindered and rheology parameters to the average values, and changing C_2 to the minimum and maximum values at the feed flow sludge concentration to the SST ($X_F = 3$ g/l) based on Fig. 6b. In the second case, the no bulking and bulking conditions are imposed to the CFD model by applying the minimum (0.1 % MPA) and maximum (extrapolated to 9% MPA) values of the hindered settling velocity parameter values based on Fig. 6a and the correlations of τ_0 to sludge concentration with the upper and lower curves in Fig. 7b.

Table 1. The CFD simulation cases and the values of the settling and rheological model parameters under investigation.

CFD simulation cases						
			Impact of C_2 (Case I)		No bulking vs. Bulking (Case II)	
			 C_2 X_{Feed} (Fig. 6b)		 v_0/r_H τ_0 No bulking Bulking MPA (%) X (Fig. 6a) (Fig. 7b)	
	Par.	Unit	$C_{2,min}$	$C_{2,max}$	No bulking	Bulking
	C_2	-	0.07	0.6	0.34	0.34
Settling (Eq. 2)	r_H	l/g	0.48	0.48	0.44	0.57
	v_0	m/s	0.0013	0.0013	0.0027	0.0029
Yield stress (Eq. 4)	A	Pa	0.0002	0.0002	0.0006	0.0051
	B	-	2.75	2.75	2.32	0.62

Case I. Fig. 8 illustrates the impact of the uncertainty in correlating the compression settling parameter C_2 with the initial sludge concentration (Fig. 6b) on the CFD simulation results. The uncertainty of C_2 is shown to result in about 10-30% variation in the pre-diction of sludge blanket height (Fig. 8a) and up to 50% in the maximum radial velocity in the density current (Fig. 8b). These results imply that the uncertainty in estimating C_2 needs to be reduced probably by performing additional settling measurements.

Figure 8. The variation in the prediction of the vertical profiles of sludge distribution (a), and radial velocity (b) by the CFD model due to uncertainty in the compression parameter (C_2). The profiles with solid lines are predicted with $C_{2, max}$, and the profiles with dashed lines are predicted with $C_{2, min}$. Profiles are shown with normalized height at four different radial distances from the centre of the tank.

Case II. To assess the impact of yield stress and hindered settling on CFD model prediction, the value of C_2 is set constant to an average value of 0.34. Fig. 9 illustrates the CFD simulations based on the impact of filamentous bulking on the hindered settling parameters and yield stress. The rise in the sludge blanket height is up to 20% under the bulking condition (dashed lines in Fig. 9). Moreover, the slight increase in the flow of thickened sludge over the inclined bottom to the hopper can be observed in Fig. 9b due to the reduced yield stress under bulking condition. In general, the impact of hindered settling velocity parameter values and yield stress under bulking is not straight forward. This is because these parameters influence the complex interaction between the sludge distribution and hydrodynamics of the tank.

Figure 9. The predicted sludge distribution (a), and radial velocity (b) with the CFD model considering the influence of bulking (dashed line) and no bulking (solid line) on the estimated yield stress and hindered settling parameters. For more information see caption of Fig. 8.

CONCLUDING REMARKS

This study investigated whether the volume fraction of *Microthrix parvicella* (MPA) filamentous bacteria, as quantified with qFISH analysis, can influence the settling and rheology of activated sludge as characterized by settling and rheology measurements. The activated sludge was sampled biweekly, during a period of four months from Lundtofte WWTP. The model parameters were estimated for the settling velocity model (Eq. 2) including hindered, transient and compression settling, and rheology (Herschel-Bulkley model, Eq. 3). Results obtained suggest that the abundance of MPA – identified as a species residing predominantly inside the microbial flocs – associates with hindered settling velocity and yield stress parameters. The obtained compression and transient settling parameters show high and low variability, respectively, in the four-month period; and, the filamentous bacteria are found not to directly relate to any of these parameters. The generality of the observations made in this study may be limited by the variability of the abundance of the filamentous bacteria during the four-month period. Therefore, future research on the association of microbial structure with functional characteristics will require higher filamentous bacteria levels than those shown in this contribution. Additionally, the impact of model structure and functionality of the events on the estimation of sludge retention time in the system should be evaluated in the future. Numerical simulations were performed using a validated CFD model from our previous study with full scale profile measurements under normal operational conditions. To further improve the prediction of the filamentous bulking effect on the sludge distribution of SSTs with the CFD model, full-scale profile measurements on the SST under filamentous

bulking conditions could possibly yield more insight into the solids mixing and transport in SSTs, and would therefore be desirable to further investigate in the future.

ABSTRACT

For implementing short cut nitrogen removal processes for mainstream wastewater treatment, out-selection of nitrite oxidizing bacteria (NOB) to limit nitrate production is the main challenge. A model-based approach was utilized to simulate the impact of individual features of process control strategies to achieve the NO_2^- -N shunt via NOB out-selection. Simulations were conducted using a two step nitrogen removal model from the literature. Nitrogen shortcut removal processes from two case studies were modelled to illustrate the contribution of NOB out-selection mechanisms. The paper highlights a comparison between two control schemes, i.e. ammonia-based control and the novel AVN [AOB Vs. NOB] control, recently described in the literature. Results indicate that the AVN controller possesses unique features that promote a better management of incoming organics and bicarbonate, which optimizes both NH_4^+ -N removal rates as well as NO_2^- -N & NO_3^- -N removal. Moreover, it allows for a more efficient NOB out-selection. Finally, the model was used in a scenario analysis, simulating hypothetical optimized performance of the pilot process. An estimated potential saving of 60% in carbon addition for nitrogen removal by implementing full-scale mainstream deammonification was found.

Anammox, AOB seeding, mainstream deammonification, NO_2^- -N shunt, NOB out-selection, online control, transient anoxia

INTRODUCTION

Traditional nitrogen removal processes are high energy consumers and not cost-effective which is a serious downside of currently used technology where cost and energy reduction are pursued. Shortcut nitrogen removal processes provide a superior alternative to conventional processes used in municipal wastewater treatment (i.e. nitrification-denitrification) since they significantly reduce oxygen demand and external carbon requirements (Vlaeminck *et al.*, 2012). These processes involve the creation of unique conditions to steer the biological conversion of oxidizable nitrogen (i.e. NH_4^+ -N and organic nitrogen) to nitrogen gas by taking a 2-step pathway shortcut and thus conserve energy. There are two main shortcut nitrogen removal processes i.e. nitrification-denitrification and deammonification via anammox. In both processes, the first step of the nitrogen shortcut pathway is converting NH_4^+ -N via ammonia oxidizing bacteria (AOB) to NO_2^- -N only. This requires repressing the NOB population to avoid producing NO_3^- -N. The second step can either be converting NO_2^- -N to N_2 gas via heterotrophic bacteria using organic carbon or via anammox bacteria without the need for organic carbon. These processes have already been implemented and controlled successfully for sidestream (i.e. nitrogen rich warm streams) treatment and the operational savings were

reported in the literature (Wett, 2007). In contrast, the potential operational savings using shortcut nitrogen removal processes can be significantly higher for mainstream applications with 40% savings for nitrification/denitrification process and 84% saving for the deammonification process compared to conventional nitrification/denitrification (De Clippeleir, 2012). In addition, potential savings in capital costs for new systems and increase in capacity for converted systems are anticipated. The savings are associated with low sludge production of 0.6 kg/kgN for nitrification/denitrification and 0.1 kg/kgN for deammonification compared to 1 kg/kgN for conventional nitrification/denitrification (De Clippeleir, 2012). These potential benefits however come with challenges associated with NOB outselection under cold and diluted loading conditions. While the operational strategies are well documented for sidestream applications (Gut *et al.*, 2005; Hellinga *et al.*, 1998; van de Graaf *et al.*, 1996; van Loosdrecht and Salem, 2005; Wett *et al.*, 2007), many recent studies were conducted to address these challenges for mainstream applications using nitrification/denitrification (Blackburne *et al.*, 2008; Gao *et al.*, 2009, 2014; Peng *et al.*, 2004, 2012; Regmi *et al.*, 2013) and deammonification (Al-Omari *et al.*, 2012; Hu *et al.*, 2013; Lotti *et al.*, 2013; Wett *et al.*, 2013; Winkler *et al.*, 2011) or both (Vlaeminck *et al.*, 2012; Stinson *et al.*, 2013). Several mechanisms were identified by which the three autotrophic groups, i.e. AOB, NOB & anammox, compete. These mechanisms include (1) operating at low dissolved oxygen (DO) concentration, (2) operating at high DO concentration, (3) operating with high residual ammonia, (4) transient anoxia where the process reactor is intermittently aerated either by turning the air flowrate on and off or by creating a spatial sequence of anoxic and oxic zones in the reactor. The use of transient anoxia is a commonly used approach for NOB out-selection (Li *et al.*, 2012, Ling, 2009, Pollice *et al.*, 2002, Rosenwinkel *et al.*, 2005, Zekker *et al.*, 2012). In the context of controlling the nitrogen process towards out-selection of NOB, transient anoxia provides means to control the aerobic SRT, as well as to introduce a lag-time for NOB to transition from the anoxic to aerobic environment, either due to NO_2^- -N limitation (Knowles *et al.*, 1966; Chandran and Smets, 2000) or by an enzymatic lag (Kornaros and Dokianakis, 2010). Aggressive SRT (i.e. near minimum SRT) is applied based on target removal rates and is controlled via manipulating wasting rates, aerobic volumes and DO setpoints to maximize NOB outselection potential (Regmi *et al.*, 2013; Wett *et al.*, 2013). For this study two case studies were selected for both shortcut processes using the HRSD pilot for nitrification/denitrification (Regmi *et al.*, 2014) and the DC Water pilot for mainstream deammonification (Al-Omari *et al.*, 2012). Figure 1 illustrates, using Monod functions of utilization rates as a function of DO, NH_4^+ -N and NO_2^- -N, some of the concepts used in these two case studies to maximize the rate differential between AOB and NOB to facilitate NOB out-selection.

MATERIALS AND METHODS

Long term experimental pilot tests

HRSD Pilot Study – AVN Controller

This pilot process is part of a larger configuration including a high rate activated sludge A-stage for COD removal providing the influent for the AVN controlled reactor (Miller et al., 2012) and a post-anoxic anammox moving bed bioreactor after the AVN controlled reactor allowing for a final polishing of the treated sewage. The reader is referred to Regmi et al. (2014) for detailed description of the pilot setup and operation. The AVN controlled process includes a single 340 L aeration tank operated as a continuously stirred tank reactor (CSTR) followed by a clarifier. Return activated sludge (RAS) from the clarifier is returned to the AVN reactor at 100% of the influent flow rate. SRT is controlled by wasting solids from the bioreactor with a programmable digital peristaltic pump. The reactor is equipped with sensors for NO_3^- -N, NO_2^- -N (Scan Spectrolyser, Austria), DO (Hach LDO, CO, USA), and NH_4^+ -N (WTW VARIO, Germany). NH_4^+ -N, NO_3^- -N, NO_2^- -N signals are used to control aeration (Figure 2).

To impose conditions favorable for NOB out-selection and to provide an effluent suitable for anaerobic ammonia oxidation (AMX) polishing, an aeration controller was developed which uses online *in-situ* DO, NH_4^+ , NO_2^- and NO_3^- sensors. The first component of the AVN control is the aerobic duration controller with the goal of maintaining equal effluent NH_4^+ -N and NO_x -N (i.e. NH_4^+ -N/ NO_x -N = 1) in the AVN CSTR at all times. The latter would guarantee a treatable effluent for the final polishing step with AMX. The other component of the AVN control is the DO controller, which maintains the DO at a desired set-point during the aerated period (Figure 2).

Under the AVN strategy, NH_4^+ -N was compared to the sum of NO_2^- -N and NO_3^- -N (NO_x -N). Firstly, the cycle duration (aerobic duration + anoxic duration) had a defined minimum and maximum aerobic duration. The cycle duration was kept constant at 12 minutes during the entire experiment. As the AVN controller aims at ammonium concentrations equal to NO_x , aerobic duration is increased up to a predetermined maximum aeration time set-point, while maintaining the cycle duration constant at NH_4^+ -N over NO_x -N ratios greater than 1. When NH_4^+ -N was less than NO_x -N, aerobic duration was decreased until it reached the minimum aeration time. When aerated, the proportional-integral-derivative (PID) controller steered a mechanically operated valve (MOV) to maintain the target DO set-point of 1.6 mg/L. Figure 3 shows the effluent quality of the pilot reactor under AVN control in terms of the nitrogen species measured in daily grab samples. The chart demonstrates the balance between ammonia and NO_x as a result of the AVN control strategy.

DC Water Case Study – Ammonia based control

The objective of the pilot process at DC Water is to evaluate the mainstream deammonification feasibility at the Blue Plains Advanced Wastewater Treatment Plant (AWTP) with an emphasis on process controls. This process appears specifically appropriate for the existing process configuration with high up-stream carbon removal (primaries followed by a high-rate process achieving 85% overall efficiency) and chemical carbon

dosing downstream to meet the extremely low total nitrogen limit of 3.9 mgN/L. The deammonification pilot consists of a 200L activated sludge tank divided into 10 sequential aerobic and anoxic zones (D1 – D10) with dissolved oxygen and ammonia based controls. Oxygen level is maintained at 1.5 mg/L in the aerated cells where oxygen is measured using an LDO sensor (HACH, Düsseldorf, Germany). $\text{NH}_4^+\text{-N}$ is measured using an NH_4D sc ammonium sensor (HACH, Düsseldorf, Germany). $\text{NH}_4^+\text{-N}$ concentration in the

Figure 3. HRSD pilot reactor effluent quality when applying AVN control

last cell (D10) is maintained above 2 mg/L. Data acquisition and control is performed using Labview (National Instruments, USA). The aerobic SRT is modified by turning downstream swing zones into aerobic or anoxic zones and by adjusting wasting rates as needed to maintain target $\text{NH}_4^+\text{-N}$ concentration in cell D10. During the period selected for the simulation runs

the aerobic SRT was adjusted by modifying the wasting rates. Anammox seed is added to the reactor on a daily basis using sludge from a full-scale sidestream DEMON reactor and AOBs are seeded using the waste sludge from a bench-scale sidestream reactor that is proportional to the full-scale sidestream DEMON facility. Anammox is selectively retained in the system using sieves with mesh size No.70 and No.120 (or 212 micron and 125 micron). Downstream of the deammonification cells a polishing step is present which consists of 8 anoxic zones (P1 – P8). The post anoxic step is not discussed in this paper. Figure 4 shows the pilot reactor and the model configuration of the pilot.

Figure 5 shows the effluent quality of the pilot reactor under ammonia based control. One interesting observation from the chart is that NO_2^- -N accumulation was observed when NH_4^+ -N and NO_3^- -N (or NO_x) were in equilibrium. The figure also shows a profile across the reactor from cell D1 until P8. NO_2^- -N is produced in the aerobic cells in the deammonification reactor (D2, D5, D8 & D10). However, NOB out-selection is not effective as observed from the relative NO_3^- -N produced compared to NH_4^+ -N removed (>85%).

Case study pilot influent characteristics

Average influent characteristics for the pilot reactors are given in Table 1. One major difference is the carbon to nitrogen ratios which is much higher in the HRSD pilot reactor. Another difference is the aerobic fraction of the reactor volume.

Table 1. Case studies pilots reactors and average influent characteristics

Parameter	HRSD AVN Control	DC Water Ammonia Control
Flow, L/d	2,722	1,840
Total COD, mgCOD/L	303.0	40.3
Total Kjeldahl Nitrogen, mgN/L	39.0	24.5

NO ₃ ⁻ , mgN/L	0.0	0.5
NO ₂ ⁻ , mgN/L	0.0	0.2
Total P, mgP/L	4.7	1.1
Alkalinity, mmol/L	3.6	4.5
Reactor Type	CSTR	Step Feed-Plug Flow
Transient Anoxia	Time	Space
Total SRT (AVG), day	6.5	8.7
aerobic fraction (AVG), %	64	22

Modelling approach

The model used for the simulations is based on the two step nitrogen model proposed by Jones et al. (2007) (Table 2). The oxygen half saturation concentrations for AOB, NOB and anammox were modified using the calibrated values reported by Al-Omari et al. (2012), which were based on actual measurements using SBR reactors.

Table 2. Autotrophic Biomass Model Parameters (Default Parameters - Jones et al., 2007).

Parameter	AOB	NOB	Anammox
Max. spec. growth rate [1/d]	(0.9)	(0.7)	(0.1)
Arrhenius on max. spec. growth rate	(1.072)	(1.06)	(1.1)
Substrate (NH ₄) half sat. [mgN/L]	(0.7)	-	(2)
Substrate (NO ₂) half sat. [mgN/L]	-	(0.05)	(1)
Aerobic decay rate [1/d]	(0.17)	(0.17)	(0.019)
Anoxic/anaerobic decay rate [1/d]	(0.08)	(0.08)	(0.0095)
Nitrous acid inhibition constant [mmol/L]	(0.005)	(0.075)	-
NO ₂ ⁻ -N inhibition constant [mgN/L]	-	-	(1000)
NO ₂ ⁻ -N toxicity constant [L/(d mgN)]			(0.016)
DO half sat. [mgO ₂ /L]	0.4 (0.25)	0.14 (0.5)	0.05 (0.01)
bicarbonate switch [mmol/L]	0.75 (0.1)	(0.1)	(0.1)
Yield [mgCOD/mgN]	(0.15)	(0.09)	(0.114)

Notes: values in brackets are default values. Values in bold are modified values.

The default inorganic carbon half saturation concentration for all autotrophic biomass reported in the Jones model was set at 0.1 mmol/L while for sidestream application the recommended parameter was 4 mmol/L for AOB in line with recommendations by Wett et al. (2005). The reasoning is to eliminate the impact of inorganic carbon at typical residual concentrations observed in nitrogen removal systems. However, in bench-scale shallow reactors, CO₂ stripping is much greater than full-scale reactors and may become limiting to autotrophic bacteria (Wett et al., 2003). In addition, Guisasola et al. (2007) suggested that AOB were limited by inorganic carbon availability at concentrations as low as 3mmol/L while the NOB were not limited even at concentrations below 0.1 mmol/L. In this modelling exercise, a value of 0.75 mmol/L was used based on a calibration using ammonia removal profiles in the DC Water deammonification reactor (not shown). It was observed that the removals were lower at these conditions than expected by the model using the default inorganic carbon half saturation concentration (i.e. 0.1 mmol/L). To model the different impact of inorganic carbon on AOB and NOB, new equations describing the growth and decay of AOB were introduced to the model in a Gujer matrix format. A user defined parameter was used to represent AOB biomass while the growth rate of AOB (X_{aob}) in the global model was set to zero. Table 3 presents the modified AOB growth and decay rate equations and stoichiometric expressions.

RESULTS AND DISCUSSION

AVN vs. ammonia based control - Modelling

A simulation of the HRSD pilot reactor operation using average loading conditions to reach steady state was used as the starting point for any dynamic simulation. The model was able to predict average NH₄⁺-N, NO₃⁻-N and NO₂⁻-N. To allow controller performance comparison, the HRSD simulation of the pilot was operated with both strategies (i.e. AVN vs Ammonia-based control) side by side. Lacking an advanced controller simulator that is able to mimic the AVN control strategy for dynamic input, the reactor influent flowrate was modified to reflect a step change in influent mass loading [kg/d] by +25% of the average loading rate for 12 hours and -25% of the mass loading rate for the following 12 hours. In an AVN control mode, the aeration time was manually adjusted as the loading changed so that the balance between NH₄⁺-N and NO_x-N was maintained. The aeration time was reduced by 0.49 min during the low loading step and increased by 0.65 min during the high loading step. Under the ammonia-based control, the aeration time was manually adjusted as the load changes so that effluent NH₄⁺-N concentration was maintained constant. The aeration time was reduced by 1.63 min during the low loading step and increased by 3.25 min during the high loading step. Figure 6 shows the simulation output of the AVN and ammonia control modes.

Comparing the two simulation outputs reveals that nitrogen removal efficiency was increased by approximately 17.5% under the AVN control. Also, the stable alkalinity level in the reactor for the AVN simulation compared to that for the ammonia-based control is noteworthy. It is important to realize that the controller under the AVN strategy controls the NH₄⁺-N removal rate based on denitrification capacity. I.e. the aerobic SRT is adjusted so that NH₄⁺-N is nitrified only if the same amount of nitrogen can be removed via denitrification. This balancing action allows for more efficient use of the biodegradable carbon for nitrogen removal, recovery of alkalinity, and applying SRT pressure on NOB. In the ammonia-based control simulation, aeration is increased during high loading conditions to maintain the effluent NH₄⁺-N level. By increasing aeration time, more COD is

aerobically oxidized and more alkalinity is consumed. As alkalinity is consumed, $\text{NH}_4^+\text{-N}$ oxidation rates slowdown due to inorganic carbon limitation. In return, the controller increases the aeration time even further, which again will cause further COD oxidation and alkalinity suppression. This continues until the $\text{NH}_4^+\text{-N}$ concentration cannot be reduced any further. Table 4 summarises the comparison between AVN and ammonia-based controls with regard to nitrogen removal, oxygen demand and NOB levels. The comparison reveals that an 8.6% reduction in NOB concentration was achieved. This incremental reduction can be significant when combined with other incremental reductions due to other mechanisms such as AOB seed, which is discussed in the following section.

Figure 6. Simulation output for AVN (top) and ammonia based (bottom) controls for HRSD pilot reactor with 12 min cycle.

Impact of AOB seeding and SRT

Seeding AOB from a sidestream process that utilizes a shortcut nitrogen removal process can be beneficial to enhance NOB repression in mainstream processes with the aim of achieving the $\text{NO}_2^-\text{-N}$ shunt. Figure 7 illustrates the concept of seeding a tank with AOB rich waste from a sidestream process where the difference in critical SRT between AOB and NOB increases with the AOB seed mass introduced to the mainstream tank.

Table 4. Comparison between AVN and ammonia based control strategies in terms of total nitrogen removal, oxygen demand and NOB suppression for simulated HRSD pilot reactor.

	(1) AVN Control	(2) Ammonia Control	% Change [(1-2)/2]
Total Nitrogen Removal, (mgN/L)	28.9	24.6	17.5%
Oxygen consumed, (mg/L)	936	1024	-8.6%
NOB Concentration, (mg/L)	39.1	42.8	-8.6%

It is assumed that 20% of the influent load is recycled back and treated in the sidestream process. Simulations of the HRSD pilot reactor with (1) 50% seeding activity assuming that 50% of activity is lost due to the difference in temperature between sidestream and mainstream processes (Wett *et al.*, 2011) and (2) 100% seeding activity assuming no loss of activity were examined. The system SRT was reduced to maintain the same $\text{NH}_4^+\text{-N}$ removal rate in the system. Figure 8 shows the simulation output for AOB and NOB under both seeding conditions. The simulation showed that the gap between AOBs and NOBs widened with increased AOB seeding rate as evident by the AOB/NOB ratios.

$$SRT_{critical} = \frac{1}{(\mu_m - b)} * \left(\frac{M_{critical}}{M_{seed} + M_{critical}} \right)$$

Assumptions:

$SRT_{side} = SRT_{side-stream} = 10$ days

AOB maximum specific growth rate (μ_m , AOB) = 0.9 d^{-1} ;

NOB maximum specific growth rate (μ_m , NOB) = 0.7 d^{-1}

Decay rate (b) = 0.17 d^{-1}

Neglect SRT impacts by seeding

Neglect AOB-activity loss due to Temperature-gap

Figure 7. Bioaugmentation versus SRT conceptual model

Impact of retention efficiency and shallow reactors on NOB outselection

Simulations of the DC Water pilot reactor are compared to the actual measurement in Figure 9. The overall profiles of $\text{NH}_4^+\text{-N}$, $\text{NO}_2^-\text{-N}$, $\text{NO}_3^-\text{-N}$ were closely predicted by the model. The model utilized activity measurement of retained sludge from the sieve mechanisms to assess AOB, NOB and anammox retention efficiency. The model predicted minor improvement in NOB out-selection with an AOB/NOB ratio of 1.8 compared to 1.6 for fully nitrifying systems. One explanation for the low NOB outselection efficiency would be the effect of the inorganic carbon limitation switch on AOB growth and the other would be the NOB retention by the sieve where NOBs may have attached onto the anammox granules. To address the impact of these two factors, the retention of the various organisms was modified in the model to reflect an ideal separation of granular anammox bacteria and AOBs and NOBs and the depth of the reactors in the model was adjusted to mimic that of full-scale tank depth. Table 5

presents a comparison between the pilot reactor performance with and without these hypothetical improvements. The model predicted an AOB/NOB ratio of 7.1 when both retention and tank depth are optimized. The optimized model was then used to determine the potential savings in carbon addition in the form of acetate between conventional nitrification/denitrification system and a system with nitrogen shortcut (i.e. repressed NOB). The model showed that for nitrogen removal efficiency of approximately 90% and effective (i.e. 70%) NOB out-selection, the acetate saving due to nitrogen shortcut was 60% compared to conventional nitrification/denitrification. However, a validation of the model will be required either with full scale or with modified pilot reactor to confirm the hypotheses introduced.

Figure 8. Simulation of HRSD pilot reactor with AVN control showing 100% and 50% seed mass rates and SRT variation

Figure 9. Simulation and measured profile of the DC Water pilot reactor

Table 5. Impact of selective retention and tank depth on NOB outselection

Parameter	Pilot	Improved Selective Retention	Improved Selective Retention+Deep Tankage
Anammox retention Efficiency, %	73	90	90

NOB retention Efficiency, %	52	20	20
Tank Depth, m	0.3	0.3	9.0
AOB/NOB ratio	1.8	2.9	7.1

CONCLUSIONS

In this paper, a model based approach of the key mechanisms for shortcut nitrogen removal to facilitate mainstream deammonification was presented. The modelling served as a useful tool to separate the impact of individual mechanisms on NOB out-selection and to identify artifacts associated with bench-scale reactors. The model illustrated the benefits of using the novel AVN controller over the ammonia-based control by managing carbon removal and recovering alkalinity. It also demonstrated the impact of AOB seeding and SRT on NOB outselection and showed the importance of applying aggressive SRT for effective NOB outselection. In addition, the model was used in a hypothetical scenario analysis to demonstrate the potential external carbon savings of 60% that would be realized by converting a conventional nitrification-denitrification system to mainstream deammonification exemplified by the Blue Plains WWTP case study.

Abstract

This paper describes the development of a modified ASM1 model framework to describe the organic substrate transformation in the high-rate activated sludge (HRAS) process. New state variables and process rate equations were incorporated. New process mechanisms for dual soluble substrate, extracellular polymeric substances (EPS) production, production of storage polymers, and adsorption of colloidal substrate were included in the modified model. Data from two HRAS pilot plants were used to calibrate and to validate the proposed model framework for HRAS systems. A dual substrate model for soluble biodegradable substrate transformation was adopted since it described the pilot plant data. The modified model incorporates EPS production as part of the aerobic growth process on the soluble substrate and flocculation of colloidal COD to particulate COD. The adsorbed organics are then converted through hydrolysis to the slow fraction of soluble readily biodegradable substrate. The proposed model framework was able to predict the performance of the pilot plants and provided better overall results than the ASM1 model.

INTRODUCTION

The high-rate activated sludge (HRAS) process for carbon removal uses high food-to-microorganism ratios and low solids and hydraulic retention times (SRT and HRT) for the biological substrate (COD) transformation from wastewater. When a HRAS system is the first step in the Adsorption-Bio-oxidation (AB) process (Böhnke et al., 1980), the general objectives are to maximize the removal of organics through adsorption rather than oxidation and to produce large amounts of waste sludge that can be converted to biogas by anaerobic digestion (Schulze-Rettmer et al., 1998). Hence, accurate modelling of this system is of importance to design, control, optimization and prediction of the performance of not only HRAS systems but of the AB process as a whole.

The modelling of activated sludge processes, particularly the COD transformations, has significantly evolved towards fundamental principles in the past decades from simple single-substrate models to more complex multiple-substrate models involving the processes of oxidation, hydrolysis and storage (Dold et al., 1980; Sin et al., 2005). However, these models have evolved to describe COD removal in systems operating at long SRT (i.e. 3 days or longer) where the biodegradable organic substrate (S_B) can be modelled as a single substrate with a single kinetic expression. In addition, flocculation and adsorption of colloidal and particulate substrate (C_B and X_B) are assumed to be complete and instantaneous; hence, it can be ignored in the models (Haider et al., 2003; Jimenez et al., 2003). However, in high-rate

systems such as those employed in the AB process (where the SRT is well below 1 day), these assumptions with respect to organic substrate transformation are no longer applicable.

Full-scale and pilot-scale results from high-rate systems (Haider *et al.*, 2000 and 2003; Miller *et al.*, 2012; Jimenez *et al.* 2014) show that very low SRT (i.e. 1 day or less) may result in a selection of fast growing bacteria, which can use only part of the influent substrate. Haider *et al.* (2003) showed that the inert soluble COD fraction (S_U) of the wastewater was always significantly higher if the wastewater was added to a HRAS with an SRT of 0.5 days in comparison to systems with an SRT of 20 days. Hence, they recommended that for modelling, the S_B fraction of the wastewater should be split into two distinct biodegradable fractions. Jimenez *et al.* (2005) recognized that in effluent from these systems, some of the particulate and (especially) colloidal COD may not be removed by flocculation and adsorption resulting in incomplete enmeshment and hydrolysis of X_B and C_B . Jimenez *et al.* (2005) recommended that flocculation kinetics should be considered as an important mechanism from a modelling perspective. Hence, for these reasons the existing model's assumption of organic substrate transformation kinetic parameters based on instantaneous flocculation/adsorption becomes questionable and should be addressed to properly model low SRT systems.

This paper discusses a modelling approach which evaluates the organic substrate transformations as it pertains to HRAS systems. This approach uses the Activated Sludge Model No.1 (ASM1) (Henze *et al.*, 2000) as the initial framework. The original framework was modified to describe the proper mechanisms required to accurately describe the performance of the HRAS system.

MATERIALS AND METHODS

Historical operating data from two pilot systems were evaluated to understand the organic substrate transformation mechanisms in HRAS and used to calibrate and validate the proposed process model. The data used during this study includes operating data from an A-Stage pilot plant owned and operated by the Hampton Roads Sanitation District (HRSD) (Miller *et al.*, 2013) and from a HRAS pilot plant operated by the University of New Orleans (Jimenez *et al.*, 2014).

HRSD's pilot plant, located at the Chesapeake-Elizabeth Treatment Plant in Virginia Beach, Virginia, uses an A-Stage process for carbon removal followed by a B-Stage system for nitrogen removal. Currently, the A-Stage includes three reactors in series (170 L per reactor), operated at an aggregate 0.2-day SRT and 0.5-hour HRT, and is fed screened and dewatered raw municipal wastewater at a constant flow rate of 24.5 m³/d.

The HRAS pilot plant operated by the University of New Orleans consists of a rotating screen, a complete mix aeration tank, and a secondary clarifier. The unit was designed for a flow rate of 7.5m³/d and a HRT in the bioreactor of approximately 0.5 hours. The pilot plant was operated at a range of SRT conditions, ranging from 0.3 days to 2 days.

MODEL DESCRIPTION

To describe the behavior of the HRAS pilot plants, the ASM model framework was modified to incorporate non-steady state material balance equations for dual soluble substrate (S_{Bf} , S_{Bs}), EPS production (X_{EPS}), production of storage polymers (X_{STO}), and adsorption of inert and biodegradable colloidal substrate (C_U and C_B). A partial list of state variables used in the modified model framework is shown in Table 1.

Table 9 Partial list of state variables

Symbol	Name	Units
S_U	Soluble non-biodegradable organics	g COD.m^{-3}
S_{Bf}	Readily soluble biodegradable organics	g COD.m^{-3}
S_{Bs}	Slowly soluble biodegradable organics	g COD.m^{-3}
C_U	Colloidal non-biodegradable organics	g COD.m^{-3}
C_B	Colloidal biodegradable organics	g COD.m^{-3}
X_U	Particulate non-biodegradable organics	g COD.m^{-3}
X_B	Particulate biodegradable organics	g COD.m^{-3}
$X_{OHO,ACT}$	Active ordinary heterotrophic organisms	g COD.m^{-3}
X_E	Particulate non-biodegradable endogenous products	g COD.m^{-3}
X_{EPS}	Extracellular polymeric substances	g COD.m^{-3}
X_{STO}	Intracellular storage polymeric substances	g COD.m^{-3}

Review of the literature (Jimenez, 2002; Laspidou et al., 2002b; Miller et al., 2013) has led to a modification of the model framework. Figure 1 illustrates the flow of electrons in the modified ASM1 model framework (Nogaj et al., 2013). Details are discussed in the following sections.

Figure 1 Electron flow for soluble substrate

Fate of Soluble Substrate

Results from the pilot plants show a higher effluent soluble COD from the A-stage than the B-stage (where it is removed at a significantly longer SRT) (Nogaj et al., 2013). Conventionally, the method to quantify the non-biodegradable soluble COD is to operate a laboratory or pilot scale activated sludge system at an SRT longer than 3 days (Ekama et al., 1986) and use the effluent soluble COD as the non-biodegradable fraction. However, at the low SRT (and low HRT) of the HRAS system, there is a fraction of the effluent COD that is biodegradable in the higher SRT, B-Stage process but not biodegradable in the conditions in the A-Stage. This has led to the establishment of two state variables for S_B designated as S_{Bf} (S_B fast) and S_{Bs} (S_B slow). S_{Bf} corresponds to the soluble COD that is biodegradable in the HRAS system at low

SRT by a fast growing population of $X_{\text{OHO,ACT}}$ (Haider *et al.*, 2003; Pala-Ozkok *et al.*, 2013). S_{Bs} is the soluble COD fraction that is non-biodegradable in the HRAS system, but is biodegradable in the B-Stage by a slow growing $X_{\text{OHO,ACT}}$. For the modified model two frameworks were evaluated. In one framework, S_{Bf} is biodegraded first, and it is only when S_{Bf} is fully utilized that biodegradation of S_{Bs} becomes significant. This is analogous to diauxic growth in which one substrate is biodegraded immediately by constitutive enzymes, and only when it runs out are enzymes induced for metabolism of the second substrate. The data does not show, or disprove, this mechanism, but this framework is at least plausible mechanistically. This framework is referred to as the Diauxic model. In the second framework S_{Bf} and S_{Bs} are utilized simultaneously with the growth on S_{Bf} occurring at a higher maximum specific substrate utilization rate than on S_{Bs} . This framework is referred to as the Dual Substrate model.

EPS Production

Extracellular polymeric substances (EPS) production impacts the biofloculation removal efficiency for particulate and colloidal substrate (Jimenez, 2002). Past models assume instantaneous enmeshment whereas the data from Jimenez (2005, 2007 and 2014) shows that this assumption may not be valid for high rate systems. The EPS data produced by Jimenez *et al.* (2013) was used as calibration data for this study. This dataset shows a linear correlation between substrate utilization rate and EPS production and an increase in EPS production with SRT (thus decrease with growth) over a range of 0.3 to 2.0 days. In addition, EPS increased with the DO concentration over the same range of SRT values. Laspidou *et al.* (2002a) indicated that the net EPS concentration is a function of the portion of influent soluble substrate (substrate electron pool) shunted to EPS formation versus the EPS hydrolysis rate. Hence, the modified model incorporates EPS production as part of the aerobic growth process on S_{Bf} and S_{Bs} . The proportionality coefficient $k_{\text{EPS,PC}}$ quantifies the portion of influent electrons shunted to EPS formation. The portion of substrate electrons that are shunted to EPS formations ($k_{\text{EPS,PC}}$) are then subtracted from the biomass yield coefficient Y_{OHO} , i.e. $Y_{\text{OHO}} \cdot (1 - k_{\text{EPS,PC}})$, reducing the electrons available for biomass synthesis. In the Diauxic model, EPS formation is first driven by S_{Bf} during aerobic growth. EPS formation on S_{Bs} does not occur until S_{Bf} starts to run out. In contrast, the EPS formation in the Dual Substrate model occurs simultaneously on both soluble substrate fractions. In both models EPS formation driven by influent S_{Bs} does not have to compete with the formation of storage products (which only occurs through S_{Bf}). Additional S_{Bs} becomes available through hydrolysis of X_{B} (Carucci *et al.*, 2001). $K_{\text{O,EPS}}$ was estimated using a nonlinear regression analysis of the EPS production data vs DO concentration data provided by Jimenez *et al.* (2000). The value $k_{\text{EPS,MAX}}$ (maximum EPS production) was determined by developing a least square logarithmic fit of the dataset provided by Jimenez *et al.* (2014) resulting in an estimated $k_{\text{EPS,MAX}}$ value of 0.25 (g COD_{EPS}/g VSS) and $K_{\text{O,EPS}}$ value of 0.55 (gSO₂/m³).

$$k_{\text{EPS,PC}} = \left(\frac{k_{\text{EPS,MAX}}}{i_{\text{CB}}} \right) \times \left(\frac{S_{\text{O}_2}}{(K_{\text{O,EPS}} + S_{\text{O}_2})} \right) \quad (1)$$

Equation 1 shows how $k_{\text{EPS,PC}}$ is calculated. The term i_{CB} (1.48 gCOD_{VSS}/gVSS) is a stoichiometric conversion factor that converts $k_{\text{EPS,MAX}}$ from units of gCOD_{EPS}/gVSS to gCOD_{EPS}/gCOD_{VSS}.

Production of Storage Polymers

Review of the literature suggests that systems operated at low DO concentrations (<0.9 mg/L; according to Third *et al.*, 2003), typical of a HRAS system, the microbial uptake of readily biodegradable COD (S_{Bf}) could result in the formation of storage polymers. Third *et al.* (2003) found using acetate as the substrate for COD, the microbial uptake of acetate and its conversion to storage polymers was strictly oxygen dependent. At low DO, the flow of electrons is used for acetate uptake and production of storage polymers. Higher DO supply rates resulted in higher growth rates with the flow of electrons to biomass production and approximately 20% of the substrate is oxidized, independent of the DO concentration. The following expression was added to the modified model framework to simulate the flow of electrons to storage as a function of DO concentration.

$$f_{STO} = (f_{shunt,max}) \times \left(\frac{S_{O_2}}{(K_{O,STO} + S_{O_2})} \right) \quad (2)$$

Where f_{STO} represents the fraction of storage products in the active biomass, $f_{shunt,max}$ represents the maximum flow electrons as a function of dissolved oxygen concentration and $K_{O,STO}$ is the half-saturation coefficient for S_{O_2} . These two values were determined from a plot of f_{STO} vs DO which represented a Monod type curve. The extrapolated values were 0.15 for $f_{shunt,max}$ and $0.7 \text{ gSO}_2/\text{m}^3$ for $K_{O,STO}$.

The diversion of substrate electrons to storage in the modified model is represented by the proportionality constant $k_{STO,PC}$. The portion of electrons that are shunted to $k_{STO,PC}$ are also subtracted from the biomass yield coefficient Y_{OHO} , i.e. $(Y_{OHO} * (1 - k_{EPS,PC} - k_{STO,PC}))$, for aerobic growth using S_{Bf} , further reducing the electrons available for biomass synthesis.

Adsorption of Colloidal COD

Typical characteristics for any municipal wastewater include both soluble and particulate organics. Before developing modifications to the mathematical model it is important to define the soluble, particulate and colloidal fractions of the influent COD. Total chemical oxygen demand (tCOD) can be defined as the sum of particulate COD (pCOD) and soluble COD (sCOD) present in the wastewater. For the purpose of this investigation, the pCOD consists of organic suspended solids (ssCOD) and organic colloids (cCOD) in the wastewater ($pCOD = ssCOD + cCOD$). The state variable X_B represents pCOD in the modified model. The dissolved COD excluding colloids is the truly soluble organic material in the wastewater and this was quantified by coagulation/flocculation followed by filtration (i.e. ffCOD) (Mamais *et al.*, 1993). The truly sCOD is defined in the modified model as the sum of the state variables S_{Bf} , S_{Bs} and S_U . The most important aspect is the differentiation of particulate and colloidal COD, which has not traditionally been done in most studies nor in the previous ASM derived models (Henze *et al.*, 2000). The reason for this is that in higher HRT and SRT systems there is plenty of time for both colloidal and particulate COD to flocculate completely and to be degraded. However, in low HRT/SRT systems (HRAS) there is not always time for this to occur. This also means that effluent CODs in HRAS systems are higher than would be predicted by existing models.

Modified model Solution

The ASM models use matrix notation for the presentation of kinetic models. The matrix approach summarizes the components (state variables) and the transformation processes

which are to be considered in the model. The stoichiometric coefficients and process rate equations are presented in the matrix. The matrix is often referred to as the Gujer matrix and will be referred to as such throughout this paper. Using the ASM1 Gujer matrix as the reference model, proposed modifications to the framework for the modified model are defined in Figure 10.

Figure 10 Proposed Mathematical Model modifications for the HRAS carbon removal model

The modified stoichiometric matrix is shown in Table with the associated process rate

The modified stoichiometric matrix is shown in Table with the associated process rate equations shown in Table . In the Diauxic model it must be noted that the pathways emanating from S_{Bf} and S_{Bs} will never both be significant at the same time. This is due to the model kinetic equations being such that S_{Bs} transformations will not be significant until S_{Bf} runs out (i.e. when $S_{Bf} < K_{Bf}$).

The colloidal substrate (C_B) is added as a new state variable. The C_B and slowly biodegradable particulate COD (X_B) are enmeshed which represents the colloidal and particulate COD adsorbed through the bioflocculation mechanism. The adsorbed organics are then converted through hydrolysis to the slow fraction of soluble readily biodegradable substrate S_{Bs} . The modified model framework incorporates two new process components; flocculation of C_B and flocculation of C_U as follows:

$$\frac{dC_B}{dt} = -(q_{ADS} \times C_B \times (X_{OHO} + X_{ANO})) \times \left(\frac{\frac{K_{SL}}{C_B}}{\left(\frac{C_B}{(X_{OHO} + X_{ANO})} \right) + K_{SL}} \right) \times \left(\frac{X_{EPS}}{K_{EPS} + X_{EPS}} \right) \quad (3)$$

$$\frac{dC_U}{dt} = -(q_{ADS} \times C_U \times (X_{OHO} + X_{ANO})) \times \left(\frac{\frac{K_{SL}}{C_U}}{\left(\frac{C_U}{(X_{OHO} + X_{ANO})} \right) + K_{SL}} \right) \times \left(\frac{X_{EPS}}{K_{EPS} + X_{EPS}} \right) \quad (4)$$

The kinetic rate expression for each process is a first-order rate expression with respect to the colloidal concentration. The kinetic parameter q_{ADS} is the adsorption rate constant and K_{SL} is the surface limitation coefficient. The C_B is flocculated onto the X_B , becoming part of that category of organics. The adsorbed organics are then converted through hydrolysis to S_{Bs} , which can then be oxidized or converted to EPS or biomass by the microorganisms. The C_U is flocculated onto the X_U and removed from the system through wasting.

Table 2 Partial Gujer matrix processes and stoichiometric coefficients for the HRAS model

	Name	S_{Bf}	S_{Bs}	C_B	X_B	X_{OHO}	ACT	X_{EPS}	X_{STO}

r2b	Aerobic growth of heterotrophs - Slow	$\mu_{OHO,SLOW} * (S_{Bs}/(K_{Bs} + S_{Bs})) * (S_{O2}/(K_{O,OHO} + S_{O2})) * (S_{NHx}/(K_{NHx,nut} + S_{NHx})) * X_{OHO}$
r3	Decay of heterotrophs	$b_{OHO} * X_{OHO,ACT}$
r4	Hydrolysis of entrapped organics	$q_{XB,HYD} * ((X_B/X_{OHO})/(K_{B,HYD} + X_B/X_{OHO})) * (S_{O2}/(K_{O,OHO} + S_{O2})) + \eta_{HYD} * (K_{O,OHO}/(K_{O,OHO} + S_{O2})) * (S_{NOx}/(K_{NOx} + S_{NOx})) * X_{OHO}$
r5	flocculation of colloidal substrate	$q_{ADS} * C_B * (X_{OHO} + X_{ANO}) * (K_{SL}/((C_B/(X_{OHO} + X_{ANO})) + K_{SL})) * (X_{EPS}/(K_{EPS} + X_{EPS}))$
r6	flocculation of colloidal inerts	$q_{ADS} * C_U * (X_{OHO} + X_{ANO}) * (K_{SL}/((C_U/(X_{OHO} + X_{ANO})) + K_{SL})) * (X_{EPS}/(K_{EPS} + X_{EPS}))$
r7	Hydrolysis of storage products	$q_{STO,HYD} * (X_{STO}/X_{OHO}/(K_{STO,HYD} + X_{STO}/X_{OHO})) * (K_{Bf}/(K_{Bf} + S_{Bf})) * (K_{Bs}/(K_{Bs} + S_{Bs})) * (S_{O2}/(K_{O,OHO} + S_{O2})) * X_{OHO}$
r8	EPS hydrolysis	$q_{EPA,HYD} * X_{EPS}$

r2a corresponds to the Diauxic model, r2b corresponds to the Dual Substrate model

RESULTS AND DISCUSSION

The modified ASM1 frameworks were analyzed using the process simulator software SUMO version 0.9.15.0 developed by Dynamita (Nyons, France). The experimental datasets from New Orleans and HRSD were used to calibrate and validate the modified model frameworks.

Model Calibration

The dataset used to calibrate the modified framework model was collected by Jimenez et al. (2014). The SRT and DO concentration were varied in order to evaluate the effect of these operating parameters on the production of EPS and the removal of organic substrate. The average influent concentrations used for the model calibration are summarized in Table .

Table 4 Influent wastewater concentrations

Symbol	Description	Value	Units
S_I	Soluble unbiodegradable organics	10	g COD.m^{-3}
S_{Bf}	Soluble biodegradable organics	60	g COD.m^{-3}
S_{Bs}	Slowly biodegradable organics	30	g COD.m^{-3}
C_U	Colloidal unbiodegradable organics	20	g COD.m^{-3}
C_B	Colloidal biodegradable organics	40	g COD.m^{-3}
X_U	Particulate unbiodegradable organics	30	g COD.m^{-3}
X_B	Particulate biodegradable organics	150	g COD.m^{-3}
$X_{OHO,ACT}$	Active Ordinary heterotrophic organisms	10	g COD.m^{-3}
X_{EPS}	Extracellular Polymer Substances	1	g COD.m^{-3}
X_{STO}	Storage Polymer Substances	1	g COD.m^{-3}

A partial list of the kinetic parameter values established through model calibration is summarized in Table . The kinetic parameters shown were added to represent the pathways incorporated to the modified model framework for soluble substrate, EPS production, adsorption/flocculation and the production of storage polymers.

Figure presents a comparison of the model results as a function of SRT and DO. These predictions are compared to the corresponding experimental data from Jimenez et al., 2014. Overall, the model predictions described the experimental trends.

Colloidal substrate removal was calibrated by adjusting the adsorption rate parameter q_{ADS} (0.08 d^{-1}) and the surface limitation parameter K_{SL} (0.002) until the HRAS model results trended well with the experimental data. Future research includes experiments to further validate these parameter values.

Table 5 Partial list of default parameter values for the mass-balance equations

Symbol	Name	Value	Unit
$K_{B,HYD}$	Saturation coefficient for X_B/X_{OHO}	0.03	$g\ X_B/g\ X_{OHO}$
μ_{OHO}	Maximum growth rate of X_{OHO} on S_{Bf}	7.0	d^{-1}
K_{Bf}	Half-saturation coefficient for $S_{Bf}(X_{OHO})$	2.0	$g\ S_{Bf}.m^{-3}$
K_{Bs}	Half-saturation coefficient for $S_{Bs}(X_{OHO})$	15.0	$g\ S_{Bs}.m^{-3}$
b_{OHO}	Decay rate for X_{OHO}	0.62	d^{-1}
$K_{O,OHO}$	Half-saturation coefficient for $S_{O2}(X_{OHO})$	0.1	$g\ S_{O2}.m^{-3}$
K_{Nox}	Half-saturation coefficient for $S_{NOx}(X_{OHO})$	0.5	$g\ S_{NOx}.m^{-3}$
$K_{NHx,nut}$	Nutrient half-saturation coefficient	0.05	$g\ S_{NHx}.m^{-3}$
q_{ADS}	Rate constant for adsorption	0.08	d^{-1}
K_{SL}	Half-saturation coefficient for surface limitation	0.002	-
q_{STO}	Rate constant for growth on $X_{STO}(X_{OHO})$	2.0	d^{-1}
$k_{EPS,MAX}$	EPS formation coefficient	0.25	$g\ COD_{EPS}.gVSS^{-1}$
$q_{EPS,HYD}$	EPS hydrolysis	0.12	d^{-1}
K_{EPS}	Half-saturation coefficient for EPS (X_{OHO})	100	$gX_{EPS}.m^{-3}$
$q_{XB,HYD}$	Particulate COD Hydrolysis Rate Constant	2.75	d^{-1}
$k_{STO,MAX}$	Maximum Production Yield for Storage Polymers	0.58	$g\ X_{STO}.gS_{Bf}^{-1}$
f_{STO}	Fraction of X_{STO} in the Active Biomass	0.15	-
$q_{STO,HYD}$	Storage Hydrolysis Rate Constant	3.0	d^{-1}
$K_{STO,HYD}$	Hydrolysis Half-saturation coefficient for $X_{STO}(X_{OHO})$	0.15	$gX_{STO}.gX_{OHO}^{-1}$
$K_{O,EPS}$	Half-saturation coefficient for S_{O2}	0.55	$g\ S_{O2}.m^{-3}$
$\mu_{OHO,SLOW}$	Maximum growth rate of X_{OHO} on S_{Bs}	3.0	d^{-1}

Figure 3 Model calibration results compared to the University of New Orleans pilot plant results

Modified Model Validation

The HRSD dataset used in this analysis spanned a five week period where the pilot plant had reached steady-state operating condition. Weakly averages were calculated for that period and the data reduced to a format compatible with the model framework. Influent values for select state variables are shown in Table . State variables not shown in Table 5 are generated by the model as such, they were not measured. The measured values were input into the model representing daily values for each corresponding week resulting in a dynamic analysis period of 35 days. Dynamic input data for model validation also included DO profiles, and return and waste activated sludge (RAS and WAS) flow.

Table 6 Influent state variables for model validation

Time (week)	Q (m ³ /d)	S _U (g/m ³)	S _{Bf} (g/m ³)	S _{Bs} (g/m ³)	C _B (g/m ³)	X _B (g/m ³)	X _{OH₀} (g/m ³)
1	24.84	28.00	78.00	43.00	44.45	312	10.00
2	24.84	19.80	79.00	58.20	40.30	278	10.00
3	24.84	19.00	113.00	31.00	32.28	355	20.00
4	24.84	27.00	99.00	26.00	53.03	362	10.00
5	24.84	26.30	112.00	24.70	57.40	299	18.00

Dynamic simulations were performed in order to compare the predicted effluent values with those of the HRSD pilot plant. As previously mentioned, two different framework models were developed for this study and Figure 4 presents a model comparison of the effluent soluble biodegradable fraction ($S_{Bf} + S_{Bs}$). Based on these results, the Dual Substrate model predicts better the performance of the HRSD pilot plant. In general, the Dual Substrate model provided a better prediction of the HRSD pilot plant results. Figure 5 shows the model predicted values for S_{Bf} and S_{Bs} . Based on the definition of the S_{Bf} and S_{Bs} fractions discussed previously, the model predicts almost full removal of S_{Bf} whereas the S_{Bs} fraction passes through the biological reactor operated at an SRT of approximately 0.2 days.

Figure 4 Comparison of the effluent S_B concentration from the Diauxic and Dual Substrate models

Figure 5 Dual Substrate model prediction for S_{Bf} and S_{Bs} concentrations

A carbon balance performed around the HRSD pilot plant shows a total COD balance distribution of approximately 55% of the COD is in the effluent, 30% of the COD is the WAS and 15% of COD was allocated to mineralization. The Dual Substrate model predicts (using a $k_{STO,PC}$ in range 0.40 to 0.45) a COD distribution of 38% of the COD in the effluent, 46% of the COD in the WAS and 16% of COD to mineralization. The difference in the COD distribution between the HRSD pilot plant and the model predictions can be attributed to excess solids carryover in the effluent of the pilot plant which was not predicted by the model. Therefore, the model predicted more COD being removed from the liquid and being directed to the WAS stream. It is important to note that the percent COD mineralized is well predicted by the model.

Figure 6 presents the model predictions and measured values for effluent colloidal COD concentration. The adsorption/flocculation model added to the model predicts negligible removal of the colloidal COD fraction. In fact, at the conditions that the pilot plant was operated, at increase in colloidal COD concentration through the reactor was predicted by the model and observed in the HRSD pilot plant data. The model suggests that because of the unfavorable flocculation conditions, a major fraction of the EPS being generated through biological activity are ending up in the effluent and being recorded as colloidal COD. At the conditions simulated, the model predicted approximately 15 mg COD_{EPS}/gX_{VSS} .

Figure 6 Comparison of HRSD pilot plant and model predicted effluent colloidal COD

ASM1 Model

The ASM1 model was developed to simulate the aerobic and anoxic treatment of domestic wastewater based on typical operating conditions, e.g. SRT greater than 3 days. These models were not developed to model activated sludge systems with very high organic loads or low SRTs (less than 1 day) where bioflocculation/adsorption of particulate and colloidal (slowly biodegradable) substrate and storage may become rate limited (Henze et al., 2000). In addition, the very short HRT of some HRAS systems may result in differences in predicted performance since the implicit assumption that substrate reactions can proceed to completion may no longer be valid. These models assume a two-step process for the removal of slowly biodegradable substrate (primarily particulate substrate and colloidal substrate): instantaneous bioflocculation and complete hydrolysis of particulate and colloidal substrate followed by oxidation of soluble biodegradable substrate. However, researchers have overlooked the effect of the kinetics of bioflocculation on the overall particulate and colloidal substrate removal process and have concentrated their attention on the kinetics of hydrolysis and oxidation when modeling carbon removal in activated-sludge systems.

Using the ASM1 framework (Henze et al., 2000) and default parameter values, e.g. $\mu_{\max} = 6.0 \text{ d}^{-1}$ and $K_s = 20 \text{ mg/L}$, the ASM1 model generated the results shown in Figure 7. This figure shows both the ASM1 model results and the HRSD pilot plant experimental data. These results clearly shows that the ASM1 framework when used at low SRT and high F:M ratios as those employed in HRAS systems, the model does not properly predicts the removal of organic substrate. In addition, it should be noted as previously mentioned, the structure of the framework for the ASM1 model does not describe properly the removal of slowly biodegradable substrate. It should be noted that the ASM1 model does not include colloidal COD as a state variable so no comparison was possible. Overall, the ASM1 model over predicts the performance of the HRAS system.

Figure 7 Comparison of HRSD pilot plant effluent quality and ASM1 model predictions

CONCLUSIONS

A new proposed model framework was developed to describe the organic substrate transformation in the high-rate activated sludge (HRAS) process. Data from two HRAS pilot plants were used to calibrate and to validate the proposed model framework for HRAS systems. Two soluble substrate models were evaluated during this study including a Dual Substrate and a Diauxic model. Both model frameworks used two state variables for biodegradable soluble substrate (S_{Bf} and S_{Bs}) and two biomass populations (fast growing and slow growing $X_{OHO,ACT}$ with maximum growth rates of 7.0 and 3.0 d^{-1} , respectively). Overall, the Dual Substrate model provided better results than the Diauxic model; and therefore, it was adopted during this study. The modified model framework described successfully the production of EPS at low SRT and variable DO conditions using a $k_{EPS,MAX}$ value of 0.15 g COD_{EPS}/g VSS and a $K_{O,EPS}$ value of 0.55 g SO_2/m^3 . This provided valuable information to relate EPS production and bioflocculation/adsorption of colloidal substrate. Colloidal substrate removal was calibrated by adjusting the q_{ADS} to 0.08 d^{-1} and K_{SL} to 0.002. Finally, the proposed model framework accurately predicted substrate utilization and mass balances, transformation and redirection of COD in the HRAS system.

INTRODUCTION

Over the past years, wastewater treatment plant (WWTP) mathematical models have been advancing towards their widespread application for sizing and operation of treatment plants to minimize energy consumption and cost while maximizing nutrient recovery and effluent quality. Effective utilisation of these models requires that they are well calibrated. However, difficulties (with important parameters not identified and uncertainties in interpretation of model output results) can be experienced in model calibration, especially due to (i) the intricate relationships of model output variables with model input factors (where parameters are inter-related to various model outputs), resulting in non-linearity, and (ii) the limitations (due to expensive and/or time consuming experimental methods) experienced in procuring and reconciling data required for determination of the model input factors (especially when the model has significantly large numbers of unknown parameters and model components).

The BIOMATH protocol, developed by Vanrolleghem *et al.* (2003), provides a systematic approach for calibration. The main objective of this paper is to apply the BIOMATH protocol in providing a guidance towards calibration of a plant-wide model that includes phosphorus. The three phase (aqueous-gas-solid) University of Cape Town plant wide (UCT-PW) model (Ikumi *et al.*, 2013) that was calibrated against the experimental layout described below is used as a case study for this calibration procedure.

EXPERIMENTAL SYSTEM LAYOUT

The experimental layout of Ikumi (2011) is used in this study. It replicates at laboratory scale three WWTP schemes, comprising (1) a Modified Ludzack – Ettinger (MLE) nitrification–denitrification (ND) activated sludge (AS) system treating raw sewage (MLE 1) with anaerobic digestion (AD) of its waste activated sludge (WAS) in AD system number 1 (i.e., AD1), (2) an identical MLE system (MLE 2) treating settled sewage with AD of its WAS in AD2 and (3) a membrane (MBR) University of Cape Town (UCT) ND enhanced biological P removal (NDEBPR) system treating settled sewage with (i) AD of its WAS in AD3 and (ii) anoxic/aerobic digestion (AAD) of its WAS in two intermittently aerated (3hour air on, 3hour air off) aerobic digesters, AAD1 fed with concentrated WAS (2x, 20gTSS/l) and AAD2 fed with dilute WAS (1/3, 3.3gTSS/l).

MODEL DESCRIPTION

The UCT three phase plant wide model was developed for simulating the biological processes to track and predict the output of materials (COD, carbon (C), hydrogen (H), oxygen (O), nitrogen (N), phosphorus (P), magnesium (Mg), potassium (K) and calcium (Ca)) along the unit processes of a WWTP. It comprises three sub-models, integrated for simulation of the entire WWTP under various configurations (e.g. NDBEPR AS system linked to an AD or an anoxic-aerobic digestion (AAD) for WAS stabilisation). These sub-models include:

1. The ionic speciation model (Brouckaert *et al.*, 2010). This model includes pairing of ionic components (the set of model ionic species is given in Table 3) and inter-phase transfers of component species. Table 4 gives an example of a set of equilibrium and mass balance equations used in the ionic speciation subroutine.
2. The ASM2-3P model: This is the Activated Sludge Model No. 2 (ASM2, Henze *et al.*, 1995), modified to include the ionic speciation model (Brouckaert *et al.*, 2010), the Inorganic Settleable Solids (ISS) model of Ekama and Wentzel (2004) and including multiple mineral precipitation according to Musvoto *et al.* (2000a,b).
3. The ADM3P Model: This is the University of Cape Town Anaerobic Digestion Model (UCTADM; Sötemann *et al.*, 2005), modified to include the hydrolysis of multiple organic sludge types (PS, ND WAS, NDBEPR WAS and PS-WAS blends), the Ekama and Wentzel (2004) ISS model, multiple mineral precipitation processes according to Musvoto *et al.* (2000a, b) and the Brouckaert *et al.* (2010) aqueous speciation model which facilitates ionic speciation (Ikumi *et al.*, 2011).

For their compatibility, the ASM2-3P and ADM3P models have the same comprehensive set of model components (supermodel approach, Volcke *et al.*, 2006; model components given in Table 1 and applied stoichiometric processes in Table 4), including parameterized stoichiometry for the bioprocesses and sharing the same ionic speciation subroutine model (1).

MODEL EVALUATION PROCESS

1. *Model Verification*: To initiate the evaluation of the UCT-PW model (Ikumi *et al.*, 2013), the systematic method proposed by Hauduc *et al.* (2010) was applied to verify that material (COD, C, H, O N, P, Mg K and Ca) balances were achieved in the determination of all stoichiometric processes.
2. *Parameter Values*: The initial values for suitable kinetic and stoichiometric parameters as obtained experimentally or from literature were entered, and given the typical value range, determined according to the methods proposed by Brun *et al.* (2002).
3. *Sensitivity Analysis*: The parameters were subsequently evaluated using two different methods of global sensitivity analysis: (1) Standardised Regression Coefficients (SRC) and (2) Morris Screening. The results obtained using these methods are used to identify important parameters (prioritisation of those with greatest effects), non-influential parameters (those that can be ‘fixed’ at any value within their range without effecting outputs) and interacting parameters (Neumann, 2012).
4. *Model Calibration and Validation*: Non-influential parameters were set at their default values and random samples were drawn from the remaining subset of parameters. For the

sampled parameter sets simulations were conducted and predicted model outputs were compared with observed outputs. During this calibration phase, a consistent set of parameter values was used to simulate all experimental systems/periods, and detailed explanations of observed discrepancies (if any) were reported by Ikumi (2011). The sensitivity analysis together with intuitive observation on a steady state stoichiometric model was a significant role in selecting the ‘best’ set of parameters. It was noted that influent sewage and sludge characterisation, and determination of hydrolysis kinetic rates were important requirements prior to any simulation. In AD, the hydrolysis process is the slowest one and requires the best possible calibration. The hydrolysis kinetic constants were fit to match experimental data by Ikumi *et al.* (2013), using the non-linear regression. The biological reactions following hydrolysis are limited by the hydrolysis rate, hence their kinetic parameters are not identifiable from these experimental data, and so were adopted without adjustment from literature. Most of the parameterised influent and sludge characteristics could be obtained or calculated from directly measured results (Ikumi, 2011). This is because the unbiodegradable fractions of influent organics and the characteristics of the biodegradable feed components have a significant effect on the quality of model predictions, but are usually specific to the feed source.

5. **Model Performance Results:** Below are observations in experimental behaviour of P removal systems, replicated by the UCT-PW model as required to promote confidence in its application:
 - i. Applying the ASM2-3P model to an MLE system with ND does not stimulate EBPR (i.e., there is no PAO growth, hence no polyphosphate (PP) storage) and its effluent P comprises mainly the OP not utilized by the biomass (mainly OHOs) for growth.
 - ii. For MLE systems with little or no nitrification taking place, high quantities of P and acetate in the un-aerated (‘anoxic’) zone will result in the growth of phosphorus accumulating organisms (PAOs) rather than ordinary heterotrophic organisms (OHOs) only as expected in fully aerobic or nitrogen (N) removal systems. The concentration of acetate available for this PAO growth (and associated EBPR) depends on the rate of fermentation of biodegradable soluble organics (BSO) that occurs and the concentration of nitrate that gets recycled to the anaerobic reactor in these systems. Moreover, as noted in 3 and 5-stage Bardenpho systems – in winter, when denitrification is lower, the nitrates recycled to the anaerobic reactor can be sufficiently high to suppress EBPR. The ASM2-3P model predicts this behaviour qualitatively well.
 - iii. Applying ASM2-3P for sludge treatment with anoxic-aerobic digestion (AAD), the absence of VFA and an anaerobic period renders the PAOs unable to compete with the OHOs. Consequently, the PAOs do not grow and undergo endogenous respiration and die, releasing their stored PP as magnesium (Mg), calcium (Ca), potassium (K) and orthophosphate (OP). Struvite (MgNH_4PO_4) precipitation occurs when the concentration of Mg, ammonia and OP is high enough (i.e., the struvite is supersaturated) in the mixed liquor. If the ammonia is low ($< 1\text{mg/N/l}$), due to nitrification, K-struvite (MgKPO_4) forms.
 - iv. In AD, organically bound N is released with the hydrolysis of biodegradable organics in the non-ionic NH_3 form, which are non-reference species (reference species of a weak acid system being one that, when added to pure water, creates a solution state, relative to which the alkalinity of the weak acid system is measured) for the ammonia weak acid/base system. Therefore, the aqueous alkalinity increases by the concentration of NH_3 transferred from the organics (the NH_3 being an intrinsic alkalinity content of the organics) to the aqueous phase. This is the main aqueous H_2CO_3^* alkalinity generation

process in an AD treating PS or WAS that is not P-rich. For P-rich systems with PP, the aqueous H_2CO_3^* alkalinity increase also depends on PP and cell bound P release because PP is released as H_2PO_4^- and biomass P is released as H_3PO_4 , which interact with the other weak acid/base systems and influence pH. The ADM3P model predicts the pH for both these systems (P- rich or not) really well.

- v. In the dynamic model of the AD, initially, PP release and poly-hydroxy-alkanoate (PHA) storage by PAOs takes place with the uptake of acetate, as would happen in the anaerobic part of the parent NDEBPR system. This results in increased alkalinity because the PP is released as H_2PO_4^- . Because the PAOs also require alternating aerobic conditions for their growth, they cannot grow in the AD. Therefore, the PAOs are modelled to “die” in AD at a rate faster than their endogenous respiration; releasing their PHA and the remainder of their stored PP, adding more H_2PO_4^- and alkalinity. Depending on the charge/proton balance requirements, some of the H_2PO_4^- species become HPO_4^{2-} species by reacting with HCO_3^- to form HPO_4^{2-} , H_2O and CO_2 . The increase in CO_2 gas increases the partial pressure of the gas phase, which influences the aqueous speciation. The split between the OP species co-dependent on the inorganic carbon (IC) system (and any other weak acid/base system that may be present), which together establish the AD pH.
- vi. Because H_3PO_4 is the reference species for the OP weak acid/base system, the total alkalinity does not change with the slower release of organically bound P, but the species that represent it do.
- vii. The rapid release of PP and associated Mg^{2+} and the slow release of biomass N and P generate high concentrations of P, NH_4^+ and Mg^{2+} species in the AD liquor, which promotes struvite precipitation. This struvite precipitation decreases the total alkalinity and so results in re-speciation of the IC system, which increases the CO_2 partial pressure and decreases AD pH.

COMPARISON OF EXPERIMENTAL AND PREDICTED RESULTS

Figures 1a to f show a comparison between the data measured and simulated by the three phase AD dynamic model for the AD1 fed with the NDBEPR WAS (i.e. the AD effluent from UCT NDBEPR linked to AD in a plant wide setting). Considering the general complexities in characterization of the AD influent (i.e. the NDBEPR WAS; Ikumi *et al.*, 2013), the simulated results match quite well for COD removal (Fig 1a, which it should because the hydrolysis rates were calibrated on to the experimental results), and FSA (Fig1b) and OP (Fig 1c) release. Because all the AD products, including the H_2CO_3 and H_3PO_4 alkalinities and gas CO_2 partial pressure (p_{CO_2}), are entirely dependent on the composition of the biodegradable organics (x,y,z,a,b,q,c,d,e in $\text{C}_x\text{H}_y\text{O}_z\text{N}_a\text{P}_b\text{qMg}_c\text{K}_d\text{Ca}_e\text{PO}_3$), if the organics' composition entered into the model is not “correct”, then the simulated and measured results will not match, even with 100% experimental material balances (which of course were not achieved on the UCT and AD systems). Improving the comparison between predicted and measured results is a complex exercise because multiple processes act on single compounds. For instance under-predicted FSA (Fig 1b) means the determined N content of the biodegradable part of the OHO and PAO biomass is too low, but this does not mean that the H_2CO_3 alkalinity also has to be under-predicted (through $\text{NH}_3 + \text{H}_2\text{CO}_3 \rightarrow \text{NH}_4^+ + \text{HCO}_3^-$, as it would for an AD fed with low P organics, Sötemann *et al.*, 2005a,b) because the release of PP also produces alkalinity (through $\text{MePO}_3 + \text{H}_2\text{O} \rightarrow \text{Me}^+ + \text{H}_2\text{PO}_4^{2-}$).

CLOSURE

The BIOMATH protocol was applied for the calibration of the UCT–PW model, for promotion of its widespread utilisation in a reproducible way. However, it is noted that the effective calibration of this model requires a further step - from modelling the laboratory scale systems (under controlled and completely mixed environments) to assessment of model predictions for full-scale wastewater treatment plant systems, interlinked to plant-wide configurations. This prospective work may be of particular interest to the IWA group on benchmarking of control strategies for WWTPs who are including P into an extended BSM model.

Abstract

The aim of this study was to develop extensions of Activated Sludge Model No. 2d (ASM2d) for modelling the behaviour of Polyphosphate Accumulating Organisms (PAOs) in biological nutrient removal (BNR) activated sludge systems with addition of an external carbon source. Two significant modifications for the expanded ASM2d were included: (1) a switch function for the inhibitory effect of dissolved oxygen on storage of poly- β -hydroxyalkanoates (PHA); (2) a new process describing the direct growth of PAOs on fermentation products (S_A) under aerobic conditions. These modifications improved the model predictions of P release and uptake processes in one- and two-phase batch experiments with acetate as an external carbon source.

Keywords

ASM2d; biological nutrient removal; EBPR; external carbon; PAOs

INTRODUCTION

External carbon sources are readily biodegradable compounds which are usually added to enhance the denitrification process and improve the overall nitrogen removal efficiency in biological nutrient removal (BNR) processes. In combined N/P removal systems, the external carbon sources may also interact with the enhanced biological P removal (EBPR) process accomplished by Polyphosphate Accumulating Organisms (PAOs). However, the possibility that PAOs may oxidize the fermentation products (S_A) has been ignored in activated sludge models (ASMs) because, as noted by Henze *et al.* (2000), “it is unlikely that such substrates ever become available under aerobic or anoxic conditions in a biological nutrient removal (BNR) plant”. This assumption is likely to fail for systems with external carbon addition, as the readily biodegradable compounds may become available for direct utilization by PAOs under anoxic and aerobic conditions. Few studies focused specifically on modelling the effects of external carbon addition on PAOs with the ASMs so far. Swinarski *et al.* (2012) developed a new model as an expansion of ASM2d to predict the effect of adding a readily biodegradable substrate to a combined N/P system. The aim of this study was to further modify the ASM2d with regard to the behaviour of PAOs under aerobic conditions in the presence of external carbon (acetate).

MATERIAL AND METHODS

Model development and simulation platform

A conceptual model of the expanded ASM2d under aerobic conditions is presented in Figure 1. The following extensions were considered: (1) the inhibitory effect of dissolved oxygen on storage of poly- β -hydroxyalkanoates (X_{PHA}) by PAOs (X_{PAO}) under aerobic conditions, (2) direct aerobic growth of X_{PAO} on fermentation products (S_A). Therefore, the kinetic expressions for storage of X_{PHA} and aerobic growth of X_{PAO} on S_A in the expanded ASM2d

become as follows:

$$q_{PHA} \frac{S_A}{K_{SA,PAO} + S_A} \frac{K_{O_2,PAO}}{K_{O_2,PAO} + S_{O_2}} \frac{S_{ALK}}{K_{ALK,PAO} + S_{ALK}} \frac{X_{PP}/X_{PAO}}{K_{PP} + X_{PP}/X_{PAO}} X_{PAO} \quad (1)$$

$$\mu_{PAO2} \frac{S_{O_2}}{K_{O_2,PAO} + S_{O_2}} \frac{S_A}{K_{SA,PAO} + S_A} \frac{S_{NH_4}}{K_{NH_4,PAO} + S_{NH_4}} \frac{S_{PO_4}}{K_{PO_4,PAO} + S_{PO_4}} \frac{S_{ALK}}{K_{ALK,PAO} + S_{ALK}} X_{PAO} \quad (2)$$

The stoichiometric matrix for these two processes is presented in Table 1. GPS-X ver. 5.0.2 (Hydromantis, Canada) was used as a simulator environment for implementing the developed models and running simulations. For model calibration, a special utility called “Optimizer” was used. Parameters were estimated based on the Nelder-Mead simplex method with the maximum likelihood as an objective function. Three different scenarios were conducted for optimizing prediction of the external carbon addition (Table 2).

Batch experiments

In order to examine the effects of external carbon addition and the PO₄-P concentration at the beginning of aerobic conditions on the PAOs behavior, two-phase (anaerobic/aerobic) and one-phase (aerobic) experiments were carried out with fresh mixed liquor withdrawn from the aerobic zone of a large BNR activated sludge plant in Gdansk (northern Poland). At the beginning of the aerobic phase, sodium acetate (CH₃COONa) and nitrification inhibitor (ATU) were added. Samples were filtered and analyzed for PO₄-P and COD. In addition, oxygen uptake rate (OUR) was measured in a cyclic (3 minutes) mode.

RESULTS AND CONCLUSIONS

In the two kinds of batch experiments, the external carbon addition at the beginning of aerobic condition resulted in a significantly different PAO behavior. In the two-phase experiment, no PO₄-P release was observed (Figure 2a), which indicated that the addition of external carbon had no or a minor effect on P uptake by PAOs. In this case, predictions of ASM2d which assume the growth of PAOs on PHA only and ignore the aerobic growth of PAOs on S_A, could not match the experiment data accurately. Therefore, the ASM2d required appropriate extensions to better predict the effect of external carbon addition on PAOs. Model predictions for Scenario 1, which considered oxygen inhibition of storage of PHA, appeared to be consistent. Results from one-phase experiment showed that PO₄-P was released in the initial 45 min of the experiment (Figure 2b). This confirmed the process of storage of PHA can occur under aerobic conditions provided that readily biodegradable substrates are available and that PO₄-P is not completely released. In this case, P release and uptake data were matched accurately by the model predictions of Scenario 2 which considered the direct aerobic growth of X_{PAO} on the external carbon. Scenario 3, considering both the aerobic inhibition of storage of PHA and aerobic growth of PAOs on S_A, can generally predict the behaviour of PO₄-P, COD and OUR for both experiments (Figure 2a-d). Further extensions of ASM2d for better predictions of the aerobic and anoxic behaviors of PAOs in the presence of external carbon addition will be presented in the full paper.

ACKNOWLEDGEMENT

This work was carried out under the project “CARbon BALAncing for nutrient control in wastewater treatment (CARBALA)”.

Keywords

Chemical phosphorus removal, physicochemical modeling, ferric chloride, hydrous ferric oxide, phosphate adsorption

INTRODUCTION

Achieving phosphorus removal from wastewater to very low levels is often performed by metal salt addition. The engineering stakes for this process consist of ensuring compliant effluent phosphorus concentrations, while at the same time saving chemicals and limiting chemical sludge production. Modeling is a commonly used engineering tool to handle such issues. However, metal salt precipitation such as iron dosing is not well described in current wastewater process models. Existing chemical phosphorus removal models are mainly focused on ferric phosphate precipitation (de Haas et al., 2001; Fytianos et al., 1998; Luedecke et al., 1989). However, this pathway occurs only at acidic pH (below pH 5) as demonstrated by Smith et al. (2008) and based on experiments and literature solubility data (NIST 2001). De Haas et al. (2001) published a series of articles presenting a pilot-plant operated with different conditions of metal salts dosage, including a study dedicated to the application of an ASM2 model combined with an iron phosphate precipitation process similar to Luedecke et al. (1989) model on their case study. The authors showed several pitfalls of their model: the Fe:P precipitate stoichiometry has to be changed depending on the sludge age (the model does not predict storage effects) and the model does not adequately predict behavior at low P concentration, high and low iron doses. Furthermore the authors underlined the necessity to improve such precipitation model by including chemical equilibria, pH and alkalinity prediction.

The combination of very fast (chemical equilibrium) and slow (kinetic precipitation/adsorption) reactions, variable molar ratios, multiple dosage points, the effect of mixing, colloidal material conversions and multiple precipitates requires a new modeling framework. This framework can then be applied to full plant process models to optimize doses and dosage locations and increase the safety of effluent compliance. A dynamic physicochemical model for chemical phosphorus removal has been developed and calibrated based on previous studies and experimental data from Smith et al (2008) and Szabo et al. (2008) (Hauduc et al., 2013). The objectives of this study are threefold: first the model is extended for a better prediction of batch data at low pH and high metal salt dosing, then it is

combined with a biokinetic model and finally compare the model with continuous data obtained by de Haas *et al.* (2001) in pilot plant with real wastewater.

MODEL DEVELOPMENT

Iron dosage leads to rapid hydrous ferric oxide (HFO, including amorphous minerals such as 2-line ferrihydrite) precipitation. Phosphorus may then be removed from the bulk solution through different pathways: 1) adsorption of phosphates onto HFO by sharing an oxygen atom with iron; 2) co-precipitation of phosphate molecules into the HFO structure; 3) precipitation of ferric phosphate and 4) precipitation of mixed cation phosphates (Smith *et al.*, 2008). These processes are taken into account in the new model, which predicts kinetically the precipitation of hydrous ferric oxides (HFO), the phosphates adsorption, and the co-precipitation mechanisms. It is combined with chemical equilibrium and physical precipitation reactions in order to model observed bulk dynamics in term of pH. The model is calibrated based on previous studies and experimental data from Smith *et al.* (2008) and Szabo *et al.* (2008). The simulations results showed that the structure of the model overall describes adequately the mechanisms of adsorption and co-precipitation of phosphates onto HFO and that the model is robust to experimental conditions: Fe/P dose, time, HFO aging and mixing intensity, as illustrated on Figure for Fe/P dose and mixing effect.

Figure 1. Left: Effect of initial Fe/P molar ratio on residual soluble phosphorus and on final pH of the batch: experimental results from Szabo *et al.* (2008) (batch tests of 11 min, $P_{ini}=3.5$ mg/L, $pH_{ini}=6.5$, $Alk_{ini}=125$ mg $CaCO_3/L$, $G=425$ s⁻¹). Right: Effect of G value (mixing intensity) on residual soluble phosphorus: experimental results from Szabo *et al.* (2008) (batch tests of 11 min, $P_{ini}=4.1$ mg/L, $Fe/P_{ini}=1.8$ mole/mole).

COMBINING FeP MODEL WITH ASM2D

To combine the FeP model with a biological model, the biological model has first to be adapted to insure continuity in charge and carbon of the processes and to the ionic species

consumed or released by biomasses. In bio-P models, at least five state variables are involved in acid-base systems: acetate, phosphate, carbonate, nitrate and ammonia. These state variables comprise all the acid-base species. However, to introduce chemical equilibrium processes and to correctly model the pH, a choice has to be made in the species consumed or produced by the biological reactions.

According to Sotemann *et al.* (2005) microorganisms are taken up the non-ionic form of acetate, propionic acid, ammonia and phosphate for cell synthesis. In the case of polyphosphate storage, phosphate is taken in the form H_2PO_4^- linked to counter ions K^+ and Mg^{2+} (Barat *et al.*, 2005). However at typical pH range of our system (7 to 8.2), the most abundant species are NH_4^+ and HPO_4^{2-} . Consequently we chose to use NH_4^+ and HPO_4^{2-} as state variables in the biokinetic model and protons are corrected accordingly.

Inorganic carbon uptake and release is considered to be the non-ionic form H_2CO_3 . The stoichiometry of H_2CO_3 is based on the difference in carbon content of substrate and product, calculated with their COD/C ratio.

CASE-STUDY APPLICATION

De Haas *et al.* (2000a) published a series of articles presenting a three-stage Phoredox (Table) operated with different conditions of metal salts dosage: alum or ferric chloride (for this study only data on ferric chloride addition are considered), doses of metal salt, sludge age and dosage points. The Table summarized the 9 experimental periods considered in this study and their respective conditions. An identical control pilot-plant is operated in parallel without metal salt addition. Therefore a new model is required to predict HFO precipitation, pH modifications through chemical equilibrium and phosphate adsorption, and co-precipitation onto/into HFO.

Table 1. Experimental periods of FeCl_3 dosing from de Haas *et al.* (2000b) with effluent phosphorous concentration obtained in the control pilot-plant (R2) and the pilot-plant with metal salt addition (R1). The figure represents the pilot-plant configuration.

Period name	Nb of days	Sludge age (d)	R2		R1	
			Pe R2 (mg/L)	Dosage point	Fe/PeR2	Pe R1 (mg/L)
1	62	20	26.95	2	0.21	22.73
2	34	20	26.98	2	0.42	15.05
3	27	20	28.34	1	0.20	23.8
4	18	10	21.27	1	0.27	18.88
5	21	10	25.29	1	0.45	16.03
6	20	10	21.64	2	0.53	15.94
7	45	10	0.43	2	13.31	0.45
8	64	10	0.62	2	9.23	0.62
9	12	10	11.15	2	0.51	10.42

The ability of the new FeP model to reproduce the behavior of a simple three-stage Phoredox pilot plant operated under different conditions will be evaluated and compare to a simple iron phosphate precipitation model. The model combined to ASM2d is implemented in Aquasim software (version 2.1g, EAWAG, Dübendorf, Switzerland) (Reichert, 1994). The behavior of the biological model will first be compared with the control pilot data. The full model will then be applied to the different periods of the pilot-plant operation.

A control-based approach to achieve efficient biological phosphorus removal in WWTPs: design, simulation, optimisation and experimental validation

Javier Guerrero, Albert Guisasola and Juan Antonio Baeza

MOTIVATIONS

The increasingly stricter legislation for WWTP has raised the need of a more efficient management and hence, successful biological P removal has become a short term aim. The implementation of enhanced biological phosphorus removal (EBPR) is considered the most sustainable approach to meet P discharge levels, and the current knowledge gained on this process has raised the opportunity of developing new control structures to specifically control P effluent concentration (Guerrero *et al.*, 2011b; Machado *et al.*, 2009; Ostace *et al.*, 2013). However, despite EBPR is nowadays a quite known technology, its interaction with biological nitrogen removal may still lead to P removal failures in full-scale WWTP (Guerrero *et al.*, 2011a).

The research presented in this work integrates a modelling-based study of a novel control strategy to minimize the existing detrimental interactions between biological N and P removal together with its experimental validation in a 170L pilot plant with on-line monitoring of nutrients (phosphate, nitrate and ammonium). The model calibrated and validated was an extension of ASM2d that also includes nitrite as state variable and corrected settler reactivity (Guerrero *et al.*, 2013). This research, thus, embraces the design, implementation, simulation, optimization, systematic evaluation and experimental validation of conventional and innovative control strategies under normal operation and stress operation (i.e. influent disturbances, ammonium, nitrate and nitrite peaks...) for two different WWTP configurations with P-removal (A²O and Johannesburg). A systematic approach was conducted to assess the performance of the control strategy based on classical benchmark indexes related to the operational costs and related to the possibility of developing microbial-related problems in the settler.

Several studies reported that the presence of VFA in the wastewater is mandatory to obtain a high P removal capacity. Unfortunately, an external VFA addition is not usually cost-effective and it increases the overall plant carbon footprint. A promising and very attractive alternative would be focused on the utilization of waste materials that could be fermented to VFA (Guerrero *et al.*, 2012). Glycerol is a good example of such wastes materials since it is a by-product of biodiesel fuel production: about 1 L of glycerol is generated for every 10 L of produced biodiesel fuel produced. Taking into account all these considerations, crude glycerol could be a very practical and cost-effective external carbon source to reduce the detrimental effect of nitrate under anaerobic conditions since it could be used in both N and P removal processes. However, there are not previous studies about crude glycerol utilization as carbon source for improving EBPR.

RESULTS AND DISCUSSION

The control strategy presented is based on external carbon addition to mitigate the detrimental effect on EBPR of nitrate entering to the anaerobic phase. The procedure used involved four steps:

1) Model calibration under open-loop conditions including experimental data when the plant is operated with different disturbances (see Figure 1). The effect of these disturbances should be minimised once the control strategy is active. The parameters were calibrated following the guidelines of GMP and using the FIM approach to define confidence intervals (see example in Table 1). Data from a high ammonium disturbance (HAD) were used for calibration and data from a high nitrite disturbance (HND) for validation.

Red colour belongs to R1 (anaerobic reactor) concentrations, white colour to R3 (effluent), grey colour to Q_{REXT} . Model predictions: blue line indicates simulation ammonium results in R3, black line belongs to nitrate in R3, grey line to nitrate in Q_{REXT} , green line to nitrite in Q_{REXT} , red line to phosphate in R1 and black dashed line to phosphate in R3.

Table 1 Parameters obtained in the model calibration by using the experimental data of AD in A²O configuration. RSF: Reduction factor applied to the reactive settler capacity.

Parameters	ASM2d value (20°C)	Calibrated value	Confidence interval	Units
q_{PHA}	3.00	2.76	$4.8 \cdot 10^{-3}$	$\text{mg } X_{PHA} \cdot \text{mg } X_{PAO}^{-1} \cdot \text{d}^{-1}$

Q_{PP}	1.50	1.70	$2.4 \cdot 10^{-3}$	$\text{mg } X_{PP} \cdot \text{mg } X_{PAO}^{-1} \cdot \text{d}^{-1}$
μ_{HET}	6.00	4.10	$3.6 \cdot 10^{-3}$	d^{-1}
$\eta_{NO_3, OHO}$	0.80	0.32	$5.7 \cdot 10^{-3}$	-
$\eta_{NO_2, OHO}^*$	-	0.48	$2.5 \cdot 10^{-2}$	-
RFS*	-	0.59	$2.6 \cdot 10^{-3}$	-

* These parameters do not appear in ASM2d model (Henze *et al.*, 2000)

2) **Design the adequate control strategy** for the existing problem. This is a theoretical step where the know-how of the designers and the previous experimental data is essential. Figure 2 shows, in this example, the description of the control strategy based on crude glycerol addition under anaerobic conditions to reduce the nitrate concentration in the anaerobic reactor. The same control strategy was proposed and evaluated for both A²O and Johannesburg configurations. The parameters of the digital controllers were tuned according to ITAE criteria.

Figure 2 Scheme of the control structure proposed to reduce nitrate effect on EBPR in an A²O configuration.

3) **Simulation-based assessment of the proposed control strategy under different scenarios.** Once the control design is implemented, several scenarios (influent variability, disturbances, parameter changes, T, pH...) can be tested depending on the model prediction capability. In this case, the optimised and tuned control strategy was implemented in A²/O and JHB pilot plants to prevent EBPR failure for different ammonium and nitrite disturbances (see Figure 3).

4) **Experimental validation.** Once the model simulations are run, the control configuration with the optimised tuning is tested in the pilot plant. The maximum number of disturbances are applied to get even more insight on the process performance and to verify the simulation-based results. Figure 3 shows the validation step when the glycerol control strategy was applied. The model predicted very well the evolution of the main parameters and the control performance.

The results show that simple PI feed-back control for crude glycerol dosage could be very useful for easily maintain proper P-removal efficiency in full-scale WWTP, even operating under high nitrate anaerobic inlet conditions. However, some limitations on control performance could appear when treating influents with sudden changes in N influent concentration, because the controlled variable (P effluent concentration) has a slow response in front of manipulated variable changes (crude glycerol addition). Two different approaches are proposed to solve this behaviour: i) a simple modification of the control strategy by

controlling the P concentration in R1 and ii) feed-forward control in combination with feed-back control.

Figure 3 Experimental and model predictions when the control was applied in the JHB scenario. \triangle represents ammonium, \square nitrate, \circ nitrite and \diamond phosphorus. Red filled colour belongs to R1 (anaerobic reactor), white colour to R3 (effluent) concentrations, grey colour to QREXT (external recycle) concentrations. Model predictions: blue line indicates simulation ammonium results in R3, black line belongs to nitrate in R3, green line belongs to nitrite in R3, grey line to nitrate in QREXT, grey dashed line to nitrite in QREXT, red line to phosphate in R1 and black dashed line to phosphate in R3.

Validation of spontaneous mineral precipitation models

Christian Kazadi Mbamba, Damien Batstone, Stephan Tait

Advanced Water Management Centre, The University of Queensland, St Lucia, Brisbane, QLD 4072, Australia (Email: c.kazadimbamba@awmc.uq.edu.au)

Abstract

Current process models used across the wastewater industry have inherent limitations due to limited physico-chemical models, especially with respect to description of mineral precipitation reactions. As part of the overall effort towards development of more general and robust physicochemical models, this paper uses acid-base titration experiments to examine an equilibrium-kinetic modelling approach. The approach was first validated without precipitation and was then tested for titration with precipitation of magnesium and calcium phosphate minerals. The results suggest that a single-parameter equilibrium-kinetic approach can provide good prediction of wastewater pH over a wide range and is generally expandable for inclusion of multiple minerals.

Keywords

Acid-base titration, physico-chemical modelling, precipitation, equilibrium, kinetics

INTRODUCTION

Mathematical models have been successfully used as tools in research, process design, training, control and optimization of wastewater treatment. However, to date the emphasis of wastewater process models has largely been on biological reactions (Batstone et al. 2002, Henze et al. 2000) rather than physico-chemistry which is also highly influential and important (Batstone et al. 2012). Consequently, physico-chemistry modelling of wastewater has become an important field of research and development during recent times (Musvoto et al. 2000a, Tait et al. 2009). To date different modelling approaches have been applied to study a particular class of influential physico-chemical reactions, namely chemical precipitation. These modelling approaches are typically equilibrium-based (time-independent, thermodynamically driven) or kinetic-based (time-dependent, reaction rate dependent).

Briefly, equilibrium-based models assume that sufficient time has passed with each model timestep so that precipitation reactions achieve thermodynamic equilibrium and solution thermodynamics then determine the final mineral phase composition (Loewenthal et al. 1995, Ohlinger et al. 1998). Thus, the equilibrium approach does not give consideration of metastability (the occurrence of a significant state of supersaturation without any spontaneous precipitation), does not give information on intermediate mineral phases along the way to achieving thermodynamic equilibrium, and does not account for precipitation interactions between various mineral phases (Valsami-Jones 2001). An equilibrium-based approach can however be computationally efficient when compared with a kinetic-based approach and does

not require calibration of model parameters because these are all pre-defined by well-known electrolyte solution thermodynamics.

On the other hand, a kinetic-based model allows chemical precipitation or dissolution reactions to occur with each model timestep to achieve a resulting solution composition which may still have a significant super-or-undersaturation state. Kinetic-based modelling approaches are helpful to capture mechanistic aspects such as intermediate mineral phases (Barat et al. 2011) and inhibition of precipitation (Tait et al. 2009). However, model complexity can be an issue with kinetic-based models. As the number of minerals and precipitating ions increase, the complexity of the model also increases (Batstone et al. 2012). Each kinetic physico-chemical reaction has a dedicated kinetic rate expression with additional parameters to determine, and can introduce additional dynamic states for the solid mineral phases.

A likely optimum scenario is a combination of equilibrium and kinetic-based model structure to increase computational efficiency as well as capture mechanistic information. Such a model treats fast physico-chemical reactions (such as aqueous phase reactions) as equilibrium, and slow physico-chemical reactions (such as minerals precipitation) as slow dynamic processes. Combined equilibrium and kinetics may be a robust modelling approach that could be adopted across the wastewater industry as a general approach that would foster collaboration and communication and allow streamlined formulation of plant-wide models (Batstone et al. 2012). The equilibrium-kinetic modelling does however require testing and validation before widespread adoption, and towards this end, the present work uses acid-base titration with mineral precipitation to evaluate the modelling approach.

Materials and Methods

Sample materials

Stock solutions were prepared with analytical grade reagent chemicals dissolved in de-ionised water. The ionic strength of the stock solutions was typically adjusted to a desired value by adding sodium chloride. No mineral precipitate seed was used in the experiments, so any precipitation occurred spontaneously.

Apparatus

Solution pH was measured with a calibrated DGi115-SC pH probe (Mettler-Toledo, Greifensee, Switzerland). Potentiometric titrations were performed with a fully automated auto-titrator (T50, Mettler-Toledo, Greifensee, Switzerland). The titrator was equipped with a 10 mL burette to add titrant to the test solution. Titration vessels used in the experiments were (a) 100 mL beakers, with working volumes of 75 mL or b) a 1 L stirred glass crystallizer. During a titration, the test sample to which titrant was added was stirred with a 25 mm teflon-coated magnetic bar stirrer at 150 rpm. The volume of each titrant added, the pH and the temperature were recorded over time through a LabX Light Titration Software interface (Mettler-Toledo, Greifensee, Switzerland).

Experimental procedure

Acid-base titration tests were performed with and without precipitation to provide experimental data for model testing. All experiments were carried out at room temperature

(20 – 25°C). The pH probe was calibrated before each titration experiment using standard calibration buffers at pH 2, pH 4, pH 7 and pH 10. The pH of a 75-1000 mL aliquot of test solution (actual volume known accurately) test solution was adjusted to acidic pH with hydrochloric acid. About 10-20 mL of sodium hydroxide (or other titrant) was then quantitatively added at a set dosing rate and pH was continuously measured. For each experiment, the volume of titrant added over time and the corresponding pH were recorded together with the initial volume of the test solution. In some of the experiments a 1 mL sample of the crystallizer contents was collected at specified time intervals, immediately filtered through 0.2 µm syringe filters (PES) membrane, diluted with deionized water to prevent post-precipitation and stored at 4°C until further analysis by Inductively Coupled Plasma Optical Emission Spectroscopy (ICP-OES) and flow injection analysis (FIA).

Analytical techniques

The major elements (Ca, Mg) in the synthetic aqueous solution were analysed with ICP-OES (Perkin Elmer Optima 7300DV, Waltham, MA, USA). Ionic concentrations ammoniacal nitrogen (NH₄-N) and phosphate phosphorus (PO₄-P) were quantified with a Lachat QuickChem 8500 flow injection analyser (Lachat Instruments, Loveland, CO, USA) as per the Lachat QuickChem Method 31-107-06-1-A.

Modelling

The model structure consisted of two parts, namely, an equilibrium part which described aqueous phase reactions such as the acid-base and soluble ion association and a kinetic part for the slower chemical precipitation or dissolution reactions.

Modelling of aqueous equilibria

The equilibrium part consisted of a number of non-linear algebraic equations which were formulated by substituting equilibrium relationships (mass action laws) into species contribution balances in accordance with the so-called Tableau Method (Morel and Morgan 1972, Morgan and Stumm 1996). This provides a reduced equation set to solve for a smaller subset of selected ingredients (the model “components”) which have been arbitrarily selected to account for the total composition of the wastewater. This is a common approach used in the formulation of equilibrium models. The selected model components in this work were H⁺, Na⁺, NH₄⁺, Cl⁻, Ca²⁺, Mg²⁺, CO₃²⁻, PO₄³⁻ and the selected species (wastewater ingredients that were not selected as components) were H₂CO₃, H₂PO₄⁻, H₃PO₄, HCO₃⁻, HPO₄⁻², Mg(NH₃)₂²⁺, Mg₂CO₃²⁺, MgCl⁺, MgCO₃, MgHCO₃⁺, MgHPO₄, MgOH⁺, MgPO₄⁻, Na₂HPO₄, Na₂PO₄⁻, NaCl, NaCO₃⁻, NaH₂PO₄, NaHCO₃, NaHPO₄⁻, NaOH, NaPO₄²⁻, NH₃, OH⁻. The effects of temperature was corrected for using the constant-enthalpy van't Hoff approach and ionic strength was corrected for with the Davies approximation of activity coefficients also with separate temperature correction. In the development of the speciation model, one of the mainstream aqueous speciation programs, visual MINTEQ (Allison et al., 1991), was used as reference model to validate the simulation outputs of the developed equilibrium model, and thermodynamic constants that are in the MINTEQ database were also used in this study. Ionic strength and activity coefficient equations were solved with the main tableau equation set such that there were 10 implicit unknowns for a like number of equations. The full implicit algebraic equation set is given in the supplementary material.

The potential for precipitation or dissolution to occur was predicted using the well-known parameter termed the saturation index (SI) which is defined as follows

$$SI = \log_{10} \frac{IAP}{K_{sp}} \quad (1)$$

where IAP is the product of the chemical activities of participating ions in the supersaturated solution and as K_{sp} is the solubility product constant. For a given solution, three states exist, depending on the saturation index:

- If $SI < 0$, the solution is undersaturated, and a solid phase can dissolve into solution;
- If $SI = 0$, the solution is said to be saturated or at equilibrium;
- If $SI > 0$, the solution is supersaturated or oversaturated with respect to the mineral in solution, and chemical precipitation can occur.

Modelling of precipitation kinetics

The second equation subset consisted of slow kinetic reactions with corresponding kinetic rate laws which in-turn influenced a dynamic state equation set via respective stoichiometric coefficients. The rates at which these slow reactions occur are dependent on the concentrations of specific ingredients which are modelled in the equilibrium equation set (that is, the participating ions for a precipitating mineral). Thus, the kinetic equation set is influenced by the model solution of the parallel algebraic equation set. The equation set included dynamic state equations for total dissolved species and each mineral phase considered and the kinetic rate laws listed in Table 1. Each rate law expression had a lumped empirical rate coefficient k , a supersaturation term between brackets which determined the thermodynamic driving force for precipitation or dissolution to occur based on the chemical activities of the respective ions and a K_{sp} value which is the solubility product constant. The power-exponent values on each of the respective supersaturation terms were set at 3 for struvite and 2 for newberyite based on the prior work of Gunn (1976) and Musvoto *et al.* (2000b), respectively. This model structure can be easily expanded to include the precipitation of many other minerals.

Table 1: Stoichiometric matrix for the precipitation/dissolution and liquid-gas transfer processes

Precipitation process	Chemical states						Precipitation rate equations (ρ)
	H^+	NH_4^+	Ca^{2+}	Mg^{2+}	CO_3^{2-}	PO_4^{3-}	
Struvite (MgNH ₄ PO ₄) precipitation		1			1	1	$k_{Struv} \left[\left(\frac{S_{Mg^{2+}} S_{NH_4^+} S_{PO_4^{3-}}}{K_{spStruv}} \right)^{1/3} - 1 \right]^3$
Newberyite (MgHPO ₄) precipitation		1			1	1	$k_{Newb} \left[\left(\frac{S_{Mg^{2+}} S_{NH_4^+} S_{PO_4^{3-}}}{K_{spNewb}} \right)^{1/3} - 1 \right]^2$

The K_{sp} value for Struvite was assumed to be $10^{-13.26}$ (Kofina and Koutsoukos, 2005) and for Newberyite it was assumed to be $10^{-18.17}$ from the thermodynamic database in Visual Minteq (Allison *et al.* 1991). The model was implemented in MATLAB/SIMULINK (Version 8.1,

MathWorks Inc.) and the code is available from the authors on request, including documentation of the code.

RESULTS AND DISCUSSION

Equilibrium validation

Figure 1 presents results for measured and modelled pH of preliminary validation experiments without any precipitation. The results show that the model reliably predicted pH in the absence of precipitation, thus indicating that the equilibrium portion of the model was correctly implemented. It is important to note that no parameter adjustment was required to achieve these predictions, because the equilibrium is based on well-established electrolyte solution thermodynamics.

Figure 1: Model and experimental results for titration without precipitation and (a) 0.5M HCl added to synthetic aqueous solution with 60mM Na_2CO_3 , 50mM NH_4Cl , 2.44mM sodium acetate and 5mM NaH_2PO_4 (initial pH was increased with concentrated NaOH); and (b) 0.1M NaOH added to synthetic aqueous solution with 5mM NaH_2PO_4 (initial pH was decreased with concentrated HCl).

Titration with precipitation

Figure 2 show modelled and measured pH values for experiments with precipitation. The model was able to describe the experimental behaviour well for a value of $k_{\text{Struv}} = 0.7 \times 10^{-6}$ moles.min⁻¹ (Figure 2a). To attempt to simulate what would happen if struvite precipitation was occurring very fast (and thus the resulting solution would be forced to achieve a constant state of thermodynamic equilibrium) The value of k_{Struv} was arbitrarily set at a high value of 0.1 moles.min⁻¹ and the simulation results for this model is presented in Figure 2b. The resulting quasi-equilibrium precipitation is clearly shown in Figure 2c by a Saturation Index value of 0 (at equilibrium) between a model time of about 100 minutes and 500 minutes. That is, a model with rate parameters which are set to be sufficiently rapid theoretically gives identical results to an equilibrium-based formulation of the same modelled system (Musvoto *et al.* 2000a). The marked discrepancy between modelled and measured pH shown in the

quasi-equilibrium simulation (Figure 2b) is clear evidence that precipitation kinetics were influential over a titration time-scale of 600 minutes (10 hours). This is also shown in Figures 2c and 2d by the highly positive Saturation Index values for struvite as calculated from the measured concentration of magnesium, ammoniacal nitrogen and phosphate phosphorus in the liquid phase (data points in Figure 2c and 2d).

Figure 2: Results with precipitation - Measured pH for 2.1M NaOH added at a rate of $5.35 \times 10^{-5} \text{ mL/min}$ to a synthetic aqueous solution with 14.27mM NaH_2PO_4 , 29.84mM NH_4Cl , 4.85mM MgCl_2 (initial pH was decreased with concentrated HCl), presented with predicted pH for (a) $k = 0.7 \times 10^{-6} \text{ moles.min}^{-1}$ and (b) $k = 0.7 \text{ moles.min}^{-1}$. Measured saturation index presented with predicted saturation index with (c) $k = 0.7 \times 10^{-6} \text{ moles.min}^{-1}$ and (d) $k = 0.7 \text{ moles.min}^{-1}$.

The precipitation kinetics only influenced predicted pH over the range of 6-9, which suggested that above pH 9, the aqueous phase equilibrium dominated pH predictions. Below pH 6 it was known that precipitation had not yet occurred, as observed from a clear test solution (no precipitates visually observed) and the negative Saturation Index values.

From the saturation index values in Figure 2 (c), it is clear that newberyite ($\text{MgHPO}_4 \cdot 3\text{H}_2\text{O}$) did not show a significant supersaturation state for the particular experimental conditions. Accordingly, it was expected that only struvite precipitated in the experiment. In general,

struvite formation dominates, unless the supersaturation of newberyite is sufficiently greater than that of struvite (Abbona *et al.* 1982).

Figure 3 shows measured and predicted results for the aqueous-phase composition. As can be seen there is a good correlation between the experimental results and theoretical model predictions. The soluble concentrations of magnesium, total ammonical nitrogen and total phosphate phosphorus remain constant when the solution is undersaturated with respect to struvite as indicated by a negative Saturation Index value, and decreases when the solution becomes supersaturated with respect to struvite as shown by a positive Saturation Index value. These observations support the view that the saturation index can provide guidance to the modeller about which minerals may be precipitating under which conditions in a wastewater as previously suggested by others (Marti *et al.* 2008).

The model as a whole was considered to be highly identifiable due to the small number of fitting parameters (only the k -values for each of the minerals). The changing mineral surface area with continuous precipitation of struvite did not need to be considered in the model to give good predictions. These results suggested that a single-parameter (k -value) equilibrium-kinetic model (which is easily expandable to include other minerals) can provide good prediction of wastewater pH with precipitation.

Figure 3: Predicted and measured soluble concentration for magnesium (top), ammonia (middle) and total phosphate (bottom) pH for 2.1M NaOH added at a rate of 5.4×10^{-5}

mL/min to synthetic aqueous solution with 14.27mM NaH₂PO₄, 29.84mM NH₄Cl, 4.85mM MgCl₂ with a $k=0.7 \times 10^{-6}$ moles.min⁻¹.

Conclusion

In this paper an equilibrium-kinetic based model is applied to simulate spontaneous mineral precipitation in wastewater treatment. In order to avoid computational inefficiency and due to timescale differences, in the reactions occurring in the aqueous phase are assumed in the model to be at equilibrium relative to reactions between the aqueous phase and a solid phase, whereas reactions between the aqueous phase and a solid phase are treated as slow dynamic processes, each with a dedicated rate expression. The model was validated both without and with precipitation of magnesium phosphate minerals. The model structure can be easily expanded to include the precipitation of many other minerals of interest in wastewater treatment. The results suggest that a single-parameter equilibrium-kinetic approach can provide good prediction of wastewater pH over a wide range and is generally expandable for inclusion of multiple minerals.

Keywords

Abiotic processes, mathematical modelling, pH calculation, water chemistry

INTRODUCTION

In recent years the awareness of the effect of abiotic processes in wastewater and sludge treatment technologies has increased rapidly (Batstone *et al.*, 2012). In the field of municipal wastewater treatment for example, chemical processes play an important role in the performance of different technologies present throughout the plant. Besides, pH has an important impact on other processes that may take place in wastewater treatment such as precipitation or liquid gas transfer. Such processes will be critical in the future of these facilities as there are attempts to operate them in a sustainable and environmentally-friendly way. For example, there is a general concern about scarcity of some natural resources and the recovery processes of these resources often rely on physico-chemical processes (Vanrolleghem, 2013). Another example is the need to reduce greenhouse gas emissions that originate in the processes occurring at the wastewater treatment plant. Therefore, an appropriate description of the abiotic processes is of high importance in the development of models for the description of wastewater treatment technologies.

Traditional mathematical models, widely used for wastewater and sludge treatment, have different levels of detail for the calculation of pH. In the models proposed for wastewater treatment (ASMs) it is considered that the buffering capacity is sufficient, therefore there is no rigorous calculation of pH included (Henze *et al.*, 1987). In the case of models describing anaerobic digestion (ADM1) (Batstone *et al.*, 2002), models describing river water quality (RWQM1) (Reichert *et al.*, 2001) or the plant wide modelling (PWM) methodology proposed by Grau *et al.*, (2007) pH calculation from chemical equilibria is included; however, these models do not consider ionic activity in the calculation, which makes the models only valid for dilute systems, with low ionic strength (Batstone *et al.*, 2012). In the UCTADM of Sötemann *et al.*, (2005a) ion pairing was included but the fast equilibrium and speciation processes were included as dynamic processes along with the slow biological and precipitation processes, causing slow calculation times and/or numerical instability. In the model proposed for biological nutrient removal N2 (BNRM2) by Barat *et al.*, (2013) water chemistry is calculated using a commercial software tool MINTQA2 (Allison *et al.*, 2009). Finally, the UCTADMP, upgrade of the anaerobic digestion UCTADM proposed by Ikumi

(2011) describes chemical reactions using an algebraic speciation model (Brouckaert *et al.*, 2010).

As a result it has been recognised that these traditional models should be updated and rewritten in order to include abiotic phenomena. To address this, the IWA Physico-Chemical Framework Task Group (IWA PCF TG) has recently been constituted with the goal of developing guidelines and procedures to assist modellers to consider all these processes (Batstone *et al.*, 2012). One particular aspect is that, from a numerical point of view, the inclusion of acid-base equilibrium and the subsequent pH calculation in biochemical models can lead to the appearance of some degree of stiffness, caused by the different conversion rates considered. This may introduce numerical instabilities and slow down the simulation speed. Tackling this problem requires analysis and testing of numerical methods that deal with combined algebraic and differential equations.

Based on these postulates, the work presented in this paper aims to introduce a methodology for incorporating aquatic chemistry into models representing wastewater treatment processes, based on different approaches found in literature for the description of aquatic chemistry and its numerical resolution. A simulation scenario has been defined in order to carry out a comparative analysis of the different approaches in terms of the accuracy of the results and the simulation time.

METHODOLOGY TO INCORPORATE WATER CHEMISTRY INTO WASTEWATER TREATMENT PROCESS MODELS

The construction of dynamic mathematical models comprises of: (1) the selection and description of the relevant biological and physico-chemical processes in the system under study and (2) the definition of water chemistry to predict pH tailored to the model defined in the first step (Figure 1).

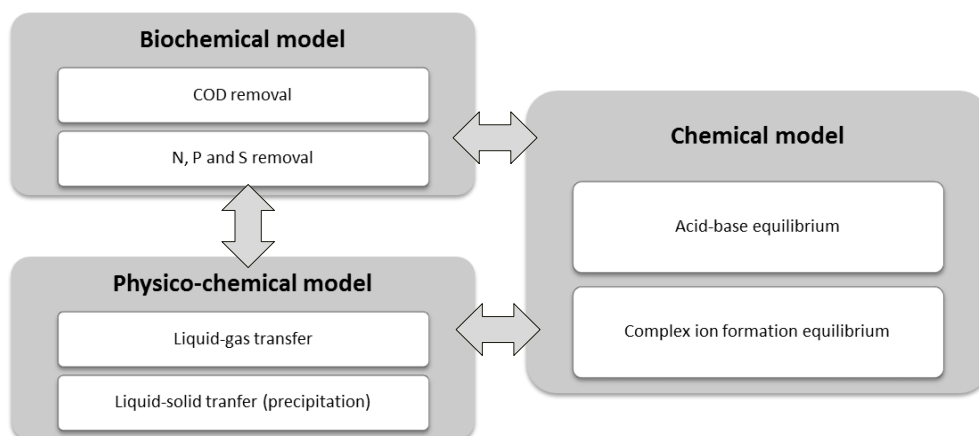

Figure 1. The selection of the chemical model depends on biological and physico-chemical model

The following sections focus on (1) the construction of the chemical model to describe chemical processes taking place in the system under study with the selected biological and physico-chemical processes; and (2) the introduction of different numerical resolution procedures to couple chemical models with biological and physico-chemical processes.

Modelling water chemistry

In order to describe the water chemistry in the system first the components and species have to be defined; as an example the 12 components and 38 species given in Table 1 were

collected for the case study presented below. Species are chemical entities taken to be physically present in the system, and for the given set of species, components are selected so that all species can be expressed as linear combination of components, and no component can be written as combination of other components. Chemical equilibrium modelling consists basically of formulation of the material balance and mass action law which determine species concentrations from a mixture composition specified in terms of component concentrations.

Table 1. List of species and components selected

Components			Species										
S _b	S _{TVA}	S _{Ca}	H	Mg	H ₂ CO ₃	H ₂ PO ₄	Hac	Hpro	CaH ₂ PO ₄	MgH ₂ PO ₄	MgCO ₃	NaHPO ₄	
S _{IP}	S _{TBU}	S _{ME}	Na	OH	HCO ₃	HPO ₄	Ac	Pro	CaHCO ₃	MgHCO ₃	MgPO ₄	NaOH	
S _{IN}	S _{TPRO}	S _{Na}	Ca	NH ₃	CO ₃	PO ₄	Hbu	Hva	CaHPO ₄	MgHPO ₄	NaCO ₃		
S _{IC}	S _{TAC}	S _{Cl}	Cl	NH ₄	CaCO ₃	CaOH	Bu	Va	CaPO ₄	MgOH	NaHCO ₃		

The principles of water chemistry modelling are set out in Stumm and Morgan (1996). The equilibrium relationships are formulated in terms of species activities (e.g. Eq1), which are related to their concentrations by activity coefficients (e.g. Eq2). Activity coefficients were modelled using the Davies equation (Eq3 and Eq4). The mass conservation equation can be expressed either to (i) guarantee electroneutrality, i.e. guarantee the sum of cations equals the sum of anions (Eq5) or (ii) using the alkalinity-acidity continuity, this is formulating proton conservation equations (Eq6). Combining these mass conservation equations and the mass action relationships, a set of simultaneous equations is obtained which can be solved for all species concentrations.

$$K_a = \frac{\{H^+\}\{A^-\}}{\{HA\}} \quad (Eq1) \quad \{H^+\} = \gamma_{H^+} [H^+] \quad (Eq2) \quad I = \frac{1}{2} \sum_i M_i \cdot z_i^2 \quad (Eq3) \quad \log(\gamma_i) = -Az_i^2 \left[\frac{\sqrt{I}}{1 + \sqrt{I}} - 0.3I \right] \quad (Eq4)$$

Where,

K_a: equilibrium constant
{S}: activity of species S

[S]: molality of species S
γ_S: activity coefficient of S

I: Ionic strength
M_i: molality of species i

Z_i: charge of species i
A: Debye-Huckel constant

$$\sum S_{C+} - \sum S_{A-} = 0 \quad (Eq5)$$

Where,
S_{C+}: represents total cation equivalent concentration; and
S_{A-}: represents total anion equivalent concentration.

$$\sum_i a_{ij} M_i - T_j = 0 \quad (Eq6)$$

Where,
a_{ij}: stoichiometric relationship of species i and component j;
M_i: molality of species i; and
T_j: molality of component j given by the process model mass balance.

Numerical resolution procedure

When combining biological and chemical reactions, numerical resolution is a critical step, because of the stiffness that arises when considering reactions with very different conversion rates. In the case of dynamic models, there are two possible resolution procedures:

- (i) All reactions are calculated simultaneously using ordinary differential equations (ODE) as in Musvoto *et al.* (2000a,b) and Sötemann *et al.* (2005a,b).

Figure 2. Model resolution procedure using the ordinary differential equations (ODE approach)

- (ii) The slower reactions are represented by differential equations and the fast reactions are calculated algebraically (DAE) at each iteration step (Figure 3) as in ADM1 (Batstone

et al., 2001), Volcke *et al.*, (2005), Rosen *et al.* (2006) or UCTADMP (Brouckaert *et al.*, 2010; Ikumi *et al.*, 2011). In the DAE approach, the modeller can choose between having a tailored code to solve water chemistry or using an external software tool such as PhreeqC+ (Parkhurst and Appelo 2013) or MINTEQA2 (Allison *et al.*, 2009; Barat *et al.*, 2013) at each iteration step.

Figure 11. Model resolution combining differential and algebraic equations (DAE approach)

COMPARISON OF DIFFERENT RESOLUTION APPROACHES

The objective of this study was (i) to check the capability of the model presented in the previous section to calculate aquatic chemistry equilibrium, and (ii) to carry out a comparison of the different approaches in terms of results accuracy and simulation speed. For this purpose, the anaerobic reactor in the Benchmark Simulation Model No 2 (BSM2) (Jeppson *et al.*, 2007) was selected as the simulation test case.

Results and discussion

Using the conditions presented above, a dynamic simulation for a period of 365 days was run in order to check the capabilities of the different models. When running the simulations, different integrators and kinetic parameters have also been tested. The comparison between results obtained with different approaches regarding simulation time, and accuracy of results is shown in Table 2. For the ODE approach, the CVODE solver was used, and two values for the equilibrium kinetic rate have been compared: 10^{12} and 10^6 . It is seen that when using the kinetic rate of 10^{12} the simulated results are more accurate, since the result is closer to equilibrium. Nevertheless, higher kinetic rates slow down the simulation speed. The DAE approach using a tailored code for equilibrium calculation showed the shortest simulation time. Finally, when simulating the scenario with the external software Phreeq C+, the highest number of species was considered, but the simulations were the slowest (in designing the tailored code, species which had insignificant impact under the conditions found in anaerobic digesters were excluded to improve the simulation speed). A more detailed comparison using the full BSM2 will be presented in a forthcoming paper.

Table 2. Simulation of the anaerobic reactor in BSM2 under dynamic conditions for a period of 365 days

	Evaluation criteria			Evaluation criteria	
	Simulation time (sec)	$\sum (K_a \cdot \{HA\} - \{H^+\} \{A^-\})^2$		Simulation time (sec)	$\sum (K_a \cdot \{HA\} - \{H^+\} \{A^-\})^2$
ODE-Kab 10^{12}	6.25	7.61^{-05}	DAE-Tailored	0.96	0
ODE-Kab 10^6	3.82	7.85^{-05}	PhreeqC+	23.36	0

The results show that the optimum resolution procedure depends on the objectives of the simulation study. However, this work shows that the methodology proposed using a tailor-made equilibrium calculation using algebraic equations, and incorporating it into the biological ODE system gave the most effective methodology, based on the simulation times of the different approaches.

CONCLUSIONS

Different approaches for calculating chemical equilibrium have been presented and a critical review has been undertaken. Based on this comparison a methodology is proposed for incorporating water chemistry into biological models.

Abstract

To date, computational fluid dynamics (CFD) models have been primarily used for the evaluation of hydraulic problems at wastewater treatment plants (WWTP). A potentially more powerful use, however, is to simulate integrated physical, chemical and/or biological processes involved in WWTP unit processes on a spatial scale and to use the gathered knowledge to accelerate improvement in plant models for everyday use. Evolving improvements in computer speed and memory and improved software for implementing CFD, as well as for integrated processes, has allowed for broader usage of this tool for understanding, troubleshooting, and optimal design of WWTP unit processes. This paper proposes a protocol for an alternative use of CFD in process modelling, i.e. as a way to gain insight into complex systems leading to improved modeling approaches used in combination with the IWA activated sludge models (ASM) and other kinetic models.

Keywords

CFD, biokinetic models, transport models, multi-phase flow, fluid motion, complex systems

INTRODUCTION

Wastewater treatment plants (WWTP) are complex systems with interacting hydraulic, biological, and chemical elements. Optimization of design and operation of WWTP unit processes is of interest, especially with respect to the challenge of highly dynamic influent flows. In this respect, mathematical modeling has proven to be a powerful tool. The main focus in the past has been on modeling chemical and biokinetic processes using simplified hydraulic assumptions. This approach has resulted in the development of the Activated Sludge Model (ASM) family of models (Henze et al., 2000) as well as the Anaerobic Digestion Model (ADM) (Batstone et al., 2002). These models typically assume a continuously stirred tank reactor (CSTR) or use relatively simplified hydraulic conceptualization, i.e. the tanks in series (TIS) approach. The latter was developed in the chemical engineering industry as a way to describe the level of macro-scale dispersion within the unit process while limiting the model's state numbers and avoiding use of spatially-varying partial differential equations as this complicates the numerical solution and slows down the simulation speed (Levenspiel, 1972). However, the industry has been well aware of

the limitations of these hydraulic simplifications for many years: "If we know precisely what is happening within the vessel, thus if we have a complete velocity distribution map for the fluid, then we are able to predict the behavior of a vessel as a reactor. Though fine in principle, the attendant complexities make it impractical to use this approach." (Levenspiel, 1972, p 253). Considering current developments in the theory and practice of computational fluid dynamics (CFD) it is time to re-assess this conclusion.

CFD has become an accepted method for process analysis in a diverse range of industries from aeronautics to ocean engineering. It has been used for analysis and design of water and wastewater treatment plant process elements since Larsen's pioneering study presented the first CFD model for activated sludge sedimentation incorporating solids transport and settling (Larsen, 1977). Use of CFD as a full transport modeling approach for wastewater treatment tanks was already visualized over 20 years ago (Samstag *et al.*, 1992), but has not been extensively or systematically applied until recently. CFD has evolved into a relatively accepted tool by consultants and practitioners for analysis of hydraulic problems in wastewater treatment plants, notably for outfalls and flow splitting devices, as well as for chemical mixing. With steadily increasing computational power over the past decades, it is no longer "impractical" to use CFD for process analysis.

In addition to CFD use in practice, it also keeps developing in academia. Initially, CFD had been used for evaluation of mixing and solids settling in sedimentation tanks and results from these models have been informative in improving process performance. Evolving promising areas of research include the use of CFD to simulate physical, chemical, and/or biological processes in WWTP tanks where fluid flow characteristics are important. This endeavor has long been hampered by lack of availability and high cost of CFD software (including pre and post-processing), steep learning curves for their use, and limitations in computational power. Hence, CFD was not used for integration with these kinetic models. Now that commercial and open-source software packages with a choice of turbulence models and graphical user interfaces for pre and post processing are available, however, researchers have been able to explore the CFD approach to investigate WWTP unit process performance.

These initial results have so increased confidence in CFD in helping elucidate the impact of the spatial variations in velocity profiles on process outcomes that it can now be used for prediction of performance of unit processes beyond sedimentation. For example, the insertion of bio-kinetic models into CFD simulations of WWTP processes as well as their validation (e.g. Le Moullec *et al.*, 2010a; Gresch *et al.*, 2011; Sobremisana *et al.*, 2011) provided significant and reliable insights into complex contaminant removal performance in these processes.

As more experience is gained in CFD-based process modeling, researchers and engineers will achieve a better understanding of where and when simpler models are adequate and be able to suggest potential improvements in the TIS models themselves. Indeed, from these insights, simpler representations of these mechanisms can now be developed and used in significantly less computationally intensive unit process models. For example, Potier *et al.*, (2005) proposed a dynamic TIS model with back-mixing which is able to simulate variations of the axial dispersion coefficient with the flowrate by taking into account a maximal fixed number of mixing cells and a variable backflow rate. This model derived from correlations with a large set of lab-scale and full-scale experiments. In the future, similar approaches could be performed using CFD to determine the appropriate number of tanks in a TIS model

depending on the influent dynamics. The issue of biokinetic-hydraulic feedback can also be incorporated (e.g., gas production, changes in fluid properties) through iterative analysis.

The present paper aims at proposing a protocol for this alternative use of CFD modeling in order to get more insight into unit process description and improve simpler models conceptualization, calibration, and validation.

PROTOCOL

To date, it is not very clear to non-CFD model users what the exact role is that CFD is playing or can play in the field of wastewater treatment modeling. It is often perceived as an overly complex modeling tool that eats too much computational time and is therefore not considered. In this contribution we want to share our views on how this simulation tool can be used in the train of thought of wastewater process modeling apart from the current usage as stand-alone tool for unit processes design and troubleshooting. In this way, it can contribute to the further development of wastewater process models to its full extent.

Fig. 1 presents a schematic visualization of a protocol for CFD use in improvement of WWTP process modelling. The protocol suggests that CFD be used as a supportive tool for wastewater process modeling rather than as replacement for simpler modeling approaches. Indeed, dynamic simulation of a whole WWTP with CFD may not be feasible for another couple of decades. But in the meantime, CFD can still serve the community.

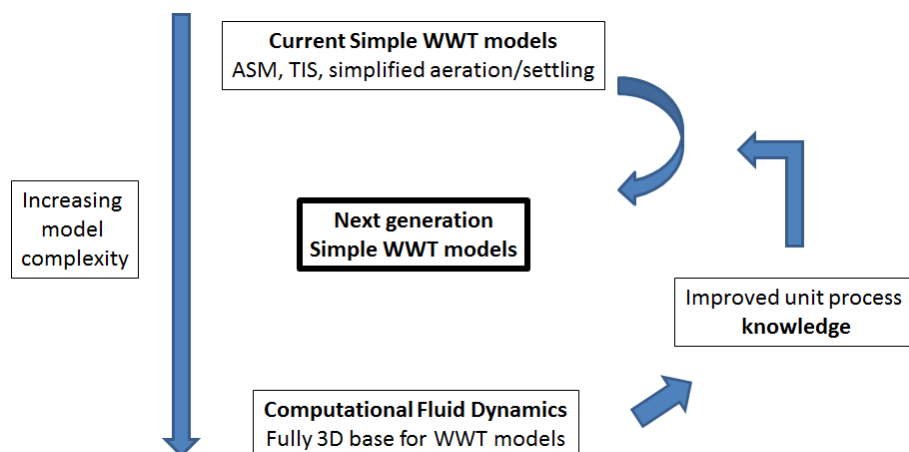

Figure 1. Conceptual map for use of CFD as a super-tool for process modeling.

The currently used “simple” WWT models are located at one end of the model spectrum (Fig. 1 – top), whereas the complex CFD models are at the other end (Fig. 1 – bottom). For certain model objectives, the former models are not adequate and slightly more complex models are required (“next generation simple WWT models”). In order to develop those, one needs improved process knowledge. It is especially in this respect that complex, validated CFD models can be of aid.

We see this as a 5-step protocol for use of CFD as a tool for improving/developing simpler models:

1. **CFD model formulation:** Development of CFD models representing detailed features of the process tank geometry, as well as other ingredients such as turbulence, a coupled ASM biokinetics model, a full-fledged detailed aeration model, viscosity models, density couples, temperature gradients, solids gradients due to settling, etc.
2. **Data collection:** Lab or field test of appropriate process variables (velocity profiles, species concentration profiles, gas hold-up measurement, residence time distribution, etc.) to validate results of the CFD model
3. **CFD model validation:** Compare the CFD model prediction with the data. If match is insufficient, one should return to steps 1&2 and recheck model formulation and data quality.
4. **Comparison to simpler model predictions:** Detailed comparison to the results of simpler models for the same geometry and loading condition. Based on this, shortcomings can be pinpointed.
5. **Improved simple model:** These shortcomings lead the modeller in developing next generation models such as dynamic systemic models, compartmental, or other non-linear macro-scale mixing models.

In the remainder of the paper we illustrate this train of thought through an example available in the literature that is actually an onset to this protocol, but not originally described in that way.

CASE STUDY: MODELING A PILOT-SCALE BIOREACTOR

The work in several papers of Le Moullec *et al.* (2008, 2010a, 2010b, 2011) is representative of what could be seen as application of the protocol introduced above. While it was never presented in the form of a protocol, we feel that the approach is important in illustrating how this protocol could be implemented.

STEP 1: CFD model formulation

The unit process used for both experiments and modeling purposes was a bench scale channel reactor with a total length of 3.6 m with a rectangular cross section of width and height, respectively equal to 0.18 and 0.2 m. One side of the walls of the reactor was fitted with stainless-steel tubes in which 1mm holes had been drilled every centimeter for air sparging. Further description is presented in Le Moullec *et al.* (2008).

Development of the CFD model utilizing an Euler-Euler approach is described in detail in Le Moullec *et al.* (2008). CFD simulations were carried out with the CFD software FLUENT. Two turbulence models were tested: a two-phase k- ϵ model and a Reynolds Stress Model (RSM). Boundary conditions were defined as presented in Table 1.

Table 1. Boundary conditions used for CFD computations.

	Inlet	Outlet	Top
Gas	Specified velocity inlet and phase fraction	/	Pressure outlet
Liquid	Specified velocity inlet and phase fraction	Specified velocity outlet and phase fraction	Symmetry boundary condition
Turbulence	Turbulence intensity (10%) and inlet hydraulic diameter	Turbulence intensity (10%) and outlet hydraulic diameter	Turbulence intensity (10%) and outlet hydraulic diameter

A second order discretization scheme (QUICK: Quadrative Upwind Interpolation for Convective Kinematics) was selected for the momentum equations, turbulent dissipation rate, and void fraction equations. The SIMPLE (Semi-Implicit Method for Pressure-Linked Equations) pressure–velocity coupling scheme was also used.

STEP2: Data collection

Experiments were carried out to validate the CFD model. Two types of data were gathered. First, laser Doppler velocimetry (LDV) allowed the axial (U_x), lateral (U_y) and vertical (U_z) time-averaged velocity fields to be measured (Le Moullec *et al.*, 2008). Second, residence time distribution (RTD) data was obtained from multiple tracer experiments (Potier *et al.*, 2005).

STEP3: CFD model validation

Mesh sensitivity was examined using different hexahedral cell sizes of 1 cm^3 (130,000 cells), 0.125 cm^3 (1,000,000 cells), and 1 cm^3 with a refinement near the walls (350,000 cells). This last grid offered the best compromise between precision and computational effort.

The results of the CFD model concerning velocity field and RTD simulation (with both passive scalar and particle tracking methods) were compared with the experimental values. The two simulated velocity fields are compared to experimental data in Fig. 2. Both models gave similar results and overall agreement was good. The observed discrepancies, respectively near the bubble injection position and near the free surface, were probably due to the simplification made for the gas inlet boundary conditions and the simplified representation of the surface, which was not planar in the experimental setup. In the RTD tests (Fig. 3), the RSM turbulence model coupled with the particle tracking method produced better fit to the experimental results than the $k-\epsilon$ model.

Figure 2. Overall representation of the experimental and simulated average velocity fields on a vertical plane (y,z) for both turbulence models (source: Le Moullec *et al.*, 2008)

Figure 3. Comparison between experimental and simulated RTD data obtained with the RSM and the $k-\epsilon$ turbulence models and the particle tracking method for a liquid flow rate of $3.6 \text{ L}\cdot\text{min}^{-1}$ and a gas flow rate of $15 \text{ L}\cdot\text{min}^{-1}$ (source: Le Moullec *et al.*, 2008)

STEP4: Comparison to simpler model predictions

TIS and CFD hydrodynamic models were coupled with ASM1 biokinetic equations using standard parameters values in order to simulate biological reactions occurring in the pilot reactor. Comparison of both models prediction with experimental nitrate concentration profiles along reactor length is shown on Fig. 4. Even if biokinetic parameters were not at all calibrated in this study, one can observe that the CFD model provided a better prediction than the TIS model.

STEP5: Improved simple model

In an effort to correct the shortcomings of the TIS model, a compartmental model was developed (Le Moullec *et al.*, 2010a). This latter approach simulates the reactor as a network of spatially distributed functional compartments (Fig. 5). Definition of this kind of model relies on the results of the steady-state CFD hydrodynamics model (STEP 1-3). The number and spatial distribution of compartments are defined according to the homogeneous character of selected parameters with a given tolerance (e.g. gas fraction), as well as the exchange between them (convective flow rates and turbulent backflow rates). Fig. 4 shows that the fit of this somewhat more complex model is much better than the TIS approach and very close to the CFD-ASM1 model (STEP 4). This work (Le Moullec *et al.*, 2011) demonstrated the possibility to accurately predict pollutant concentrations, not only with a detailed CFD-biokinetic model (STEP 4), but also with a simpler hydrodynamic model of which the structure is derived from the results of a single steady-state CFD simulation without biokinetics.

Figure 4. Nitrate concentration profile along the reactor for two experiments carried out on the pilot-scale bioreactor (source: Le Moullec *et al.*, 2011)

Figure 5. Structure of the compartmental model (source: Le Moullec *et al.*, 2011)

COMPARISON OF THE COMPUTATIONAL REQUIREMENTS OF CFD AND SIMPLER MODELS

The compartmental model allowed the prediction of pollutant concentration within a pilot-scale activated sludge reactor after a few minutes of calculation compared to 1 week of calculation for the CFD-biokinetic approach (Le Moullec *et al.* 2011). Compartmental modeling can be used where the incorporation of biokinetics within a CFD model would be computationally cost prohibitive and where the TIS model is not able to sufficiently describe the macro-scale mixing behavior of the complex system (Alvarado *et al.*, 2012).

PERSPECTIVES ON FUTURE APPLICATION

The example illustrates the power of CFD as a supportive tool in developing improved “next generation” WWTP models. Further application of this protocol may even lead to certain recurrent patterns which exclude the necessity to build a CFD model in certain cases.

A logical next application for the protocol is in modeling the anaerobic digester process and more specifically, the mixing component of the process. Two-phase gas-liquid models have been performed of anaerobic digesters using CFD to help improve mixing performance. Yet, no CFD transport model of the anaerobic digester had been developed that captured both the biological processes and complete complex three phase fluid characteristics, until quite recently (Gaden, 2013). This type of model is needed to completely understand the impact of digester mixing systems and changes in digester influent characteristics on biogas production, or to assess the potential upgrades of digester capacity. TIS modeling is widely used to simulate tracer testing (Batstone *et al.*, 2005), which may include feedback and bypass links, and it is a straightforward extension to validate these using CFD and to implement improved

biokinetics for an assessment of how the hydraulic regime influences process stability. There is every reason to believe that this approach will also prove fruitful for evaluation of suspended growth treatment tanks.

One question that remains is when exactly one considers the CFD model to be sufficiently validated. What deviations are acceptable? Tools for evaluating this question need to be developed. Where the validation is determined to be inadequate, one needs to reiterate Steps 1 and 2. With regard to model formulation, recent work on process tank mixing (Samstag et al., 2012) has suggested an explanation for past failures to adequately size mixing devices resulting from ignoring density effects in the CFD analysis. In the future, this approach should be incorporated into CFD models and will, hence, be included in evaluation of simpler models.

Another major challenge that exists in biologically driven wastewater unit processes is due to the complex intersection between potential macro- and micro-scale reactions that occur outside and inside biological floc particles. These two-scale processes can be difficult to model and computationally expensive. Yet, the lack of modeling these two-scale processes can reduce the effectiveness of CFD in simulating specific phenomena in activated sludge systems such as the occurrence of simultaneous nitrification-denitrification processes, etc. Next to these examples, several other submodels can be added to the plain CFD models to further validate them and build even better process knowledge. This further knowledge development runs in parallel with the application of already gathered knowledge to build the next generation of practical models.

CONCLUSION

Direct use of CFD approaches that allow substantial expansion to include complex biokinetics or other behavior is currently challenging for practical use due to computing and numerical issues. However, CFD studies in the field of wastewater treatment can, next to their current application as design and troubleshooting tool, be used to develop the next generation of more practical, everyday models. A 5-step protocol was outlined describing how this can be done and was illustrated using an example from the literature. This shows the power of this approach and how it can lead to more reliable everyday models. Further perspectives were given as well as how current CFD model development fits into this train of thought.

Abstract

Due to the elevated energy intensity inherent of fine-pore diffuser aeration within wastewater treatment, it is important to describe the real nature of aeration systems for improved design and optimization. We compiled two experimental datasets and developed a dynamic model to predict air flow for fine-pore diffuser aeration systems. The model was applied to two water reclamation plants, calibrated and validated with a time-sensitive database. Our model improves both prediction and description of field data with the introduction of an improved aeration model structure based on the organic load. Our results are a quantitative tool for prediction of energy wastage, and for minimizing aeration design uncertainty.

Keywords - Activated sludge; aeration; alpha factor; fine-pore diffusers; oxygen transfer

INTRODUCTION

Aeration is an essential and energy-intensive process for most wastewater treatment plants, and contributes 45 to 75% of process energy demand (Reardon, 1995). Fine-pore diffusers are preferred in the aeration of municipal wastewater treatment plants for their generally higher oxygen transfer efficiency (OTE, %). OTE tested in clean water is corrected to standard conditions (i.e., zero dissolved oxygen, 1 atm, 20°C, zero salinity) to produce the standard OTE, or SOTE (%). OTE in process water is lower compared to clean water due to the effects of contamination, quantified by an α factor, which is the ratio of the oxygen transfer coefficients in process to clean water (Stenstrom and Gilbert, 1981). Thereby α SOTE (%) is used to define standard oxygen transfer efficiency in process water. Evidence of the dynamic nature of α ranging from 0.25 to 0.55 was presented by Leu et al. (2009) with 48 off-gas tests over a 24h cycle. Blower power is dependent on air flow rate (AFR), hence on α SOTE. Hence, a dynamic estimation of α and SOTE is key to curbing the uncertainty in modelling aeration energy and in aeration design. The goal of this research is to present a dynamic model to predict air flow from for diffused aeration accounting for the variation of α SOTE with plant load.

METHODS

Process conditions. Both plants selected to test our model are located in California in areas characterized by a two-season climate with temperature oscillating between 19°C and 27°C. The summary conditions for both plants are reported in the Table 1. Water reclamation plant 1 (WRP1) uses an activated sludge process that nitrifies and denitrifies using the modified Ludzack-Ettinger (MLE) configuration. WRP2 is a fully denitrifying water reclamation plant, operating biological nutrient removal in MLE configuration with tertiary operations.

Table 1. Summary of average process conditions at the two plants studied.

	Q (MLD)	MCRT (days)	Diffuser Type	Diffuser Area (m ²)
WRP1	37	7.0	Polyurethane membrane strip	0.61
WRP2	57	8.5	EPDM membrane disc	0.041

Field measurements. In order to estimate the specific SOTE, i.e. SOTE/Z or SSOTE (%/m), of new diffusers clean water, tests were performed beforehand following the American Society of Civil Engineers standard procedure (ASCE, 2007). The measurements of α SOTE and α SOTE/Z were performed according to the ASCE off-gas protocol (ASCE, 1996), which uses the same saturation depth correction as the ASCE clean water. Measurements at WRP1 were taken every 30 minutes for 24 hours. The ratio of the results from the off-gas tests and the clean water tests were used to calculate α factors.

Model characteristics. This model used the WRP1's α vs. COD set for calibration (Fig. 1). The calibration set of time-dependent data for α versus plant load (oxygen demand and flow rate) were previously presented by Leu *et al.* (2009). In short, instead of predicting the oxygen transfer rate OTR from the air flow multiplied by a constant α , the model uses an α that is variable as a function of the COD. Thus, after selecting a reasonable initial guess value for AFR, the model iterates the re-calculation of AFR using α and SOTE as power fits functions of COD and AFR, respectively, until the DO target is met. This model is not aimed at substituting the ASMs, but is an extension of their structure to include dynamic modelling of O₂ transfer.

Figure 1. Case of WRP1, used as calibration set for α vs. COD.

RESULTS AND DISCUSSION

The model applied to WRP2 for validation. As showed in Fig. 2(a), the model on average describes well the actual trends of AFR. A comparative analysis of our dynamic α modelling vs. the traditional static modelling that is currently state-of-the-practice is also presented in Fig. 2. Due to the unavailability of a dynamic α model, aeration modelling is performed by selecting constant α values (typically based on one or a combination of recommendations from: diffuser manufacturers; modeller experience; design/process engineers) and using a dynamic function to compensate SOTE with different air flux. In Fig. 2b, the results from

dynamic modelling (grey cross symbols) are compared with static modelling results, calculated with constant α values (blue trend lines). The linear trend that describes the data points is not plotted here as it has a slope of 0.961, and for clarity of plotting we use the diagonal instead. The coloured trend lines show the result of predicting air flux using static modelling: the region where the regression lines encounter the diagonal describes where (in terms of air flux) it is appropriate to use that α value. It appears evident that the range of alpha values to be employed in modelling is wide (0.4-0.8) depending on the air flux, as reported from previous field observations (*inter alia*, Rosso et al, 2005; Gillot and Héduit, 2008).

One should discuss here the implications of operating the plant at constant DO set point. Currently, new technologies in process control are gaining wider distribution, such as variable set point DO/ NH_4^+ control systems. These allow an adaptive variation of DO controls based on the effluent ammonia levels, so to adjust the DO set point to the actually required value to meet effluent limit, thus curbing excess aeration and energy wastage. Neither plant modelled here had such system installed, but a next research step would be to model processes so equipped.

Figure 2. Predictive use of the dynamic model: simulation of WRP2. (a) Actual vs. predicted air flux for 1 month with dynamic α and with a constant α of 0.35 and 0.80; (b) Comparative results of 2 years of air flow rate (AFR) prediction using a dynamic α calculation from process parameters (described for plotting clarity by the diagonal in lieu of the actual linear fit with slope 0.961) versus using the classical approach of constant α (curves): the point where each curve meets the diagonal is the air flux point where the use of the curve's corresponding α factor is appropriate.

Some uncertainty is still evident in the data scatter of Fig. 2b. This may largely be attributed to the use of COD instead of its fraction rbCOD , which is expected to be descriptive of the surfactants present in municipal wastewater. These have been associated with the alteration of

diffuser performance from clean water (i.e., α factors) since the 1980s (Zlokarnik, 1980). Future steps should include the model recalibration using fractionated COD, to test the hypothesis that rbCOD is indeed the variable needed for aeration modelling.

Also, the present model version does not include the effects of diffuser fouling. Therefore, the model extension presented here should be used by design engineers to reduce the design uncertainty. Current work is undergoing to include the effects of diffuser fouling on α . When these effects are embedded in future revisions of the model structure, the unified model can be applied also to predict future aeration performance.

CONCLUSIONS

A dynamic model to describe the load dependence of α factors in activated sludge diffused aeration is introduced. This is an extension to the ASM structure to include the dynamic recalculation of air flow using a dynamic α (i.e., as a function of COD). The results show the model adequacy to describe the true dynamic nature of the α factor and oxygen transfer. The calibration using a 24h set of data from WRP1 allowed the validation on a 2-year data set from WRP2. We present here the discrepancy between the static α modelling practiced hitherto and our dynamic results. The results from current static modelling efforts are valid in a restricted domain of air flow, whereas our dynamic results transition smoothly from different regions of air flow.

The application of removal coefficients for viruses in different wastewater treatment processes calculated using stochastic modelling

Edgard Dias¹, James Ebdon¹, and Huw Taylor¹

¹School of Environment and Technology, University of Brighton, Lewes Road, Brighton, United Kingdom, BN2 4GJ (Email: e.dias@brighton.ac.uk ; je3@brighton.ac.uk ; h.d.taylor@brighton.ac.uk)

Abstract

The current study proposes the calculation and interpretation of removal coefficients (K_{20}) for bacteriophages in activated sludge (AS) and trickling filter (TF) systems using stochastic modelling. Initial results have demonstrated that the removal of somatic coliphages is higher than that of F-RNA coliphages in both AS and TF systems and that AS more effectively removes both phage groups than TF. The results also suggest that the obtained removal coefficient (K_{20}) values may be used to estimate the quality of final effluents in AS and TS systems using simplified models. Future work will include enumeration and modelling of specific enteric viral pathogens in order to develop practical predictive tools and to support integrated water and sanitation safety planning approaches to human health risk management.

Keywords

bacteriophages, viral particles, wastewater treatment, sanitation safety planning

INTRODUCTION

Human enteric viruses are commonly found in municipal wastewaters and many of them are capable of causing illnesses in humans (Bosch, 1998; Metcalf and Eddy, 2003). Viruses have been shown to be more resistant to wastewater treatment processes than other microorganisms. Furthermore, the limitations of traditional bacterial water quality indicators (e.g., faecal coliforms and *E. coli*), such as differences in their occurrence and persistence compared with enteric pathogenic microorganisms both in engineered and natural environments, have led to research into numerous novel viral indicators (Jofre et al., 1995; Purnell et al., 2011; Ebdon et al., 2012).

Emerging potential indicators include bacteriophages, or simply phages, which are a group of viruses capable of infecting prokaryotic organisms that are, as are all viruses, obligate intracellular parasites (Metcalf and Eddy, 2003; Withey et al., 2005). The phages used in water and wastewater quality monitoring fall into three main groups: (i) somatic coliphages – phages that infect *E. coli* strains; (ii) phages infecting *Bacteroides spp.* – strict anaerobic bacteria comprising the major part of the human gastrointestinal microbiota; and (iii) male-specific F-RNA coliphages – phages commonly used as indicators of human enteric viruses (Grabow, 2001).

In order to estimate the concentration of physico-chemical or microbiological parameters in treated effluent from wastewater treatment plants (WWTP), different models are required, depending on the nature of the treatment hydraulics (e.g., plug-flow vs. mixed reactors) and the kinetics of such reactions (e.g., first or second order). Uncertainties around specific parameters can also be factored in using a ‘stochastic modelling’ approach, which assigns the

input variables to value ranges according to their specific frequency or probability distributions (Morgan and Herion, 2007; Vose, 2008).

Therefore, this initial study (part of a larger evolving investigation that also considers enteric viruses and faecal indicator bacteria) demonstrates the potential application of stochastic modelling to improve our understanding of the removal of phages in activated sludge (AS) and trickling filter (TF) treatment systems, using data collected from four WWTPs situated in southern England. As such, it supports an effective multiple barrier approach to disease control, as part of a Sanitation Safety Plan (SSP).

MATERIAL & METHODS

Samples of settled wastewater and post-secondary sedimentation wastewater were collected every two weeks from May to November 2013, from four WWTP situated in southern England, including two Activated Sludge (AS) and two Trickling Filter (TF) systems. The WWTP can be regarded as small to medium-scale, having population equivalents of 14,554 and 44,930 (for the AS systems) and 5,084 and 33,229 (for the TF systems). For all samples, somatic coliphage (WG-5) and F-specific coliphages (WG-49) were enumerated using standardised double-layer techniques (BSI, 2001; 2002) and expressed in terms of Plaque Forming Units (PFU) per 100mL.

To calculate the removal coefficients (K_T), a completely-mixed model, based on hydraulic retention time (t), was used for AS systems (Eq. 1), while for TF, a plug-flow model, based on hydraulic loading rate (HLR), was adopted (Eq. 2). However, in order to be able to compare the removal coefficients obtained from both AS and TF systems, certain mathematical adjustments were made, from Eq. 3 to 5, to obtain Eq. 6. In this case, the unit for removal coefficient in TF systems is d^{-1} , as with AS. What's more to standardise the removal coefficients according to an ambient temperature of 20°C, the Arrhenius equation was used (Eq. 7). The final models used to calculate removal coefficients at 20°C (K_{20}) for AS (as d^{-1}) and TF (as d^{-1} and $m^3.m^{-2}.d^{-1}$) systems are presented in Eq. 8, 9 and 10, respectively. All equations are presented in Table 1.

Table 1 – Equations used for the estimation of removal coefficients.

$N = \frac{N_0}{(1 + K_T \cdot t)}$	Eq. 1	$N = N_0 \cdot \exp(-K_T \cdot t/h \cdot n)$	Eq.6
$N = N_0 \cdot \exp(-K_T/HLR)$	Eq. 2	$K_T = K_{20} \cdot \theta^{(T-20)}$	Eq.7
$t = Vol/Q$	Eq.3	$K_{20} = \left(\frac{N_0}{N} - 1\right) \cdot \frac{1}{t \cdot \theta^{(T-20)}}$	Eq.8
$HLR = Q/A$	Eq.4	$K_{20} = \ln\left(\frac{N_0}{N}\right) \frac{HLR}{n \cdot h \cdot \theta^{(T-20)}}$	Eq.9
$Vol = A \cdot h \cdot n$	Eq.5	$K_{20} = \ln\left(\frac{N_0}{N}\right) \frac{HLR}{\theta^{(T-20)}}$	Eq.10

Where: N = final conc. (PFU.100mL⁻¹); N_0 = initial conc. (PFU.100mL⁻¹); t = hydraulic retention time (d); HLR = hydraulic loading rate (m³.m⁻².d⁻¹); Q = flow (m³.d⁻¹); Vol = volume (m³); Q = flow (m³.d⁻¹); A = surface area (m²); h = height (m); n = empty space; K_T = removal coefficient at temp T (d⁻¹ or m³.m⁻².d⁻¹); K_{20} = removal coefficient at

20°C (d^{-1} for AS; $m^3.m^{-2}.d^{-1}$ for TF); θ = temp coefficient; T = temperature ($^{\circ}C$).

Probability density functions (PDF) were fitted for the database using the adherence test option present in the statistical software @Risk version 5.5.0. The removal coefficients were then estimated by stochastic simulation (Eq. 8, 9 & 10) with Latin Hypercube sampling and 100,000 iterations, again using the software @Risk version 5.5.0.

RESULTS & DISCUSSION

Figure 1 presents the concentrations of somatic and F-specific coliphages in the settled wastewater (N_o) and post-secondary sedimentation wastewater (N_f) of both AS and TF systems. The initial and final concentrations of somatic coliphages were approximately $2 \log_{10}$ higher than those of F-specific coliphages in the systems monitored. Furthermore, it is apparent that, in general, the concentrations of somatic coliphages varied more than those of F-specific coliphages. With regard to the geometric mean values of initial and final concentrations, the removal of somatic coliphages in the AS systems was of the order $1.86 \log_{10}$, while for F-specific coliphages it was $1.41 \log_{10}$. In the TF systems, the removal of somatic and F-specific coliphages was of the order 0.44 and $0.46 \log_{10}$, respectively. These results demonstrate that the removal rate of somatic coliphages was higher than those of F-specific coliphages in AS systems, whilst for TF the removal rate of both phage groups was very similar. Furthermore, AS systems appear to remove both phage groups more effectively than TF systems. Similar removal rates of somatic and F-specific coliphages in AS systems are presented in the literature (Zhang & Farahbakhsh, 2007; De Luca et al, 2013). No study involving the removal of bacteriophages in TF systems has been found to date.

Figure 1 – Box-plot of the concentration of somatic and F-specific coliphages in the settled wastewater (N_o) and post-secondary sedimentation wastewater (N_f) of the Activated Sludge (AS) and Trickling Filter (TF) systems monitored.

Probability distribution functions (PDF) were adjusted for the initial and final concentrations (N_0 and N) and temperature (T) data collected using adherence tests. Hydraulic retention time (t) (uniform PDF: min=0.25; max=0.33 d), hydraulic loading rate (HLR) (uniform PDF: min=1; max=4 $m^3.m^{-2}.d^{-1}$), temperature coefficient (θ) (triangular PDF: min=1.00; max=1.19; mean=1.07), height (h) (uniform PDF: min=1.8; max=2.5 m) an empty space (n) (uniform

PDF: min=0.5; max=0.6) were assumed in accordance with the literature (Marais, 1974; Castagnino, 1977; Thomann and Mueller, 1987; Yanes, 1993; Metcalf and Eddy, 2003; von Sperling, 2007a; von Sperling, 2007c). Table 2 summarises the PDF fitted for each input variable of the model. The removal coefficients were then estimated by stochastic simulation (Eq. 8, 9 & 10) with Latin Hypercube sampling and 100,000 iterations using the software @Risk version 5.5.0.

Table 2 – Probability density functions^(a) of the input variables of the models (Eq. 8, 9 & 10) to estimate the removal coefficient at 20°C (K_{20}) for somatic and F-specific coliphages in activated sludge (AS) and Trickling Filter (TF) systems.

^(a) Values in d⁻¹; ^(b) values in m³.m⁻².d⁻¹.

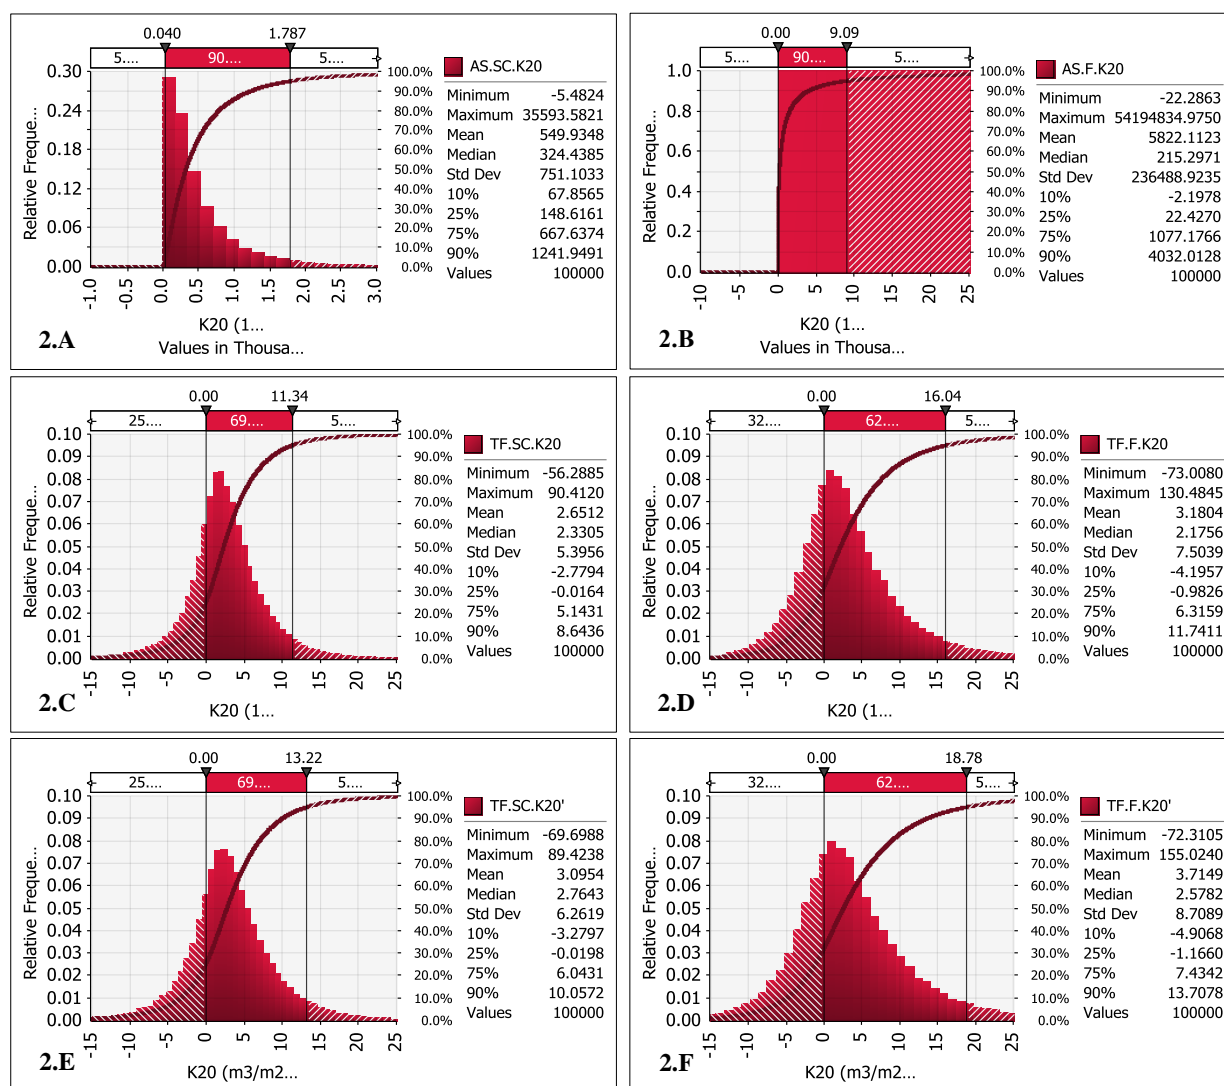

Figure 2 – Histogram and cumulative frequency curve of removal coefficients at 20°C (K_{20}) for somatic coliphages and F-RNA coliphages, based on the hydraulic retention time (t) in AS systems (2.A & 2.B, respectively) and in TF systems (2.C & 2.D, respectively), and based on the hydraulic loading rate (HLR) in TF systems (2.E & 2.F, respectively).

Stochastic modelling revealed that the K_{20} values for the AS systems were an order of magnitude higher than those of the TF systems, possibly as a result of the different models used for each system. Median K_{20} values for AS were 324.4 d⁻¹ for somatic coliphages and 215.3 d⁻¹ for F-specific coliphages (Figures 2.A & 2.B; Table 3), while median K_{20} values for TF were 2.33 and 2.18 d⁻¹ for somatic and F-specific coliphages, respectively (Figures 2.C & 2.D; Table 3). With regard to the mean values of K_{20} , the numbers were higher for both systems: 549.9 and 2.65 d⁻¹ for somatic and F-specific coliphages, respectively, in AS systems (Figures 2.A & 2.B; Table 3); 5822.1 and 3.18 d⁻¹ for somatic and F-specific coliphages, respectively, in AS systems (Figures 2.C & 2.D; Table 3).

The differences between K_{20} values obtained here for each system, and more specifically the considerably higher K_{20} values observed for TF systems compared with AS systems, could be explained by the inadequacy of the idealised models. As mentioned by von Sperling (2007b), even for the same conditions (initial and final concentrations, hydraulic retention time), the equations representing the plug-flow and complete-mix reactors would result in different

removal coefficient (K) values. This is because, in theory, the ideal complete-mix reactors are the least efficient reactors for first-order removal kinetics. In other words, the lower efficiency is compensated by a higher K value (von Sperling, 2007b). Conversely, ideal plug-flow reactors are the most efficient reactors, and the K value necessary to produce the same effluent quality is reduced (von Sperling, 2007b).

The K_{20} values for TF systems previously discussed, given as d^{-1} , were obtained from Eq. 9 for comparison with the K_{20} of AS systems (Eq. 8). However, the parameter that is normally used for the design of biofilters is the hydraulic loading rate (HLR). Thus, Eq. 10 was also used to calculate K_{20} values for TF systems, given as $m^3.m^{-2}.d^{-1}$. Using both Eq. 9 & 10, median K_{20} values were very similar for each microorganism: 2.33 and 2.18 d^{-1} for somatic and F-specific coliphages, respectively, from Eq. 9; and 2.76 and 2.58 $m^3.m^{-2}.d^{-1}$ for somatic and F-specific coliphages, respectively, from Eq. 10 (Figures 2.C to 2.F; Table 3). Again, mean values of K_{20} were higher than median values, but were similar for each microorganism: 2.65 and 2.3.18 d^{-1} for somatic and F-specific coliphages, respectively, from Eq. 9; and 3.10 and 3.71 $m^3.m^{-2}.d^{-1}$ for somatic and F-specific coliphages, respectively, from Eq. 10 (Figures 2.C to 2.F; Table 3). The reason for similar values of K obtained from Eq. 9 & 10 results from the PDF assumed for the input variables height (h) (uniform PDF: min=1.8; max=2.5 m) and empty space (n) (uniform PDF: min=0.5; max=0.6) in Eq. 10.

Interestingly, the cumulative frequency curves for both AS and TF were markedly different in their appearance, as the output data are skewed towards the left side of the distribution for both phage groups in the AS systems (Figures 2.A & 2.B), while in the TF systems, the data seem to follow a normal distribution (Figures 2.C to 2.F). With regards to the variation around the mean/median values, the standard deviation was higher for F-specific coliphages than for somatic coliphages, in both the AS and TF systems (Figure 2). Finally, comparison of the findings discussed in this paper with the scientific literature are limited due to the paucity of data currently available in this area.

CONCLUSION

The work to date has demonstrated that appropriate forms of stochastic modelling may elucidate the behaviour of enteric bacteriophages in traditional biological wastewater treatment processes. Furthermore, using this approach it may be possible to export the results obtained from the monitored systems to other systems and predict final concentrations of coliphages using simple models.

Future work will compare the behaviour of these indices with the behaviour of specific enteric viral pathogens of human health significance. It is envisaged that the research will contribute new knowledge to inform better design and operation of wastewater treatment systems. At a time when greater emphasis is being placed on human health protection by minimising the transmission of pathogens at several points within the water cycle, this work will support more integrated water and sanitation safety planning approaches to human health risk management.

Abstract

The number of alternative WWT technologies has grown steadily to meet increasingly stringent performance demands which increased the importance and complexity of early-stage decision making in WWTP design and retrofitting problems. Currently the conceptual design task is handled based on expert decisions and previous experiences. In this contribution, we propose a new approach based on mathematical programming to manage the complexity of the problem and generate novel and optimal WWTP network designs for domestic WWT. Within this context, a superstructure concept is used to represent the alternative WWT technologies described as a series of reaction and separation tasks at different treatment levels. Each process alternative is described by a generic model and the required data for both performance and economics of each alternative are collected and sorted in a multi-dimensional database. This database is embedded within the mixed integer nonlinear programming problem formulated and solved in GAMS for different objective functions (e.g. total annualized costs, etc.) and constraint definitions (e.g. effluent discharge limits). The developed framework is highlighted using the benchmark plant as a case study to generate and screen optimal concepts for retrofitting options under different scenarios.

INTRODUCTION AND MOTIVATION

Recently, the WWTP process selection and network design problem has evolved from being a simple technical design problem to a complex integrated decision making task, and this is mainly because of the numerous aspects that are being considered in the early decision making stage (Hamouda, 2009). Currently, the early stage decision making for WWTP design – i.e. which technology and treatment concept to employ – is mainly based on expert decisions and experiences accumulated internally in an engineering company from solving previous problems. This approach takes values like environmental issues, water reuse, by-product recovery (if possible) and public impacts into account and identifies the alternatives based on experience, similar existing solutions and brainstorming to come up with the most viable WWTP network (Daigger, 2005). This study on the other hand, proposes a superstructure based optimization methodology which represents different aspects considered during the early stage decision making with the help of mathematical programming, and designs/retrofits the domestic WWTP network in a novel and optimal manner.

FRAMEWORK FOR SYNTHESIS AND DESIGN OF WWTP NETWORKS

The mathematical programming based optimization theory developed for chemical process synthesis and design by Quaglia et al. (2012) was modified and adapted in the context of the WWT design problem. The framework is seen in Figure 1 (Bozkurt et al., 2014). After defining the wastewater characterization, sink limitations and the objective function in the

first step of the framework, one can define a superstructure where the treatment plant is defined as a sequence of treatment tasks (columns) and alternative technologies are placed in the rows, as seen in Figure 2. The superstructure is then formulated by defining connection streams between treatment tasks. Each process interval in the superstructure is structured using a generic model, which describes the treatment alternatives by input-output mass balances, as also illustrated in Figure 2.

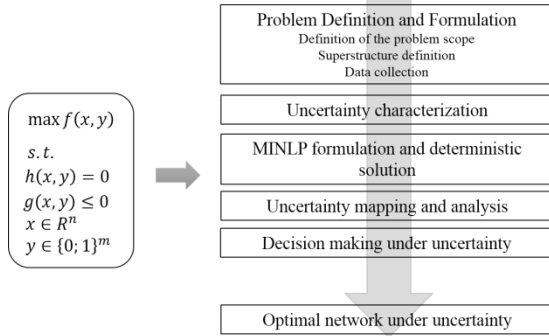

Figure 1. The superstructure based optimization methodology adapted for design of optimal WWT systems

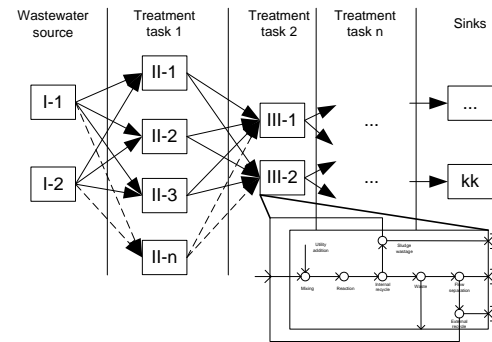

Figure 2. A representative superstructure for WWT networks and the generic process interval structure

The intervals are composed of a number of phenomena, namely: mixing the flows and the utilities added, reaction, separation of flow for internal recycle and sludge wastage, waste separation, flow separation for external recycle and sending the flow to the process intervals of the next column. The mathematical equations defining the intervals can be seen in Table 1. A database lies behind the superstructure which contains the data to define the parameters of the generic model, e.g. process performances, utility consumptions, volumes, sludge production for each treatment alternative. To this end, a systematic data collection procedure was developed by integrating the procedures given by ATV design standards, Tchobanoglous (2003), WEF (2010) and Henze et al. (2008). The details of the procedure can be found elsewhere (Bozkurt et al., 2013). The optimal wastewater network problem is then formulated as a Mixed Integer (Non)Linear Programming (MI(N)LP) problem in GAMS and solved for different scenarios. The optimization model in GAMS consists of an objective function covering both operational and capital cost, logical constraints defining the topology of the solution and process constraints describing the process models of each treatment technology in the superstructure. The problem is also solved under uncertainty in order to identify the sensitivity of the optimal solutions to the data used in the optimization.

Table 1. Mathematical equations representing the process model in each interval

Phenomena	Equation	Explanations
Mixing	$Fin_{i,kk} = \sum_k F_{i,k,kk}$	i, ii : Component index
	$Fmix_{i,kk} = Fin_{i,kk} + \alpha_{i,kk} * R_{i,kk}$	k, kk : Process interval index
Utility addition	$R_{i,kk} = \sum_{ii} (\mu_{i,ii,kk} * F_{ii,kk})$	$Fin_{i,kk}$: Inflow to the process interval
Reaction	$Freac_{i,kk} = Fmix_{i,kk} + \sum_{rr,react} (\gamma_{i,kk,rr} * \theta_{react,kk,rr} * F_{react,kk,rr})$	$F_{i,k,kk}$: Inflow of component i to process kk coming from k
Waste separation	$Fw_{i,kk} = Freac_{i,kk} * (1 - W_{i,kk})$	$Fmix_{i,kk}$: Flow of component i after mixing
Flow separation	$Fout1_{i,kk} = Fw_{i,kk} * Split_{i,kk}$	$R_{i,kk}$: Utility flow
	$Fout2_{i,kk} = Fw_{i,kk} - Fout1_{i,kk} - Freac_{i,kk}$	$\alpha_{i,kk}$: Fraction of utility consumed
	$Fout3_{i,kk} = Freac_{i,kk} * SW_{kk}$	$\mu_{i,kk}$: Specific consumption of utility
	$Frec_{i,kk} = (Fw_{i,kk} - Fout1_{i,kk}) * rec_{kk}$	$Freac_{i,kk}$: Flow after reaction
	$FX_{i,k,kk} = FoutX_{i,k} * S_{k,kk}$	$\gamma_{i,kk,rr}$: Matrix representing reaction stoichiometry
		$\theta_{react,kk,rr}$: Conversion efficiency of the key reactant $react$
		$Fw_{i,kk}$: Flow after waste separation
		$W_{i,kk}$: Waste split factor
		$Fout1_{i,kk}, Fout2_{i,kk}, Fout3_{i,kk}$: Outlet streams from interval kk
		$Split_{i,kk}$: Flow split factor
		SW_{kk} : Sludge wastage flow rate ratio

Activation	$y_{kk} * x_k^{LO} \leq x_k \leq y_{kk} * x_k^{UP}$	$Frec_{i,kk}$: External recycle flow rec_{ik} : External recycle ratio X : 1,2,3 (representing three different outlet flow streams)
Logical cuts	$\sum_{kk} y_{kk} \leq 1$	$S_{k,kk}$: Parameter containing superstructure information y_{kk} : Binary variable describing the process interval x_k : Variable bounded by x_k^{LO} and x_k^{UP}

CASE STUDY

The problem is defined as treatment of domestic wastewater comprising mainly COD, nitrogen and solids as pollutants. The objective is to design the WWTP network with the minimum operational and capital cost possible while satisfying the effluent limitations for organics and nitrogen. The superstructure is defined as shown in Figure 3. It consists of wastewater source (I-1) and sinks for water (VI-1) and sludge (VI-2), primary sedimentation (II-1), pre-denitrification with different SRTs (III-1 and III-2), anaerobic treatment (III-3), different innovative nitrogen removal technologies (IV-1 and IV-2), disinfection options by means of UV, ozone and chloride (V-1, V-2 and V-3) together with by-pass intervals (II-2, III-4, IV-3 and V-4). The database has been developed by following the systematic procedure and the optimization problem was solved.

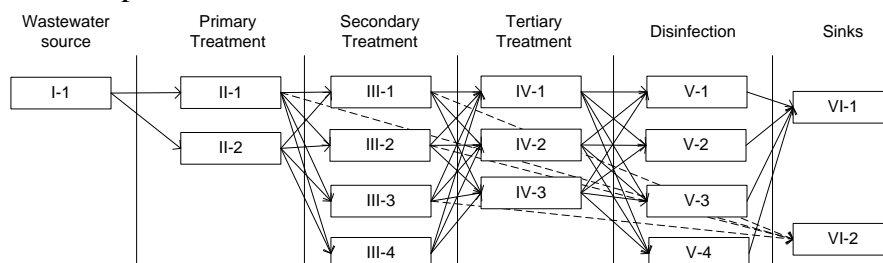

Figure 3. An example superstructure for the case study

The problem was solved under three different scenarios: the first scenario takes only operational cost into account, while the second one considers total annualized cost. The third scenario imposes a stricter effluent limit on the nitrogen concentration. All the scenarios by-passed the primary and tertiary treatment steps together with disinfection. The secondary treatment selection was the high SRT pre-denitrification technology for the first and third scenario and short SRT pre-denitrification for the second scenario. The fact that the short SRT system has a lower capital cost promoted its selection in the second scenario and the high SRT system was favoured due to its ability to remove nitrogen with higher efficiency. Apart from the topology information, the tool also enables the user to track the concentration of the pollutants throughout the treatment line. Moreover, cost breakdown information can also be obtained in the final report.

CONCLUSIONS

A mathematical programming concept has been introduced in this study to support the early stage decisions on WWTP network selection. By casting the problem as an optimization problem, the decision on which technology to employ is rendered on quantitative metrics which complements the experience based approach used today. Hence the tool is expected to support and facilitate generation and evaluation of ideas for identifying optimal solutions to design new or retrofit existing WWTPs. We also hope that this contribution will open the debate on how we identify novel processes and technologies for WWTPs (be it treatment or resource recovery as the final purpose). This activity is arguably more an art than a science the way it is carried out today.

Abstract

The main objective of this study was to compare the capability of empirical and knowledge-based theory to model the filtration process in submerged anaerobic MBRs (SAnMBRs). To this aim, the following three models were developed and validated using data obtained from a SAnMBR system fitted with industrial-scale hollow-fibre membranes: (1) an empirical model; (2) a neural-network based model; and (3) a fuzzy-logic based model. The proposed models represented adequately the filtration process in SAnMBRs, resulting all in a Pearson Product-Moment correlation coefficient (r) above 0.9.

Keywords

Industrial-scale hollow-fibre membranes; knowledge-based modelling; submerged anaerobic MBR

INTRODUCTION

Further studies are needed in submerged anaerobic MBR (SAnMBR) technology in order to gain more insight into the optimisation of their efficiency, mainly regarding membrane fouling phenomenon. In this respect, mathematical modelling of filtration in SAnMBR technology may help in gaining insights about the aspects that play a key role in membrane fouling (Mannina et al., 2011), and are valuable for the design, prediction, and control of this technology (Ng and Kim, 2007). Models focused on filtration in MBR technology usually rely on parameters that are not measurable, neither on-line, nor with standard laboratory equipment (e.g. soluble microbial products). Moreover, some of them are not able to reproduce the effect of the different stages that form the operating mode of the membrane modules (relaxation, back-flushing...), or cannot be easily coupled to a given biological model. In this respect, some authors (see e.g. Sarioglu et al., 2012) currently tend to develop new simple empirical models that try to reproduce the effect of the most critical variables taking place in the membrane fouling phenomenon: mixed liquor total solids (MLTS) concentration and shear intensity in the membrane tank. However, due to the strongly non-linear relationships existing between the process inputs and outputs, empirical models could only result in proper results when the process dynamics are bounded by a defined linear zone. In this respect, knowledge-based theory (e.g. neural networks or fuzzy logic) may represent a

* **Current address:** aqualia, gestión integral del agua, S.A., Avenida del Camino de Santiago, 40, 28050 Madrid, Spain (Email: mavictoria.ruano.garcia@fcc.es)

powerful tool for modelling filtration in SAnMBRs since they allow applying the valuable expert knowledge and allows developing multiple-input-multiple-output process schemes.

The main objective of this study was to compare the capability of empirical and knowledge-based theory to model the filtration process in SAnMBR systems not only in the short term but also in the long term. Since the effect of the main operating conditions on membrane fouling cannot be properly evaluated at the lab scale because they depend heavily on the membrane size (particularly in hollow-fibre (HF) membranes the HF length is a critical parameter), the proposed models were validated in a SAnMBR system fitted with industrial-scale HF membrane units. This semi-industrial SAnMBR plant was operated using real wastewater from the pre-treatment of the Carraixet WWTP (Valencia, Spain). Thus, the main disturbances that take place in full-scale plants were reproduced.

MATERIAL AND METHODS

Semi-industrial SAnMBR plant description

This study was carried out in a semi-industrial SAnMBR plant fed with the effluent of a full-scale WWTP pre-treatment. It consists of an anaerobic reactor with a total volume of 1.3 m³ connected to two membrane tanks each one with a total volume of 0.8 m³. Each membrane tank includes one ultrafiltration HF membrane commercial system (PURON[®], Koch Membrane Systems, 0.05 µm pore size, 30 m² total filtering area, and outside-in filtration). The membrane system was operated according to a specific schedule involving a combination of different individual stages (back-fluxing, ventilation and degasification) taken from a basic filtration-relaxation cycle. Further details on this SAnMBR system can be found in Robles *et al.* (2013a).

Filtration process modelling

Empirical modelling

The proposed empirical filtration model (resistance-in-series based model, Robles *et al.*, 2013b) considers the following four kinetically governed physical processes: (1) cake layer formation during filtration due to solids deposition; (2) cake layer removal due to membrane scouring by gas sparging; (3) cake layer removal during back-flushing; and (4) irreversible fouling consolidation.

Knowledge-based modelling

In this study, the following two knowledge-based theories are proposed for modelling filtration in SAnMBRs: (1) neural networks; and (2) fuzzy logic (data not shown). The proposed knowledge-based models calculate the change in the transmembrane pressure (TMP) over time on the basis of the following inputs: 20 °C-standardised transmembrane flux (J_{20}), MLTS, specific gas demand per square metre of membrane area (SGD_m), and total volume of treated water (V_T).

RESULTS AND DISCUSSION

Figure 1 provides an example of the results obtained from the short-term validation of both the empirical and neural-network based model proposed in this study. This validation was carried out using experimental data obtained by applying different J_{20} and SGD_m values. The results shown in Figure 1a (corresponding to the empirical model) were obtained when operating with a MLTS concentration of 21 g L⁻¹, SGD_m from approx. 0.13 to 0.4 m³ h⁻¹ m⁻², and gross J_{20} from approx. 4 to 12 LMH. The results shown in Figure 1b (corresponding to the neural-network based model) were obtained when operating with a MLTS concentration

of 17 g L^{-1} , SGD_m from approx. 0.17 to $0.3 \text{ m}^3 \text{ h}^{-1} \text{ m}^{-2}$, and gross J_{20} from approx. 12 to 26 LMH .

As Figure 1a shows, the results indicate that the empirical model predictions (TMP_{SIM}) accurately reproduce the experimental data (TMP_{EXP}): an adequate Pearson Product-Moment correlation coefficient (r) of 0.925 was obtained. On the other hand, Figure 1a shows that the empirical model is capable of reproducing the reduction in TMP caused by ventilation (V) or back-flushing (BF) (see, for example, minutes 285 and 615, respectively). Results of the neural-network based model are shown in Figure 1b. It can be seen that the neural network is also capable to reproduce the change in TMP over time when the flux changes. Also in this case, the correlation between experimental data ($d\text{TMP}_{\text{exp}}/dt$) and model predictions ($d\text{TMP}_{\text{sim}}/dt$) was characterised by a high r value ($r = 0.989$).

Figure 1. Example of the results obtained from the short-term validation of (a) the empirical model and (b) the neural-network based model proposed in this study.

Once the models were calibrated, their generalising capability was evaluated by simulating different operating periods. The performance of the models was evaluated and compared each other.

CONCLUSIONS

Three models aimed to represent filtration in SAnMBRs were developed and validated: (1) an empirical model; (2) a neural-network based model; and (3) a fuzzy-logic based model. All these models were capable to adequately reproduce the filtration process in SAnMBR technology, resulting in adequate Pearson correlation coefficients (above 0.9).

Abstract

An Activated Sludge Modelling framework for Xenobiotics (ASM-X) was recently developed to mechanistically predict the fate of pharmaceuticals in a full-scale treatment plant. In this study, we generalized ASM-X to international literature data. Through the generalization, we assessed the influence on the biological removal efficiency of specific factors, namely influent loading dynamics, SRT and retransformation processes (from e.g., human metabolites back to parent chemicals). With regard to the latter, we show that the estimation of removal efficiency based only on parent chemical (a predominant practice in literature) can lead to an underestimation of the environmental risk.

Keywords

Pharmaceuticals elimination; ASM-X; model validation; retransformation; hospital WWTP

INTRODUCTION

Dynamic fate models can represent a cost-saving option to investigate the elimination of xenobiotic trace chemicals in biological wastewater treatment plants (WWTPs). An Activated Sludge Modelling framework for Xenobiotics (ASM-X) was developed and validated in the fate prediction of pharmaceuticals in a full-scale WWTP (Plósz *et al.*, 2010, 2012). These studies highlighted the potential impact of human conjugated metabolites or other commercial chemicals to retransform back to parent forms, leading to a distinction between the concentration of parent (C_{LI}) and retransformable fractions (C_{CJ}) of pharmaceuticals. In this study, we validated ASM-X by comparing predicted removal efficiencies of three pharmaceuticals (sulfamethoxazole, ciprofloxacin and tetracycline) in Bekkelaget WWTP (Oslo, Norway), with published international data whereby sound sampling techniques were used. The validation with literature data, also referred to as generalization (Plósz *et al.*, 2012), aimed at: (i) assessing the underestimation of removal by considering only the parent fraction; (ii) estimating the significance of this underestimation in terms of risk predictions; and (iii) evaluating factors known to affect pharmaceuticals removal. With regard to (iii), we focused on dynamics of influent load of the substances, WWTP operation (e.g., solid retention time—SRT) and retransformation occurring in upstream sewer systems.

MATERIALS AND METHODS

The full-scale implementation of ASM-X in WEST 2012®, calibrated with the results of batch experiments as presented by Plósz *et al.* (2010), was used to estimate the elimination of sulfamethoxazole, ciprofloxacin and tetracycline in Bekkelaget WWTP. We distinguished between removal efficiency [-], in the biological treatment, referred to parent fraction (Eq.1) and to both parent and retransformable fraction (Eq. 2)

$$\eta_{LI} = (C_{LI,in} - C_{LI,eff}) / C_{LI,in} \quad [1]$$

$$\eta_{TOT} = (C_{LI,in} + C_{CJ,in} - C_{LI,eff} - C_{CJ,eff}) / (C_{LI,in} + C_{CJ,in}) \quad [2]$$

where C_{in} and C_{eff} [$ng\ L^{-1}$] were concentrations in secondary influent and effluent, respectively. Estimated removal efficiencies were plotted as a function of the normalized influent load of the chemicals [$mg\ h^{-1}\ 1000PE^{-1}$], calculated from the design population equivalent of the WWTP. A literature review was performed for the generalization of ASM-X predictions, with the collection of international data on the full-scale removal of pharmaceuticals. Only data derived from flow-proportional sampling campaigns were included. Additionally, literature studies on the separate treatment of hospital wastewater were selected to characterize a “zero-catchment” scenario, describing the removal of pharmaceuticals in WWTPs with negligible upstream sewer transport.

A preliminary environmental risk assessment of the pharmaceuticals was performed. Predicted environmental concentrations (PECs) were estimated from the effluent concentrations from Bekkelaget WWTP (assuming 10-fold dilution). We distinguished between PECs accounting for only effluent C_{LI} , and for both effluent C_{LI} and C_{CI} . PECs were then compared to predicted non-effect concentrations (PNECs) reported in literature to assess risk dynamics.

RESULTS AND DISCUSSION (the case of sulfamethoxazole)

Scenario simulations, considering increased influent loads compared to measurements in Bekkelaget WWTP, were used to generalise ASM-X predictions of sulfamethoxazole removal with literature data. In Fig. 1a, we compared model predictions (5-fold increased influent loading) with removal efficiencies of sulfamethoxazole in municipal WWTPs. Predicted η_{LI} and η_{TOT} were consistent with data reported by Göbel *et al.* (2005, 2007), including a comparable underestimation of the efficiency when the retransformable metabolite (N4-acetyl sulfamethoxazole) was not considered. A similar underestimation error was shown by Yang *et al.* (2011). Values of η_{LI} reported by Radjenovic *et al.* (2009) were significantly higher than our estimations and any other literature data at comparable influent loads, suggesting a possible enhancement of biotransformation (due to e.g., operation at high SRT). With regard to the zero-catchment scenario (Fig. 1b), predicted η_{LI} and η_{TOT} at a 25-fold increased load are in close agreement with values reported by Kovalova *et al.* (2012).

Figure 1. Generalization of ASM-X predicted removal of sulfamethoxazole (SMX) with literature data for municipal WWTPs (a) and for the hospital wastewater treatment—zero-catchment scenario (b). ASM-X predictions of removal efficiency accounted for only parent SMX (grey diamonds) and for parent and retransformable fractions of SMX (black circles). 5-fold and a 25-fold increased influent load, as compared to Plósz *et al.* (2010), were used for the validation in (a) and (b), respectively. Error bars refer to standard deviations in influent loads and removal efficiencies.

In Fig. 2, values of the PECs in the recipient water body of the Bekkelaget WWTP were shown. Results obtained in this preliminary assessment suggest that tetracycline (Fig. 2a) and—significantly—ciprofloxacin (Fig. 2b) can represent a considerable chemical risk. The predicted effluent C_{CJ} of tetracycline can pose a substantial additional risk (up to 130% increase as compared to parent-based PEC), whereas the parent-based tetracycline results suggested a marginal violation of the no-effect limit. Estimated as 131–397 times higher than the respective PNEC value, PECs of ciprofloxacin exhibited a marked temporal variability (3-fold increase at the peaks).

Figure 2. PEC values of tetracycline (a) and ciprofloxacin (b) calculated from ASM-X predictions. For PNEC values used, please refer to Grung *et al.* (2008). Quasi MECs (measured environmental concentrations) identify effluent measured environmental concentrations divided by a dilution factor.

Overall, these results suggest the importance of using dynamic models for and the necessity of considering retransformable chemical fractions in assessing pharmaceuticals removal in biological WWTPs. Additionally, we show that environmental risk assessments should account for (i) concentrations of retransformable chemicals released in WWTP effluents, potentially representing an additional source of hazard; and (ii) temporal variations in effluent concentrations.

ACKNOWLEDGEMENT

The authors express special thanks to WWTP operators, in particular Helle Frodahl, and to Xin Yang and Lubomira Kovalova for providing additional details on their study.

Abstract

Methane is an potent greenhouse gas and its emission from municipal wastewater treatment plants should be prevented. One way to do this, would be to promote the biological conversion of methane over stripping in the aeration tanks. In this study we extended Activated Sludge Model n° 1 with biological methane oxidation to verify the effect of aeration rate, solids retention time and influent methane concentration on the balance between conversion and stripping. This knowledge helps to stimulate the methane oxidizing capacity of activated sludge to abate methane emissions to the atmosphere.

Keywords

Activated sludge, ASM, climate footprint, greenhouse gases, methane

INTRODUCTION

Municipal wastewater treatment of gives rise to the emission of the greenhouse gases carbon dioxide, nitrous oxide and methane. Methane is a potent greenhouse gas with a global warming potential of 25 CO₂-equivalents (IPCC, 2007). In an long-term study on a municipal wastewater treatment plant (WWTP) methane was found to make up 13.5 % of the plants greenhouse gas footprint, exceeding the amount of emitted carbon dioxide related to the plant's electricity and natural gas consumption (Daelman et al., 2013). Globally, sewage treatment accounts for 4 % of the total methane emission (Conrad, 2009).

Basically, the methane that is emitted from a WWTP can be traced back to two sources. Either it is stripped from the incoming wastewater after it has been produced in the sewer (Guisasola et al., 2008), or it is produced during the storage and manipulation of sludge (Daelman et al., 2012). Dissolved methane can be biologically converted, besides being stripped. It was recently discovered that about 80 % of the dissolved methane entering an aerated activated sludge tank was converted with the remainder being stripped (Daelman et al., 2012). Aerobic conversion of methane is performed by methanotrophic bacteria (Ho et al., 2013). Harnessing this methane oxidizing capacity of activated sludge could be a way to avoid the emission of methane. In the end, this could lead to more sustainable wastewater treatment.

The objective of this study was to investigate the effect of a number of operational process conditions on the fate of dissolved methane in an activated sludge plant. To this end, the Activated Sludge Model n° 1 (ASM1) was extended with aerobic methanotrophic growth. The resulting model, called ASM1m, was implemented in Benchmark Simulation Model n° 1 (BSM1) (Copp, 2001) and termed BSM1m Taking into account biological oxidation and stripping of methane, BSM1m is the first model describing dynamic emissions of methane

during wastewater treatment. As such, it complements existing models for the emission of nitrous oxide in estimating greenhouse gas emissions from WWTPs.

MATERIALS AND METHODS

ASM1m adds two processes to ASM1: aerobic growth and decay of methanotrophs. The two additional state variables are methane as substrate (S_{CH_4}) and methane oxidizing bacteria (X_{MOB}).

To describe the behaviour of the overall WWTP, ASM1m was implemented in BSM1m, which consists of two anoxic tanks followed by three aerated tanks and a settler and a secondary settling tank (Copp, 2001). BSM1m was used to investigate the effect of the following three operating variables on methane conversion rate and methane stripping: aeration rate (in reactor 3 and 4), influent methane concentration and solids retention time. Table 1 gives an overview of the relevant parameters as well as their default values and the range over which they were varied. Besides the percentage of incoming methane that is stripped, also the conventional BSM1 criteria Effluent Quality (EQ) and Operational Cost Index (OCI) were calculated.

Table 1. Overview of the operating conditions applied in the scenario analysis.

Operating condition	Parameter	Default value	Range
Aeration rate in reactor 3 and 4	$k_L a_{O_2}$	240 d ⁻¹	0 - 400 d ⁻¹
Influent methane concentration	$S_{CH_4, infl}$	10 g COD.m ⁻³ (*)	0 - 50 g COD.m ⁻³
Solids retention time	SRT	9.18 d (**)	2 - 12 d

(*) Daelman et al. (2012)

(**) Calculated from solids balance

RESULTS AND DISCUSSION

Figure shows the influence of the operating conditions on the percentage of incoming methane that is emitted and on the plant's performance in terms of effluent quality and operational costs.

At very low aeration rates ($k_{LA} < 52$ d⁻¹), methanotrophs are outcompeted by ordinary heterotrophs (data not shown), while methane stripping increases with increasing k_{LA} , resulting in higher methane emissions. At higher, but still low aeration rates ($k_{LA} = 52$ -126 d⁻¹) the increasing methanotrophic growth is reflected in decreasing methane emissions. Beyond the optimum of 126 d⁻¹, stripping takes over from methanotrophic growth and the methane emission increases again. The optimal aeration rate to curb the emission does not coincide with the best effluent quality (lowest EQ) or the lowest operating costs (lowest OCI).

At low influent methane concentrations, most of the methane is converted in the anoxic tank using the oxygen entering with the recycle sludge. As the influent concentration increases, more methane passes through the anoxic tanks to the aeration tanks where it is stripped. Upon a further increase in the influent methane concentration, the conversion in the aeration tanks takes over from the stripping. The impact on the plant's effluent quality and operational cost is negligible.

The percentage of incoming methane that is emitted decreases with increasing SRT, at least for SRT-values lower than 6 d. When the SRT increases beyond 6 d, the emission first increases and then decreases gradually. This is explained by the growth of methanotrophic biomass (data not shown). For SRT-values increasing up to 6 days, the amount of methanotrophic biomass increases, which is reflected in a decrease of the methane emissions. From an SRT of 6 d onwards, the biomass increase slows down. The optimal SRT to minimize the emission does not coincide with the best effluent quality (lowest EQ) or the lowest operating costs (lowest OCI).

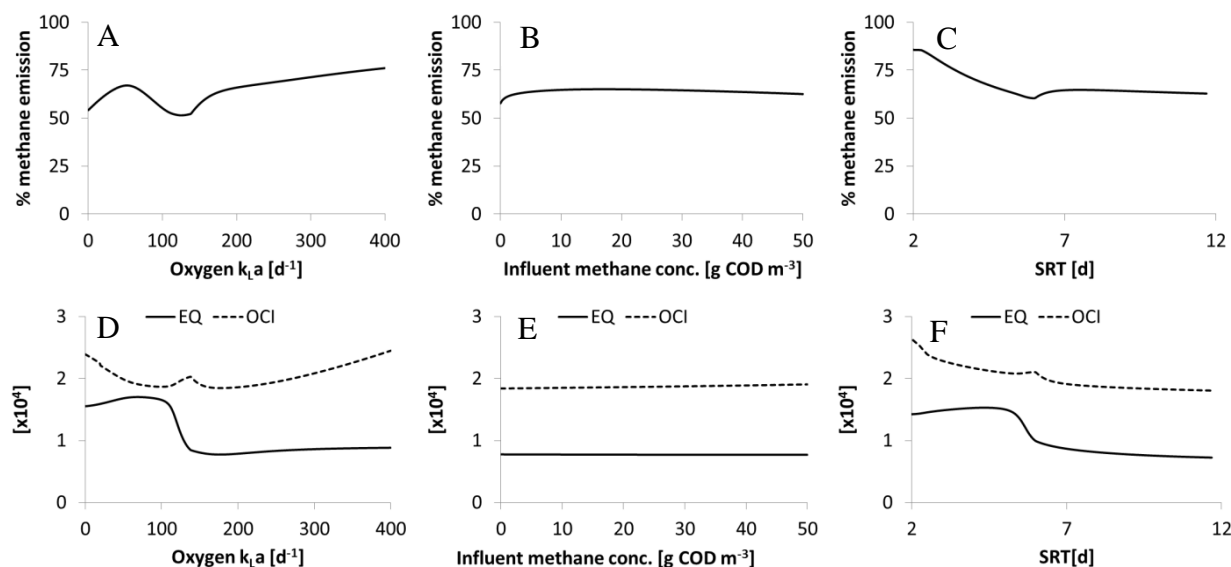

Figure 1. Top: emission of methane as percentage of incoming methane vs. aeration rate (A), influent methane concentration (B) and SRT (C). Bottom: Effluent Quality and Operational Cost Index (for both: the lower the better) vs. aeration rate (D), influent methane concentration (E) and SRT (F).

CONCLUSIONS AND PERSPECTIVES

- Aerobic methane oxidation during biological wastewater treatment was modelled (ASM1m) and its interaction with methane stripping was assessed in a simulation study for a municipal WWTP.
- Aeration rate, influent methane concentration and solids retention time affect methane emission and could therefore be used for mitigating methane emissions from WWTPs.
- The model will be used to elucidate how the methane emission relates to the plant performance in terms of effluent quality and operational cost, resulting in a multi-criteria analysis.

Background

The Sacramento Regional County Sanitation District (SRCSD) in California, USA has embarked upon the EchoWater Project to upgrade the Sacramento Regional Wastewater Treatment Plant (SRWTP) to include biological nutrient removal (BNR) in order to meet new standards for discharge and reuse. The permit limits require SRWTP to meet instantaneous daily composite ammonia limit of 3.3/2.0 mgN/L (summer/winter), a monthly average ammonia limit of 2.4/1.5 mgN/L (summer/winter), a monthly average nitrate limit of 10 mgN/L, and to mitigate the effluent total phosphorus to achieve an annual average target of 2.2 mgP/L.

Design Approach

The process design of the new BNR facility made extensive use of process modelling including several innovative and distinct aspects which are described below. Raw wastewater flows, loads, and characteristics were determined using historical data and special samplings. This data was then used to produce a design case which was a single 6-month influent “itinerary” that included the maximum month, week, and day loadings for flow and COD/N/P loads, and associates the most adverse temperature conditions with these maximum loading periods. Additionally the influent itinerary includes periods which are more representative of typical conditions, and periods which represent minimum loading periods. Diurnal patterns derived from special samplings were applied to these flows and loads to produce an hourly dynamic itinerary. One of the lower loading periods takes place immediately before the maximum month period. The critical period for design is governed by the ability of the biological process to respond to the extreme swings in loading when transitioning from the lowest load period to the maximum month. Examples of the influent itinerary for COD and TKN can be found in Figure and Figure below.

The inclusion of maximum month, week, and day loadings after a relatively low loading period and along with the high variability of influent flows and loads leads to a design case which is more realistic and stringent than typically used in design. Because of this approach engineering adjustments typically applied to address influent variability were not applied allowing for a more aggressive and economical design. Indeed other failure scenarios which are hard to quantify with design approaches that do not use dynamic models and therefore require the application of additional engineering adjustments can be more accurately estimated using this dynamic approach.

Figure 1 – Influent COD Load itinerary used in modelling (1 lb=0.45 kg & 1 mgd=3800 m³/day)

Figure 2 – Influent TKN Load itinerary used in modelling (1 lb=0.45 kg & 1 mgd=3800 m³/day)

Design SRT Selection

Selecting an appropriate aerobic solids retention time (SRT) to meet the stringent ammonia requirement of the permit was a primary objective for the dynamic modelling. This was accomplished with a sensitivity analysis on the preliminary design performed only varying SRT in which the impact to peak effluent ammonia and peak solids loading rate (SLR) were monitored, the results of which can be seen in Figure below. Here the peak effluent ammonia crosses the line of the daily composite permit limit when operating below a 4 day SRT aerobic. A 6 day SRT was chosen as it is near the peak SLR for the preliminary design volume and provides a safety factor of about 2 days which allows for some operational problems and plant upsets; one of which will be discussed below. This is significantly below the aerobic SRT which was initially suggested of 7.5 days for a minimum daily average temperature of 16°C. As the selected SRT and the limiting SLR sets the volume requirement of the basin; the aggressive selection of an aerobic SRT of 6.0 days was able to substantially reduce the required volume from what would be required with a 7.5 day aerobic SRT which a more traditional nitrifying SRT selection criteria would have required.

Figure 3 – Sensitivity of Effluent Ammonia and Solids Loading Rate to Aerobic SRT (1 lb/ft²=4.88 kg/m²)

Ammonia Control Modelling

Swing zones are included in the design to minimize the total volume and energy requirements for nitrification while achieving the maximum amount of nitrate removal; a concept which was modelled with the dynamic itinerary and included in the sensitivity analysis discussed previously. Swing zones were controlled in modelling by a feed forward ammonia control system which activated when ammonia in the last dedicated aerobic pass was raised above a set concentration. In modelling the chosen concentrations were 2.0 mg-N/L which would cause the first 4 (of 7) swing zones to aerate and 3.5 mg-N/L which caused the remaining 3 swing zones to aerate. This dynamic modelling of swing zone control allows for realistic testing of plant performance given an aggressive design and SRT selection. Figure shows the model output ammonia concentration in aeration zone 4, one of the last dedicated aeration zones and the location where ammonia concentration was monitored for feed forward ammonia control in the model. As you can see the model predicts that aeration of the first 4 swing zones is only needed during higher loading months while aeration of all swing zones will only be needed for sporadically for short durations like weeks.

Figure 4 – Ammonia monitoring for feed forward ammonia based control of the swing zones (crossing blue band triggers aeration in first swing zones while red band activates all swing zones)

Given that swing zones were included in the definition of aerobic SRT, reliable operation of the swing zones is important in assuring that the target aerobic SRT is achieved and so failure of the swing zones to aerate when needed was considered a major risk. The risk of noncompliance associated with the chosen SRT due to failure of the swing zones was analyzed by plotting hourly effluent ammonia concentrations as probability distributions under various failure scenarios. In Figure below these probability distributions are given for a scenario in which the ammonia probes which control swing zone aeration have drifted out of calibration by 1 mg-N/L, and in which the swing zones are not engaged at all due to a complete failure of the control system. The former was modelled by adjusting the set points in the controller from 2.0 and 3.5 mg-N/L to 3.0 and 4.5 mg-N/L and the latter was modelled by turning off the swing zone aeration controls entirely causing these zones to operate anoxically throughout the entire itinerary. Here we can see that only in the most extreme events when the swing zones were not aerated at all did the effluent ammonia exceed the design limit, and in that event only for a few hours at a time.

Figure 5 – Probability Distribution of effluent ammonia under normal operation and two failure scenarios of ammonia based swing zone control

Dynamic Aeration Design

A novel approach to aeration design was used in which the dynamic oxygen uptake rates (OURs) produced by the model for different periods, years, and operating conditions were exported to the aeration model developed by Johnson (1993) to determine the required airflow and number of diffusers at both start up and design conditions. In this method hourly OURs for each zone were exported from the model for the entire itinerary. As can be seen in Figure 6, OURs in individual zones varied significantly over time and maximums/minimums of different zones were not necessarily concurrent, for example the maximum OUR in the first aeration zone is associated with periods of high COD loading while the maximum OUR in the last aeration zone is associated with periods of high TKN loading. Maximum and minimum hour, day, and month values were determined for each zone individually and input to the aeration model to determine the range of airflows to each zone and the appropriate number of diffusers. Additionally the peak oxygen demand or oxygen transfer rate (OTR) across all zones was used to determine the maximum and minimum periods of air demand overall for blower sizing.

Figure 6 – Example of Dynamic OUR output from two zones.

There were several benefits to dynamic modelling for aeration design. Firstly due to the lack of concurrence of carbonaceous and nitrogenous loads in the provided dynamic itinerary the design airflow was able to be reduced from what would be determined if considering concurrent maximum COD and TKN loads. Secondly modelling the full range of conditions provided data about the variability of airflow demand to each zone which allowed a distribution of airflow demands at each zone to be considered when selecting the number of diffusers per zone.

Chemical Feed Design

Additionally dynamic control in activated sludge modelling allows carbon feed requirements to be more accurately predicted and has helped in chemical feed system design and chemical feed point selection. Carbon in the form of acetate was fed to the swing zones; controlled by a proportional gain controller which activated in the event of effluent nitrate exceeding a set value with the goal of keeping the monthly average effluent nitrate below 8.0 mg/L. If the swing zone was being aerated at the time another controller was used which override the acetate feed controller. The performance of the acetate feed system can be found in Figure below. Here we see that regular feeding of acetate from day 80 onward is required for the removal of nitrate below 8 mg-N/L. Here modelling was used to validate the design maximum acetate feed rate determined separately, and the cumulative acetate feed volume

was tracked to determine the required 7 day storage volume. It is worth noting here that the system is very carbon limited in the provided itinerary due to a high phosphorus concentration. The itinerary influent phosphorus may be revised to a lower concentration upon further investigation.

Mixed Liquor Fermentation

Provision of a MLF is a promising option for carbon supplementation for enhanced biological phosphorus removal and is described by Houweling (2010). The first purpose-built MLF in the world was utilized at the Cedar Creek Wastewater Treatment Plant (CCWTP) in Olathe KS (Kobylinski, 2013). Ongoing operational activities, biological process modelling, and bench scale testing at CCWTP are being used to better predict the VFA production capacity of the MLF. The information from this modelling and test work is being used to provide guidance for modelling the MLF proposed for the Sacramento plant.

To calibrate the mixed liquor fermenter; batch tests were performed on Cedar Creek WAS at 4 different Mixed Liquor Suspended Solids (MLSS) concentrations over 6 days with the filtered COD (fCOD) being measured over the duration of the test. A process model was developed using the BioWin simulator platform to generate appropriate WAS characteristics and to simulate the batch fermentation tests of the WAS. The simulation fCOD concentrations were compared to the measured values and the hydrolysis rate was adjusted to match these observations as can be seen in Figure . The adjustment that was made was to increase the hydrolysis factor for anaerobic zones by a factor of 5 (from 0.04 to 0.20 in the simulator defaults). This higher factor matches the hydrolysis factor used as a default in the simulator for anaerobic digesters. This adjustment would seem to take account for the lower ORP which is achieved in the mixed liquor fermenter which is closer to the conditions observed in anaerobic digesters than activated sludge anaerobic zones. Inspection of Figure shows that the current model matches data well for the lower MLSS concentrations but under-predicts fCOD production at higher sludge concentrations. This suggests that the structure of the model for hydrolysis is not correct (second order kinetics with respect to biomass may be more appropriate and will be investigated further). Other research has shown the difficulty of

accurately predicting hydrolysis rates (Morgenroth, Kommedal, & Harremoes, 2002). Clearly more investigation of mixed liquor fermentation is needed and currently the authors are partnering with others to do more research on this topic through the Water Environment Research Foundation (WERF).

Figure 8 – Production of fCOD through WAS fermentation; experimental and modelling results

To model a continuous MLF, an unaerated activated sludge element and a clarifier were used and the hydrolysis factor for anaerobic zones was adjusted locally in the activated sludge element as described above. SRT in the MLF was set to 1 day while MLF solids were controlled at 9500 mg/L by adjusting the feed rate of mixed liquor to the MLF. The benefit of the MLF was estimated using the model by tracking the change in VFA and PHA concentration across the fermenter. This showed that with the MLF approximately 30% more VFA was produced which leads to an improved reduction in N and P compared to not using a mixed liquor fermenter. The positive benefit of utilizing a mixed liquor fermenter can be seen in Figure which corresponds to Figure above but without the mixed liquor fermenter. Comparing the two we can see that utilizing a fermenter leads to lower nitrate concentrations when acetate is not supplemented and a reduced total and 7 day storage requirement. Additionally acetate only needs to be supplemented from days 80 to 108 in this case compared to being required from day 80 onward in the scenario without MLF.

Abstract

The aim of this work was to evaluate bioaugmentation with nitrifiers at pilot scale using two Membrane Bioreactors (MBRs) in order to assess the suitability of state of the art activated sludge models (ASM) in predicting the efficiency of bioaugmentation as a function of operating conditions. It was verified that the difference of temperature between seeding and seeded reactors (ΔT) is affecting bioaugmentation efficiency and that the experimental data can be accurately simulated when ΔT is within a given range (about 10 °C). On the contrary, when the temperature is significantly lower in the seeded reactor than in the seeding one, standard ASMs overestimate bioaugmentation efficiency. An ASM able to accurately represent biomass transfer in the presence of high ΔT will require the inclusion of mathematical modelling of the effect of temperature time gradients on nitrifiers.

Keywords

Activated sludge models, nitrifiers, bioaugmentation, membrane bioreactors.

INTRODUCTION

Bioaugmentation with nitrifiers is a cost-effective strategy to obtain high nitrification efficiencies at relatively low solids retention time (SRT) (Bartoli *et al.*, 2011; Szoke *et al.*, 2011). It consists of enriching the mixed liquor of the main-stream reactors of an activated sludge system with nitrifying biomass collected from a side stream reactor where the environmental conditions are favourable for nitrifiers growth.

Several phenomena can influence bioaugmentation efficiency (i.e. predation, large temperature differences and different nitrifying biomass in the seeding and the seeded reactor) that are not included in state-of-the-art of activated sludge models and only in few cases bioaugmentation efficiency has been accurately predicted using conventional IWA ASMs (Munz *et al.*, 2012).

Bioaugmentation is not yet easy to predict and control (Van Limbergen *et al.* 1998) and its success depends on the effective establishment and metabolic adaptation of the added biomass in the treatment system (Satoh *et al.* 2013).

A Membrane Bioreactor (MBR) offers more accurate control of some important parameter (SRT, total undifferentiated bacteria retention) and this can facilitate the verification of ASMs suitability to predict bioaugmentation.

The use of MBRs both for the seeding and the seeded reactors, ensures similar selective conditions and the possibility of maintaining seeded nitrifiers inside the new environment.

The aim of this work was to model the bioaugmentation process at pilot scale using two MBRs operating in different conditions of ammonia loading rate (ALR), SRT and hydraulic retention time (HRT).

MATERIAL AND METHODS

The experimental set-up consisted of two MBRs as shown in Figure 1. The first pilot scale MBR (MBR1- the seeding reactor) consisted of pre-denitrification, nitrification and of a filtration tank equipped with three flat membranes (DF-10 Kubota, Japan). MBR1 was fed with synthetic high strength ammonia influent simulating anaerobic digester supernatant ($650 \text{ mg N-NH}_4^+ \text{ L}^{-1}$; $250 \text{ mg COD L}^{-1}$) and operated for more than 600 days with an SRT of 20 d. The second pilot scale MBR (MBR2 - the seeded reactor) was equipped with a hollow fiber filtration module (Module ZW10 GE-Zenon Environmental) and fed with real domestic wastewater continuously collected from the sewer at the Cuoiodepur WWTP (San Romano – San Miniato, Pisa, Italy). ALR was close to $18 \text{ g N-NH}_4^+ \text{ L}^{-1} \text{ d}^{-1}$. Dissolved oxygen (DO) concentration and pH were the same in both reactors: $\text{pH} = 7.5 \pm 0.5$, $\text{DO} = 4 \pm 0.5 \text{ mg L}^{-1}$. In MBR1, temperature was controlled and maintained at $20 \pm 0.5 \text{ }^\circ\text{C}$ while in MBR2 temperature depended on environmental temperature without any control and varied from 24 to $6 \text{ }^\circ\text{C}$ during the experiment. MBR2 was operated in steady state conditions for more than 400 days without any external seeding before bioaugmentation started with a constant flow of 2.5 L d^{-1} of nitrifying sludge from the filtration tank of MBR1 (Figure 1). Bioaugmentation phase lasted more than 150 d.

Figure 1 Schematic of the experimental pilot scale set-up

In order to study the kinetic behavior of the MBR pilot plant nitrifying biomass, a series of 7 conventional kinetic batch test were performed. 1 L of mixed liquor was collected from nitrification tank of the MBR pilot plant and maintained in mixed and aerated conditions until reaching endogenous. A fixed amount of NH_4Cl was dosed in order to obtain an initial concentration that will not be neither limiting nor inhibitory, based on observation and literature data. The pH was controlled at 8 ± 0.1 and the DO higher than 4 mg L^{-1} through fine bubbles aeration. A sample was collected every 10 minutes and the N-NH_4^+ was analyzed through colorimetric analysis. Each test was repeated in triplicates.

An activated sludge model with a two-step nitrification-denitrification (ASM_N, Hiatt and Grady, 2008) was used to describe the processes (autotrophic and heterotrophic biomass) in both pilot plants and to estimate the amount of active AOB biomass at the time of batch tests according to Munz *et al.* (2011). The model, that separately represents AOB and NOB populations, was used to calibrate the maximum specific growth rate for AOB ($\mu_{\text{max,AOB}}$) and the half-saturation constant for ammonia (K_{NH}) with the results of batch tests.

RESULTS AND CONCLUSIONS

Ammonia Removal Efficiency (ER) estimated in MBR2 under bioaugmented (ON) and non bioaugmented (OFF) period is reported in Figure 2 as a function of the actual temperature. Ammonia RE increase in presence of continuous AOB seeding from MBR1 and

bioaugmentation efficiency (as RE increasing) depends on MBR2 temperature and presents a peak when temperature was in the range 15-17 °C (Figure 6).

Figure 2 Ammonia Removal Efficiency (ER) in MBR2 under bioaugmented (ON) and non bioaugmented (OFF) period

The AOB concentration of the samples used in kinetic test was determined through the modeling of the nitrification capacity of the MBR1 and MBR2 pilot plants; AOB concentration was then used to calibrate $\mu_{\max, \text{AOB}}$ and K_{NH} using ASM_N model on the ammonia bulk liquid concentration obtained in conventional batch kinetic tests.

An example of experimental and modeled ammonia concentration for the MBR2 nitrifying biomass is reported in Figure 3.

Figure 3 Experimental results and calibration with ASM_N of a test for half-saturation constant and maximum specific growth rate estimation

Average values of $\mu_{\max, \text{AOB}}$ and K_{NH} obtained from kinetic batch tests and long term monitoring data elaboration are reported in Table 1.

Table 1 Calibrated ASM_N parameters in batch tests

Parameter	Unit	MBR1		MBR2 Bioaug OFF.		MBR2 Bioaug. ON	
		Avg.	Std. Dev.	Avg.	Std. Dev.	Avg.	Std. Dev.

K_{NH}	mg L ⁻¹	0.8	0.28	0.4	0.14	0.39	0.24
$\mu_{max, AOB}$	d ⁻¹	0.95	0.025	0.85	0.015	0.84	0.019

As reported in Table 1, the main kinetic parameters of AOB in MBR2 were not influenced by continuous seeding of nitrifiers with different kinetics; thus, for further simulations, an unique nitrifying biomass in MBR2 also in presence of bioaugmentation was considered.

ASMN model and calibrated kinetic parameters have been validated on experimental effluent quality data in non-bioaugmented period (until day 440) in MBR1 (data not shown) and MBR2 (Figure 4) before modelling the effect of bioaugmentation process (from day 441 to day 525).

Until the difference between temperature in MBR1 and MBR2 (ΔT) was lower than 10°C (T in MBR1 > 10 °C) ASMN model was able to describe MBR2 effluent quality in the presence of bioaugmentation. Differences between experimental data and model output started when ΔT is higher than 10 °C (Figure 5).

The results confirmed the possibility of modeling bioaugmentation effects using a single nitrifying biomass in both seeded and seeding reactors and highlighted the importance of temperature stress.

Adopted model does not consider some important biological adaptation mechanisms reported in literature that can explain bacterial growth reduction due to sudden temperature changes higher than 10°C.

The observed phenomena can be explained when assuming that the investigated biomass was subject to an adaptation phase and a subsequent partial lag-phase, depending on temperature shock, during which many physiological changes as the induction of the cold-shock proteins occurs (Beales, 2004; Lee et al., 2011).

Due to the presence of a lag phase necessary for the biomass to recover its full activity, the effect of the sudden temperature change should be related to the HRT (in the seeded reactor) and this relationship should be further explored.

As evident from the results of experimental and simulated data reported in Figure 5, where the whole experiment was summarized, ΔT between seeding and seeded reactor plays a very important role on the effect of bioaugmentation on nitrification efficiency and has to be taken into consideration in order to improve bioaugmentation modelling.

As reported by Oleszkiewicz and Berquist (1988) and Guo et al. (2010) temperature correction factor depends on the studied temperature range. In this work, temperature in MBR2 reactor varied in the range 7°C – 20°C in order to study nitrification process in the range of temperature of civil wastewater, but the effect of the same ΔT in a different temperature range needs to be evaluated.

Abstract

Recent research focuses on the use of photobioreactors (PhBRs) as a means to recover wastewater resources and/or as a tertiary treatment process used to polish wastewater treatment plant (WWTP) effluent. Several models have been developed to simulate algae growth. However, there is no accepted process model developed using the systematic approach proposed in the activated sludge modeling (ASM) framework. In this paper, we present a mathematical model developed to simulate green micro-algal growth (ASM-A). It was developed as an extension to the ASM-2d (Henze *et al.*, 2000), hence it can be readily coupled with this commonly used wastewater treatment model. We identified and calibrated a suitable model structure that can describe factors, influencing autotrophic algal growth and nutrient uptake, including macro-nutrient availability and light irradiance in photobioreactors. For model calibration, parameters were estimated through micro-batch (microplate) and a series of batch experiments using a mixed green micro-algal culture isolated in a wastewater pond, growing strictly in suspension. The model was evaluated using independent data obtained in batch experiments with synthetic growth medium.

Keywords

Process modeling, nutrient recovery, microalgae, wastewater

INTRODUCTION

Microalgae photobioreactors offer the potential to recover nutrients contained in wastewater and provide an opportunity for efficient nutrient recycling (Samorí *et al.*, 2013), while serving as tertiary wastewater treatment step. In addition, their biomass can be used for biogas or biodiesel production through anaerobic digestion and the utilization of lipids, respectively. Unlike crop-based biofuels, microalgal biomass does not compete with food production, which qualifies it as a third generation biofuel. However, the production of microalgae has a higher environmental impact (carbon footprint) than the production of crops used for biofuel production. This is due to the comparably higher water demand and energy consumption as well as the greenhouse-gas (GHG) emission associated with the production of nutrients used for cultivation of microalgae (Clarens *et al.*, 2009). With the current technologies, large scale biofuel production from microalgae is neither energetically nor economically favorable, unless wastewater treatment is the primary goal (Lundquist *et al.*, 2010 and Pittman *et al.*, 2011). Moreover, the combination of wastewater treatment with microalgae cultivation eliminates the need to add scarce and potentially costly nutrients like phosphate to the culture medium (Cheng and Ogden, 2011). An accurate model able to simulate algal growth in PhBRs connected with conventional WWTP would be a powerful tool for process design and evaluation of this innovative technology, an area this research addresses.

The main objectives of this study are (i) to develop a micro-algal model in the ASM framework that can combine the bacterial and micro-algal wastewater treatment processes; (ii) to simulate the micro-algal uptake, storage and growth on nitrogen and phosphorous; (iii) to model the co-limitation of various substrates.

Modelling the growth of green micro-algae

Several models exist, describing green micro-algal growth. Table 1 summarizes all the models used for model identification in our study. The models range in complexity, from modelling the influence of one single variable on growth e.g. light (Grima *et al.*, 1994; Huesemann *et al.*, 2013) to models incorporating the influence of multiple variables combined e.g. light, nutrient availability, temperature and pH (Ambrose *et al.*, 2006; Wolf *et al.*, 2007; Quinn *et al.*, 2011; Broekhuizen *et al.*, 2012; Guest *et al.*, 2013 or Decostere *et al.*, 2013). Even when the complexity and the number of factors taken into account are high, some of these models are still missing important aspects related to micro-algal growth and their applications. As an example, the PHOBIA model, developed by Wolf *et al.* (2007), is a biofilm model that includes growth of heterotrophs, nitrifiers and micro-algae, but disregards the algae growth on phosphate, making it inefficient for applications like polishing steps in effluents from WWTP. The modified IWA River Water Quality Model no. 1, described in Broekhuizen *et al.* (2012), developed to simulate a pilot-scale high rate algae pond, is a model accounting for pH, carbon, oxygen, nitrogen and phosphate. Both models estimate the algal biomass concentration on COD concentration units, which allows closing the mass balances between the different organic components and microbial groups. However, growth on nutrients is described through Monod kinetic formulations and do not account for i) uptake and storage and ii) growth on the stored nutrients – factors crucial to predict nutrient recovery from wastewater. The model by Droop (1973) describes uptake and storage as well as growth on stored nutrients. Models with multiple substrate limitations, in accordance to Droop's approach, are those by Ambrose *et al.* (2006), Quinn *et al.* (2011) or Guest *et al.* (2013). Nevertheless, this approach is still under discussion due to the different approaches to model the nutrient growth limitation (the threshold model or the multiplicative model, described in Bourgaran *et al.*, 2010) and the presence of a nitrogen quota (Richmond 2004). None of these models include the bacterial growth, so coupling them with a WWTP model may fail because they do not take into account the synergies between the different microorganisms (e.g. inorganic carbon or light availabilities due bacterial growth). Although several studies report the growth of algae on different organic substrates (Mata *et al.*, 2010 or Brennan and Owende 2010), none of the models takes into account the mixotrophic or heterotrophic algal growth. Organic carbon sources like glucose or acetate, can enhance algal growth to some extent, but become inhibitors for some algae at high concentrations. Therefore, Moya *et al.* (1996), proposed a simple model that takes into account the microbial growth rate of algae as a function of light (autotrophic growth) and acetate (heterotrophic growth). While this model would be useful to predict heterotrophic algal growth, the effect of nutrient availability, amongst others, is missing.

The effect of light on algal growth has been modeled by using expressions accounting for different parameters. In certain cases the effect of light on algal growth is modeled by taking into account light inhibition, i.e. Steele, Peeters and Eilers or Haldane (Ambrose *et al.*, 2006, Bouterfas *et al.*, 2002) while in other models photo-inhibition is not included, i.e. Monod, Platt and Jassby, Poisson single-hit models or Smith equations (Ambrose *et al.*, 2006, Bouterfas *et al.*, 2002 and Skjelberd *et al.*, 2012).

Table 1: Review of algal models considered for the model development of the ASM-A. The green filling indicates the structure and parameters included in each of the models. P&E stands for Peeters & Eilers; P&J stands for Platt & Jassby.

ASM-A MODEL DEVELOPMENT

The model presented in this study was developed in the framework of the well established model for activated sludge ASM-2d (Henze et al., 2000). This ASM model includes all the relevant bacterial groups involved in enhanced biological phosphorus removal systems (EBPR), i.e. heterotrophs, nitrifiers and polyphosphate accumulating organisms (PAOs). However, the expressions included in this section, as well as the model assessment, only refer to the algal processes (Table 2). The units are expressed in accordance with the ASM framework where closed mass balances are used over electron equivalents, expressed in COD, nitrogen and phosphorous and inorganic carbon. ASM nomenclature was followed to make the integration of the algal model into the existing model structures easier.

Uptake and Storage of Nitrogen (R1 and R2)

Ammonia is the preferred form of nitrogen over nitrate for algal growth. In ASM-A, algal uptake and storage of nitrogen is modelled using ammonia (Eq.1) or nitrate (Eq.2) as nitrogen forms. In ASM-A the uptake and storage of N is described in relation to the availability of external N in the wastewater (S_{NH_4}/S_{NO}), as well as to the internal cell quota of N ($X_{Alg,N}$), defined as cell internal storage of N per total mass of biomass. Nutrient uptake rate decreases as $X_{Alg,N}$ approaches the maximum internal cell quota, $X_{Alg,Nmax}$, in the biomass (X_{Alg}). To take into account the algal preference for ammonia, an inhibition term for nitrate uptake is included when ammonia is available.

$$\frac{dX_{Alg,N}}{dt} = k_{NH_4} \cdot \frac{S_{NH_4}}{S_{NH_4} + K_{NH_4}} \cdot \frac{X_{Alg,Nmax} \cdot X_{Alg} - X_{Alg,N}}{X_{Alg,Nmax} \cdot X_{Alg}} \cdot X_{Alg} \quad (1)$$

$$\frac{dX_{Alg,N}}{dt} = k_{NO} \cdot \frac{S_{NO}}{S_{NO} + K_{NO}} \cdot \frac{K_{NH_4}}{K_{NH_4} + S_{NH_4}} \cdot \frac{X_{Alg,Nmax} \cdot X_{Alg} - X_{Alg,N}}{X_{Alg,Nmax} \cdot X_{Alg}} \cdot X_{Alg} \quad (2)$$

Uptake and Storage of Phosphorous (R3)

The uptake and storage of P is defined relative to the availability of external soluble PO_4^{3-} in the wastewater (S_{PO_4}), as well as to the internal cell quota of P ($X_{Alg,PP}$), defined as cell internal storage of P per total mass of biomass. Nutrient uptake rate decreases as $X_{Alg,PP}$ approaches the maximum internal cell quota for P, $X_{Alg,PPmax}$ in the algae biomass X_{Alg} .

$$\frac{dX_{Alg,PP}}{dt} = k_{PO_4} \cdot \frac{S_{PO_4}}{S_{PO_4} + K_{PO_4}} \cdot \frac{X_{Alg,PPmax} \cdot X_{Alg} - X_{Alg,PP}}{X_{Alg,PPmax} \cdot X_{Alg}} \cdot X_{Alg} \quad (3)$$

Photoautotrophic Growth (R4)

Nutrient limitation is described by the Droop model, assuming that growth is dependent on the internal cell quota of the different nutrients. Growth rate decreases as the internal cell quota approaches the minimum subsistence cell quota ($X_{Alg,Nmin}$ or $X_{Alg,PPmin}$) in the algae biomass. The uptake of dissolved inorganic carbon (DIC) is modeled using Monod kinetics. Light limitation is determined by the photo-synthetically available irradiance passing through the PhBR. We assume that the algae are exposed to a constant light intensity, denoted as I_{Av} . To identify a suitable model structure to describe the light influence on micro-algal growth, six different model equations were fitted to the obtained experimental data (not shown) using Sigmaplot®. Two out of the expressions include the photo-inhibition, i.e. Steele and Peeters and Eilers while in the other models photo-inhibition is not included, i.e. Monod, Platt and

Jassby, Smith and Poisson single-hit models. Light dependence is modeled using the Steele equation that was chosen based on experimental results (see the results section).

$$\frac{dX_{Alg}}{dt} = \mu_{A,max} \cdot \left(1 - \frac{X_{Alg,Nmin} X_{Alg}}{X_{Alg,N}}\right) \cdot \left(1 - \frac{X_{Alg,PPmin} X_{Alg}}{X_{Alg,PP}}\right) \cdot \frac{SDIC}{SDIC + K_{DIC}} \cdot \frac{I_{Av}}{I_S} \cdot e^{\frac{1+I_{Av}}{I_S} \cdot X_{Alg}} \quad (4)$$

Heterotrophic Growth (R5)

Micro-algae are able to grow on readily biodegradable organic carbon sources. However, high concentrations of organic substrate can result in substrate inhibition of growth (Richmond, 2004). In accordance with the ASM-2d, acetate is assessed as the organic carbon substrate (S_A). The Haldane model is employed to describe the effect on growth rate as a function of the substrate concentration. Oxygen serves as a substrate for heterotrophic growth (S_{O_2}), and its effect on growth rate is described using the Monod kinetics. The model also takes into account the inhibition due to light intensity of the heterotrophic growth, as well as the nutrient consumption associated with algal growth.

$$\frac{dX_{Alg}}{dt} = \mu_{H,max} \cdot \left(1 - \frac{X_{Alg,Nmin} X_{Alg}}{X_{Alg,N}}\right) \cdot \left(1 - \frac{X_{Alg,PPmin} X_{Alg}}{X_{Alg,PP}}\right) \cdot \frac{S_A}{S_A + K_A + \frac{S_A^2}{K_i S_A}} \cdot \frac{S_{O_2}}{S_{O_2} + K_{O_2}} \cdot \frac{K_I}{K_I + I_{Av}} \cdot X_{Alg} \quad (5)$$

Algal Decay (R6)

The algal decay process includes all forms of algal biomass loss and energy requirements not associated with growth. This includes internal resources used for maintenance, biomass loss during dark respiration, death and lysis that will reduce the amount of active biomass in the culture. In addition, the term includes reduction in biomass due to predators grazing on the algal biomass.

$$\frac{dX_{Alg}}{dt} = b_{Xal} \cdot X_{Alg} \quad (6)$$

MATERIALS AND METHODS

Process model calibration and implementation

Table 2 shows the stoichiometry of each of the processes of the ASM-A model. The ASM-A model was implemented as an extension of the simulation model of ASM-2d implemented in Matlab R2012a (The MathWorks, Natick, MA) by Flores-Alsina et al. (2012).

Microorganisms and media

The mixed green micro-algal consortium used in this study was isolated in a natural pond in contact with wastewater, including mainly *Chlorella sp.* and *Scenedesmus sp.* (data not shown). Importantly, the algae grow strictly in suspension, without significant biofilm formation. The mixed culture was cultivated using synthetic cultivation medium, MWC+Se medium (Guillard and Lorenzen, 1972) under standard temperature.

Micro-batch (microplate) experiments

Micro-batch experiments for assessing exponential growth rate were set up in 24 wells black microplates (VisiPlate, PerkinElmer Inc., Waltham, MA). In this study we refer to the experiments conducted in microplates as micro-batch experiments. Each well can hold a 2 mL sample. Temperature was regulated at 19.8 ± 1.0 °C. The inoculated micro-batches were placed on a shaker table (*Lab-Saker LS-X*), operated at 160 RPM. Light was supplied by six 15 W fluorescent lamps (GroLux, Sylvania®, Danvers, MA). In Vivo Fluorescence (IVF) was used

to measure the algal growth because of its high sensitivity at low biomass concentration. This methodology was successfully applied by Van Wagenen *et al.* (2014) to determine reliable model parameters describing the light dependence of algal growth for different algae species. In the present work, the methodology is extended to assess the nutrient limitation effect by modifying the MWC+Se medium, progressively decreasing the content of either nitrogen (from ammonia or nitrate) or phosphate in each of the wells. In this way, specific growth rates were obtained as a function of the concentration of the different nutrients.

Batch experiments

For assessing the effect of nutrient availability on growth, nutrient uptake and storage, batch experiments were set up using 1 L wide-neck glass bottles (Duran ®, Germany) with a multi-port system allowing for sample extraction and aeration with CO₂ enriched air. Light was supplied from the two sides of the batches using 18 W fluorescent lamps (GroLux, Sylvania®, Danvers, MA). Dilutions were made with the cultivation medium when the optical density reached the value of 0.4 to avoid self-shading in the culture, thus light inhibition. During the batch experiments the limiting substrates were monitored using Hach-Lange test kits and cell density analysis (APHA, 1995). A control batch was run and monitored parallel to the experiments, yielding an independent data set used for model assessment.

RESULTS AND DISCUSSION

Model calibration

Between the six different models of light effect over algal growth, the Steele expression (included in eq. 4) was found to most accurately describe the light dependence of algal growth (Fig. 1). This expression includes the photo-inhibition however, which is not fully-supported by the measured data, and hence further assessment at higher light intensities will be carried out in this project. The maximum microbial growth rate (μ_{\max}) is found at an optimal light intensity (I_s) of $758.2 \mu\text{mol m}^{-2} \text{s}^{-1}$, its value being 3.6 d^{-1} .

Figure 1: Specific microbial growth rate plotted as function of light intensity according to the Steele equation. Dots represent the value obtained in the micro-batch experiments and the error bars represent the standard deviation on the light intensity and the optical density measured in the micro-batches.

Once the effect of light over algal growth was defined, we conducted micro-batch and batch experiments for model parameter estimation. The nutrient limitation of the microalgae was assessed in both micro-batch and batch experiments. Table 3 shows that results obtained in micro-batch and 1 L batch experiments are comparable. Van Wagenen *et al.* (2014) also reports that the parameters describing the light effect over algal growth estimated through micro-batch experiments were comparable to those obtained at larger scale. Therefore, it can be concluded that micro-batch experiments are an efficient tool to estimate the effect of different substrates on microbial growth of micro-algae, saving time and costs.

Table 3: Parameters estimated in micro-batch (2 ml) and batch (1 l) experiments:

Parameter	Microbatch	Batch
$\mu_{A,\max}$	3.6	3.25
$K_{\text{NH}_3,\text{Alg}}$	0.5	0.88
$K_{\text{NO}_3,\text{Alg}}$	-	3.39
$K_{\text{PO}_4,\text{Alg}}$	0.1	0.25

The complete parameter set of the ASM-A, including among others the minimum and maximum internal cell quota for nitrogen and phosphorous, the specific uptake rates and the decay rate, are presented by Wágner *et al.* (2014).

Model evaluation

Simulations were carried out using the Matlab implementation of the ASM-A model. A reference parameter set was derived from micro-batch and batch experiments carried out in this study and some parameters were taken from literature (Wágner *et al.*, 2014). The model was calibrated and the prediction was compared with an independent data set from batch experiments. Two cycles were modelled including the point of dilution at the third day, which was done to avoid self-shading effect. Results are shown in Fig. 2:

Figure 2: Control batch simulation. a) algae growth in the control batch reactor, in terms of the concentration of algae biomass; b) internal nitrogen storage of algae, in terms of the nitrogen quota; c) bulk nitrate concentration.

According to Fig. 2, ASM-A can predict the algal biomass growth reasonably well during the batch experiment (Fig. 2 a). In these simulations it is assumed that light intensity is constant during the experiments and thus the entire photo-bioreactor is exposed to an average light intensity (I_{av}) measured at the beginning of the experiment. However, since the biomass concentration increases in the batch, the light availability decreases due to self-shading by the algae. The discrepancies between measured and simulated data in Fig. 2, indicate the importance of using a more realistic model describing the light absorption in PhBR. In Fig. 2 b, the prediction of the nitrogen content in biomass shows some limitations at low concentrations. The model predicts well the second cycle of the measurement, however underestimates the measured values in the first cycle. The bulk liquid concentration of nitrate (Fig. 2 c) is reasonably well described by the model.

CONCLUSION

In this study, a process model for green micro-algal growth has been identified and developed using the systematic approach of the activated sludge models. The model accurately describes the micro-algal growth under constant light intensity within the culture. In order to improve the estimation of the biomass concentration, the integration of a model for light distribution in PhBR is needed. The model prediction of nitrogen uptake and storage process needs further improvement. Therefore, our future research activities will focus on the development of a better understanding of the internal nutrient storage in algae in order to reduce the prediction uncertainty derived from the identified model structure.

ADM1 implementation with an innovative organic matter characterization methodology: extension to organic micropollutants fate

Julie Jimenez, Quentin Aemig, Jean-Philippe Steyer, Dominique Patureau

INRA, UR0050, Laboratoire de Biotechnologie de l'Environnement, Av. des Etangs, Narbonne, F-11100, France (E-mail: julie.jimenez@supagro.inra.fr)

Abstract

Advanced dynamic anaerobic digestion models, such as ADM1, requires both detailed organic matter characterisation and intimate knowledge of the involved metabolic pathways. In the current study, a methodology for municipal sludge characterization previously developed is used to describe two key parameters: biodegradability and bioaccessibility of organic matter. The methodology is based on coupling sequential chemical extractions with 3D fluorescence spectroscopy. The proposed approach showed a strong application potential for reactor design and advanced control of anaerobic digestion processes. In order to complete the modified model, the organic micropollutants fate modeling is considered, since their degradation is strongly linked with the organic matter biodegradation, and addition of micropollutants kinetics terms in the overall model is proposed.

Keywords

Modelling; ADM1, organic matter characterization, bioaccessibility, organic micropollutants

INTRODUCTION

In the current context, where anaerobic digestion (AD) has become a key process for organic matter treatment and energetic valorization, precise control and prediction of process performance is a must-be. Concomitantly to the organic matter degradation and valorization, some Organic MicroPollutants (OMPs) like Polycyclic Aromatic Hydrocarbons (PAHs) have been shown to be removed during AD and are strongly correlated with organic matter (OM) removal (Barret *et al.* 2012). During the biological wastewater treatment, the main pathway of degradation of OMPs is the sorption on sludge (Barret *et al.*, 2012). As a consequence, AD of sludge has to deal with the OMPs degradation, above all from a sanitation and regulations point of view. In terms of OM characterisation and degradation prediction, three concepts are of the most relevance for a particulate substrate such as municipal sludge: bioavailability, bioaccessibility and biodegradability. As OMPs sorbed to the particulate evolves with OM, these concepts would impact them. Recently, a methodology based on chemical sequential extractions and 3D fluorescence spectroscopy has been developed for sewage sludge. A successful correlation with bioaccessibility and biodegradability was found and variables from modified Anaerobic Digestion model n°1 (ADM1) have been characterized (Jimenez *et al.*, 2014). In this study, the methodology is applied before and after AD samples. OMPs measurement was done in each organic matter fractions in order to adapt the ADM1 model to the fractionation developed and to propose a first model of OMPs degradation.

MATERIAL AND METHODS

Organic matter characterization

Based on the floc definition, the applied sequential extraction (SE) correlates bioaccessibility of sludge organic matter to its chemical accessibility. The obtained fractions were Dissolved Organic Matter (DOM) obtained by centrifugation and filtration at 0.45µm, soluble Exo-Polymeric Substances (S-EPS), readily bound EPS (RE-EPS) and Humic Like Substances (HLS) obtained by chemical extractions using salt and/or soda of increasing molarity. The

non extracted (NE) fraction is the non extractible fraction. Extracts were then measured by fluorescence spectroscopy as explained by (Jimenez *et al.*, 2014).

Batch reactors test

Two biochemical methane potential (BMP) were operated with a secondary sludge from a wastewater treatment plant in France. The methodology followed was the same than in Angelidaki *et al.*, (2009). Concerning OMPs fate, the first BMP reactor (named BMP1) was operated without PAH addition while the second (BMP2) was operated with PAH addition. OMPs which are sorbed into the particulate fractions SEPS, RE-EPS, HSL and NE were measured after solvent extraction (50:50 v:v of hexane/acetone) and high-performance liquid chromatography analysis.

RESULTS

New implementation of organic matter variables in ADM1

Concerning the organic matter degradation, the modified ADM1 model used by Jimenez *et al.* (2014) has been chosen because (i) the limiting step in sludge AD is the hydrolysis (Contois equation) and (ii) two complex substrates with different hydrolysis rates are considered on the two-shaped curve obtained for methane production rate for sludge. The 3D-SE-LPF methodology is used in order to calculate the non biodegradable fraction, the readily and slowly biodegradable fractions through the Partial Least Square model developed by Jimenez *et al.* (2014). As shown by the authors, DOM, S-EPS and RE-EPS are the most accessible fractions while HLS and NE are the least one. In order to make more easier the OMP degradation model implementation, ADM1 input variables (readily and slowly biodegradable) are replaced by the extracted fractions : S-EPS and RE-EPS as the particulate COD readily bioaccessible and HSL and NE as the particulate COD slowly bioaccessible (cf. Figure 1). Applied on the batch reactor test, methane production curve and output fractions were well predicted as shown by figure 1 by calibrating the maximum growth rate of hydrolytic biomass.

Figure 1. Simulations of methane production and particulate fractions of sludge during BMP tests

OMPs mass balance and model proposition

Delgadillo-Mirquez (2011) has demonstrated that the OMPs biodegradation are mainly related with the upper biological pathway of anaerobic digestion (hydrolysis and acidogenesis). As a consequence, the bioavailability and bioaccessibility concept of organic matter could be useful for OMPs fate characterization. Consequently, the SE protocol has been applied for OMPs partition assessment into the organic matter compartments in order to estimate their bioavailability. Barret *et al.* (2012) and Delgadillo (2011) confirmed that the bioavailable fraction is contained in the aqueous phase (free OMPs and sorbed to colloidal matter) and that the bioaccessibility depends on the pollutants sorbed to particles.

OMPs mass balance obtained during BMP tests are presented in the figure 2 where 3 PAH (Fluorene, Pyrene, Benzo(b)Fluoranthene) from 13 are considered. It appeared that in both BMP1 and BMP2, OMPs degradation was negative in some fractions. One hypothesis would be that during hydrolysis process, OMPs molecules passed from the least accessible fraction to the most one (i.e. DOM). Moreover, in the case of BMP2 where OMPs addition occurred, a bound-residue seemed to be created in the NE from the degradation of OMPs located in HLS.

Figure 2. OMPs mass balance during BMP1 and BMP2 tests

Delgadillo *et al.* (2011) showed that combining bioavailability and cometabolism concepts on a dynamic simplified model allowed the prediction of the OMPs fate in anaerobic digestion. Consequently, OMPs degradation model is proposed (cf. figure 3) based on cometabolism during hydrolysis (with Contois hydrolytic biomass) and during the degradation of the bioavailable fraction DOM into metabolites. Finally, a process of bound residue formation is added.

Figure 3. Model proposed for OMPs degradation during anaerobic digestion of sludge

PERSPECTIVES

Based on previous work, modified ADM1 was able to predict methane production and the different OM particulate fractions simulating bioaccessibility. Concerning OMPs degradation, a new distribution from NE fraction to HLS, RE-EPS, S-EPS and then DOM was observed. Based on these observations, a model was proposed and future data coming from a continuous reactor will provide validation or not of these hypothesis.

Abstract

Co-digestion is the anaerobic digestion of several types of waste and can be used to increase resource recovery. However, co-digestion can exacerbate a digester's tendency to become unstable and stop working. In addition, the quantitative relationship between a diverse set of waste combinations and codigester stability is largely unknown. To address this concern, we created a stability assessment that employs the Anaerobic Digestion Model No. 1 (ADM1) and stability metrics, such as alkalinity concentration, in order to identify influent characteristics that achieve stable operation. The characteristics of particulate-only influent compositions that support stable digester performance have been identified. Also, current design guidelines, which have enabled the effective design and operation of sludge digesters, have been found to be too limited when applied to codigestion systems. Overall, this work contributes to the establishment of case-specific digestion guidelines, which can include re-defining design guidelines for anaerobic co-digestion.

Keywords

anaerobic co-digestion, ADM1, stability, resource recovery

INTRODUCTION & MODELING APPROACH

While anaerobically co-digesting several types of wastes can increase the recovery of resources, it can also reduce digester stability and lead to higher costs and lower reliability. Therefore, we developed a digester stability assessment that can be used to establish influent guidelines for codigestion and to improve resource recovery from waste without compromising digester stability.

Stability Index

Stability indicators are chemical and biological compounds that can indicate if a digester is stable or unstable (Boe et al., 2010; Ferrer et al., 2010; Schoen et al., 2009; Switzenbaum et al., 1990). These stability indicators can be used to compare simulated digester effluent concentrations against values expected for a stable codigestion system. For each indicator, a digester's simulated effluent was compared to the indicator's concentration range in order to rate the digester's stability based on that indicator (e.g., highly stable, borderline stable, or unstable). For example, a stable pH range was assumed to be 6.1 – 8.3, and a digester with a pH of 6.2 was considered less stable than a digester with a pH of 7. Table 1 compiles the stability indicators used in this research along with their target concentration ranges, as found in the literature. Next, each indicator was assigned a weight to represent that indicator's ability to describe a digester's overall stability, which is evaluated by assessing its link to the anaerobic microbial food web, the validity of its concentration range, and its independence from other indicators. Finally, a weighted sum of all the indicators' ratings was calculated to represent the digester's overall stability.

Table 1. Stability indicators' stable concentration ranges and weights used in the stability index.

<i>Indicator</i>	<i>Units</i>	<i>Minimum</i>	<i>Maximum</i>	<i>Weight</i>	<i>Citations</i>
Methane Biogas Composition	% (by volume)	55	n/a	1	AB
pH	(--)	6.1	8.3	1	ABC
Alkalinity	mg CaCO ₃ /L	2,000	20,000	1	BDE

Anaerobic Digestion Simulation & Uncertainty

Influent compositions were created to represent a wide range of potential waste combinations, and the digester performance was simulated using the Anaerobic Digestion Model No. 1 (ADM1) (Batstone et al., 2002). In order to represent a large particulate influent space, 10,000 influent compositions were randomly generated using the following criteria: (1) the total organic loading rate (OLR) was within a range of 1-11 kg COD/m³/d, which includes a maximum loading that is about 20% greater than experimentally determined stable loadings (Björnsson et al., 2000; Ferrer et al., 2010; Westerholm et al., 2012) in order to provide a large range of influent compositions; (2) the loading of carbohydrates, lipids, and proteins were each within a range of 0-11 kg COD/m³/d in order to represent many different influent composition possibilities; and (3) the loading of inert compounds were within a range of 0-20% of the influent's total COD to represent an average inert concentration for a variety of wastes (Zaher et al., 2009).

ADM1 was chosen to simulate the digestion process because it has effectively simulated both experimental and full-scale digesters (e.g., Batstone et al., 2006; Jeppsson, 2007). The differential and algebraic implementation of ADM1 as modified by Rosén and Jeppsson (2006) was used along with ADM1's default biochemical and physicochemical parameters for mesophilic digestion. In addition, alkalinity concentration was estimated from ADM1 outputs using the activated sludge model interface calculations (Nopens et al., 2009). The simulated digester had a volume of 3,400 m³ and perfect mixing was assumed. The temperature was set

at 35 Celsius, and the retention time was 20 days. All simulations were run for 1,000 simulated days in order to represent steady-state operation.

RESULTS AND DISCUSSION

The value of the stability index was examined by comparing the performance of full-scale and lab-scale digesters with the estimated stability assessment (i.e., stability index rating). Data from 4 full-scale domestic wastewater sludge digesters with stable, long-term operation (Hampton Roads Sanitation District, 2013) were evaluated using the stability index, and the stability index rating was representative of the full-scale digester's stable performance. In addition, data from two lab-scale codigestion reactors, one reactor codigesting domestic wastewater sludge and potato processing industrial waste and the other codigesting manure, slaughterhouse and agricultural waste (Murto *et al.*, 2004), were also evaluated, and the stability index rating was also representative of the experimental codigesters' performance. Testing the stability index calculations with full-scale and lab-scale stable digesters showed the ability of the stability index to estimate stable digester performance. In addition, the stability indicator ranges that are most important to the stability estimation were identified by conducting a Monte Carlo assessment. This assessment found that the minimum percent methane biogas composition, maximum long chain fatty acids (LCFA) concentration, and minimum percent COD removal were all significantly ($p\text{-value} < 0.5$) and strongly ($|\rho| \geq 0.7$) correlated with overall digester stability for at least one simulated influent composition. More information about the stability bounds for these indicators can improve insight about digester stability.

Wide-ranging influent compositions were simulated using ADM1 and evaluated using this stability index in order to identify a digester's stable influent space, which is comprised of the influent compositions that result in stable operation. Figure 1 shows a digester's stable influent space for particulate influent compositions. In addition, Figure 1 suggests that there are key digester operational considerations. For example, it shows that instability is likely at high OLRs, and this trend is reinforced with experimental data from the literature that shows digester overloading is possible with OLRs greater than 5 kgCOD/m³/d (Björnsson *et al.*, 2000; Ferrer *et al.*, 2010; Gomez *et al.*, 2006; Grady *et al.*, 2011; Kusowski *et al.*, 2013). Also, the simulations show that there may be a minimum nitrogen requirement for digester stability. The main reason for digester instability in this minimum nitrogen region is due to a lack of biomass growth, as indicated by the total biomass concentration predicted by ADM1. This minimum requirement is around a protein loading of 1 kg COD/m³/d, which equates to a minimum nitrogen loading of 7.5 mole/m³/d. Overall, this stable influent space highlights a relationship between influent composition and digester stability that matches current knowledge about stable digester performance under steady-state conditions. Also, it provides the opportunity to inform design guidelines and the selection of wastes in order to achieve reliable anaerobic codigestion.

The applicability of conventional design guidelines to codigestion was investigated by comparing recommended influent guidelines with the modeled stable influent space. The OLR design recommendations is 1-5 kg COD/m³/d for continuously-stirred tank reactors (Grady *et al.*, 2011). When comparing this recommendation with the stable influent space, the simulations suggests that many stable influents can have an OLR larger than the recommended range. Stable digester operation at OLRs greater than 5 kg COD/m³/d is also seen experimentally (Björnsson *et al.*, 2000; Gomez *et al.*, 2006; Kusowski *et al.*, 2013). Overall, modeling results and experimental data from the literature suggest that the OLR recommendation may be too conservative.

Another main design guideline is the influent carbon-to-nitrogen (C/N) ratio. The very general ratio range is 10-90:1 (Wang *et al.*, 2012), with an stated optimum usually around 20-30:1 (Stroot *et al.*, 2001; Wang *et al.*, 2012). Data from the experimental literature (Astals *et al.*, 2012; Stroot *et al.*, 2001; Wang *et al.*, 2012; Wu *et al.*, 2010) suggest that the C/N ratio range for stable digestion is based on a specific influent composition, and the stability modeling results also suggest that the C/N ratio may have limited applicability. The C/N ratio recommendation may be too specific to a type of waste and too focused on an optimal range to provide a good correlation between a large range of influent compositions and general reactor stability.

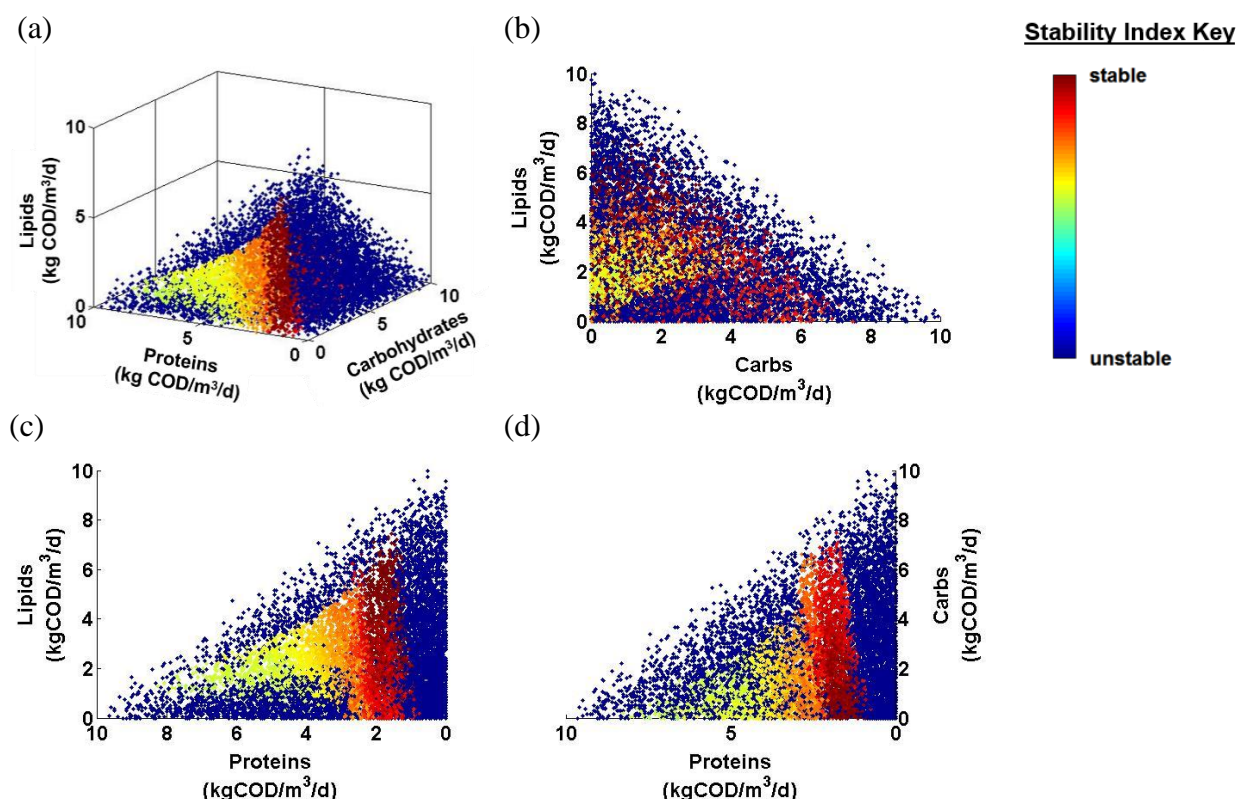

Figure 1. Particulate influent compositions and their relationship to digester stability: (a) 10,000 particulate influent compositions (inert substrate loading not shown); (b-d) influent compositions (each representing a varying concentration of 4 substrates) projected onto 2 substrate loading axes.

CONCLUSIONS

This work shows that a stable influent space can be estimated using ADM1 and this work's stability index. Also, it shows that a digester's stable influent space for particulate influents may be larger than current design guidelines suggest. Codigestion design guidelines that use substrate composition data (i.e., characterization of carbohydrates, lipids, proteins, etc.), include higher OLRs, and are more inclusive of a diverse range of substrates would be more helpful to improve resource recovery without compromising stability.

Abstract

A customized Activated Sludge - Anaerobic Digestion Model (ASDM) from BioWin 3.2™ by EnviroSim was used to develop a future operational process control strategy for Blue Plains Advanced Wastewater Treatment Plant's (AWTP) anaerobic digesters with CAMBI™ thermal hydrolysis process (THP) pretreatment. This model was developed to understand the relative importance of free ammonia on gas production and accumulation of volatile fatty acids (VFA). Under any given loading conditions, the operational setpoints of solids retention time (SRT) and free ammonia can be controlled by adjusting the influent solids concentration. This model helps to predict which setpoints would allow for maximum gas production while maintaining digester stability.

Keywords

Modeling; ASDM; anaerobic digestion; ammonia inhibition; thermal hydrolysis

INTRODUCTION

Anaerobic digesters with CAMBI™ THP pretreatment are currently being constructed at Blue Plains AWTP located in Washington, DC, United States. Partial solubilization of particulates and disintegration of cells in the THP reduce sludge viscosity, improve bioavailability of organics, and allow the digester to be loaded at higher solids concentrations. However, increased feed concentration and destruction of protein and other complex organic materials also result in free ammonia (NH₃) levels that are much higher than what is typically seen in conventional mesophilic digesters (Kepp *et al.*, 2001). Free ammonia has inhibitory effects on the methanogens that are responsible for completing the final step in anaerobic digestion systems where acetic acid is converted to methane gas (Eldem, 2005, Wilson, 2009, Wett, 2012). Compared to hydrolysis-limited conventional digestion (Siegrist, 2002, Wilson, 2009), Blue Plains thermal hydrolysis-digestion (THD) is expected to be methanogenesis-limited, and therefore, minimizing the unionized ammonia level becomes a major concern while developing a process control strategy.

One of the key operational controls for Blue Plains is the dilution water feed rate that follows the THP system, which can be used to adjust the digester influent solids concentration, SRT and ammonia concentration. Operating at higher influent concentrations would allow for longer SRT in the digesters but could also result in greater inhibition from higher ammonia concentrations. However, operating at lower solids concentrations could result in lower inhibition but would also reduce digestion time. A calibrated model could assist the plant staff in finding the optimum digester influent concentrations and resulting ammonia concentrations and SRTs that would maximize gas production while maintaining digester stability.

METHODOLOGY

Model development

Various advancements have been made to the original ASDM to simulate the unique impacts of THP and high-loaded digestion process. The effect of THP can be modeled by converting portions of slowly biodegradable COD (X_{sp}) to readily biodegradable COD (rbCOD), and active biomass to X_{sp} , while tracking the release of inert materials and nutrients (Wett *et al.*, 2009). This model was further improved by incorporating ammonia inhibition of acetoclastic methanogens (AM) and alternative degradation pathways through acetic acid oxidizers (ACOX) and hydrogenotrophic methanogens that are more tolerant of higher ammonia levels (Wett *et al.*, 2012). The NH_3 inhibition was modeled using the logistic model and the parameters were calibrated using results from bench-scale digesters fed with thermally-hydrolyzed Blue Plains sludge (THD) running in parallel with a conventional mesophilic digester (Wilson *et al.*, 2009). Additionally, the non-ionized form of acetic acid was designated as an inhibitory substrate using the Haldane equation as suggested by Fukuzaki *et al.* (1990). Detailed descriptions on modeling of THD are provided in previous publications by Wett *et al.* (2009 and 2012).

The feed sludge characteristics were obtained from a calibrated, full-plant model at Blue Plains. The liquid side treatment at Blue Plains consists of a chemically-enhanced primary treatment (CEPT), a high-rate secondary treatment that is bioaugmented with waste sludge from the nitrification/denitrification (NDN) stage, an NDN system with methanol addition and multimedia filtration. A typical primary sludge (PS) to waste activated sludge (WAS) ratio at Blue Plains is 55/45 but the portion of WAS becomes higher during the winter months when solids decay in the biological reactors slow down.

Figure 1. Model configuration in BioWin 3.2.

Experimental Setup

Three pilot scale digesters were set up to test the effect of varying influent solids concentrations on the digester performance. A blend of PS and WAS dewatered to 25 to 28% TS at Blue Plains high-solids centrifuge was collected and diluted to approximately 16 to 18% TS prior to thermal hydrolysis. The pilot thermal hydrolysis system supplied by CAMBITM consisted of a 15 L reactor, a 50 L flash tank and a boiler. The reactor was operated at 160°C for 30 minutes and flashing pressure of 3.1 bars. TH sludge with concentrations of 10-12.5% TS was then shipped from Blue Plains to Bucknel University's Anaerobic Digestion Lab to be fed into pilot-scale digesters.

The three digesters were fed at the same solids loading rate of 7 kg TS/m³-day but the influent concentrations were adjusted, which in turn determined the target SRT. The operating

parameters are presented in Table 2. The reactors were operated semi-continuously by batch feeding once a day. The same amount of sludge was withdrawn from the reactor after a 24-hour reaction period prior to the next pulse feed. The digester headspace was hooked up to a respirometer to measure the gas production volume and rate. The temperatures inside the reactors were maintained at 38°C.

Table 1. Operating parameters of the pilot scale digesters

Digester Number	Influent Solids Concentration (% TS)	Feed Rate (L/day)	Target SRT (days)	Solids Loading Rate (kg/m ³ -day)
1	7.0	1	10	7
2	10.5	0.67	15	7
3	12.5	0.56	18	7

The seed sludge for the digesters came from a previous set of experiments where the impact of TH reaction temperature was investigated (in preparation). In these experiments, five digesters were fed with sludge from Blue Plains that had been thermally hydrolyzed at reaction temperatures of 130, 140, 150, 160 and 170°C. They were operated in the same condition as Digester 2 with influent solids concentration of 10.5% TS and 15 days SRT. Since these digesters had been operating for close to six months, the anaerobic biomass had been acclimated to high solids conditions and free ammonia concentrations of 130 to 160 mg/L.

Figure 2. Photos of the pilot TH reactor at Blue Plains [left] and pilot digesters at Bucknell [right].

RESULTS AND DISCUSSION

Dynamic runs were used to investigate the impact of changing influent concentrations on digester performance. The initial conditions used in the model were assumed to be a steady-state digester that had been operating at 15 days SRT and 10.5% TS influent. The feed concentrations were adjusted according to Table 1 to simulate the desired SRT.

The measured data and model both show that digester ammonia concentrations can be controlled based on the influent solids concentrations as shown in Figure 3. Even under the same loading rate the total ammonia concentration can be adjusted to from 1,500 to 3,700 mg/L. The experimental data and model both agreed with a previous study (Kepp *et al.*, 2001) that showed that total ammonia has a stoichiometric relationship with the influent solids concentrations.

Figure 3. Simulation output and experimental data on the total ammonia concentrations inside the digester.

The model and experimental data also demonstrated that increasing SRT would result in greater specific methane production despite higher ammonia inhibition as shown in Figure 4. The simulation results showed that an increase of even 3 days in the SRT may result in approximately 4% increase in specific methane production. Our theory is that although THP greatly increases the rbCOD of feed sludge, a large portion of biodegradable COD is still in particulate form and needs to be enzymatically hydrolyzed. That is why the model output showed that total mass of sbCOD was much higher in 10 day SRT compared to 18 day SRT.

Figure 4. Simulation output compared to experimental results of daily methane production.

However, increasing the ammonia concentration has a negative impact of elevating the VFA levels in the digesters. The current inhibition constants cause the growth rate of methanogens to reduce significantly as the ammonia level reaches what is observed in the digester operated at 18 days SRT. At this point in the experiment, the VFA levels in the 18 days have not reached steady state as the last VFA measurement taken is much higher than the value from the previous week. It is difficult to tell if the VFA levels would increase to the level near what is being predicted by the model.

Another observed model limitation is that the model is predicting that the effect of ammonia inhibition would start to manifest much faster than what the experimental data is indicating. Despite the ammonia level that was increasing quickly in the 18 day SRT reactor, the digester was able to maintain its VFA levels for a longer time than what the model predicted. This may be from the fact that the digester ecology had been exposed to the higher ammonia concentrations for long a time and can withstand a short-term increase in the ammonia level.

Figure 5. Simulation output compared to experimental results of VFA buildup in digesters.

CONCLUSION

A model was developed to understand the relative importance of ammonia on gas production and VFA in high-loaded digestion processes. This model helps to predict operational setpoints of SRT and ammonia by controlling the influent solids concentration. Thus, under any given loading conditions, SRT and ammonia can be controlled to maximize the gas production while maintaining digester stability.

Abstract

The paper outlines a protocol for comprehensive evaluation of mixing devices for activated sludge tanks using field testing for calibration of computational fluid dynamic (CFD) modelling to compare the impacts of tank and mixing device geometry on mixing and energy efficiency. The protocol includes a CFD model for activated sludge solids settling and transport which captures the influence of solids concentration gradients on fluid motion. This element of the protocol is unique in that almost all analyses completed to date for activated sludge biokinetic modelling or mixing have assumed either 1) complete mixing or 2) neutral density CFD neglecting the true multiphase conditions. To date, the protocol has been applied to several types of mixing devices including jet aeration and mixing, horizontal shaft propeller mixers, and diffused aeration. Field testing of several other types of mixing devices has also been accomplished. The protocol is recommended to optimize design and application of mixing devices for activated sludge service in aerated, anoxic, and anaerobic tanks as part of biological treatment processes. The approach can be extended to incorporate biokinetic models that more accurately predict the impact of tank geometry and mixer configuration on treatment efficiency than can be achieved assuming complete mixing or neutral density CFD.

Keywords

Mixing, activated sludge, modelling, CFD, energy efficiency

INTRODUCTION

With increasing recognition of the importance of nitrogen and phosphorus removal from wastewater discharges and recognizing the proven economy of biological treatment processes for nutrient removal, the wastewater treatment industry has seen an increase in the use of un-aerated tanks for anoxic uptake of nitrate and anaerobic tanks to facilitate phosphorus removal from wastewater effluents. Anaerobic tanks are also increasingly used to improve activated sludge settleability. In order to facilitate these treatment goals, biological treatment tanks with significant concentrations of suspended solids must be mechanically mixed. With this increasing importance of mixing in standard biological treatment processes, optimization of tank geometry and mixer configuration becomes more important. We want the most efficient mixing in two senses: 1) we want near uniform distribution of suspended solids across our treatment tanks and 2) we want to use tank geometries and mixer configurations that minimize consumption of energy. It is towards this optimization of mixing and energy efficiency that the proposed protocol aims.

PROTOCOL APPROACH

The elements of the proposed protocol include the following:

- Field testing for comparison with CFD results
- Development of CFD models for the conditions of the field test
- Calibration of the CFD models
- Development of CFD models for alternate basin geometry and mixer type and configuration and comparison of CFD results from alternative geometries and mixing devices in terms of mixing and energy efficiency

Field Testing

Field tests used by the authors to date have included: 1) solids profiles, 2) velocity profiles, 3) flow pattern distribution tests, and 4) residence time distribution dye tests. In the current paper only solids profiles will be discussed.

Solids profile tests are arguably the most important data for evaluation of mixers for activated sludge service. In suspended growth wastewater applications a uniform distribution of solids concentrations at the lowest power level is the primary goal. Solids profile tests can be implemented in the field in a number of ways. Solids samples can be withdrawn by Kemmerer samplers or by a series of sample pumps using the techniques developed by Robert Crosby (Bender and Crosby, 1980) or by solids probes. In the Crosby technique a grid of approximately 25 samples are withdrawn across the tank width and depth at locations chosen to illustrate mixer influence. The samples are then analyzed for suspended solids content (*Standard Methods* 2540D.) For measurements discussed below we used an Insite Instrumentation Group Model 3150 probe.

Detailed TSS measurements for four vertical shaft mixers have been conducted by Carollo Engineers for the Orange County Utilities' (OCU) South Water Reclamation Facility (SWRF) in Orlando, Florida. A cross sectional grid of 25 data points were measured for each mixer. Three hydrofoil mixers from different manufacturers were compared to a hyperboloid mixer. Hydrofoil I had three flat impellers each with a downward bending trailing edge. Hydrofoil II had three curving impeller blades of relatively large diameter. Hydrofoil III was constructed of a single flat plate with three downward folding projections. These impellers all produce a downward pumping action through the impeller. The Hyperboloid I mixer also produced a downward pumping action using a series of upwardly projecting shallow ridges of hyperboloid shape. Measurements were taken over the course of a one-hour period on different days for each mixer. The deviation of the measured concentration from the average concentration across the entire section was then calculated. This deviation may be considered the coefficient of variation (CoV) of the sample data for each mixer.

Contour plots of the measured concentration data for two of the hydrofoil mixers are presented in Figure 1. The contour plots indicate an asymmetry across the tank. This asymmetry is thought to have been caused by upstream conditions in the racetrack tank. The three hydrofoils were all arranged on their vertical shafts at approximately one third depths in the tanks. The one hyperboloid mixer was nearer to the bottom of the reactor tank. The contour data for this mixer (not shown) indicated relatively uniform concentrations across the tank, but significantly higher concentrations in the tank bottom.

Carollo Engineers also conducted limited field tests of jet mixing and aeration of an operating sequencing batch reactor (SBR) at the Blacks Ford Regional Water Reclamation Facility (BFRWRF) of the JEA Utility in Jacksonville, Florida. The tests (Samstag et al., 2012) were conducted to establish solids concentration profiles under normal operating conditions for use in calibrating CFD modelling. Solids concentration measurements were taken at multiple depths at two locations at the edge of the operating SBR using a calibrated optical solids measurement probe. Mixed liquor suspended solids (MLSS) measurements were made during mixed cycles with both air and pumping operational and during pumping-only mix cycles.

Figure 1. Solids profiles for two vertical shaft mixers.

Development of CFD models for the conditions of the field test

The first step in development of a calibrated CFD model is to produce a geometric and computational mesh of the field-tested reactor. Modern tools for CFD allow construction of extremely detailed models of complex geometries and optimized computational meshes. The authors have ANSYS GAMBIT, Version 2.4.6 for both modeling and meshing for the case studies referenced here.

Figure 2 presents an illustration of the three-dimensional geometric model and a projection of the computational mesh prepared for the BFRWRF SBR tanks for CFD analysis. The model shows the three jet headers, the main header pump intake, the auxiliary header pumps and intakes, and the effluent decanters. The effluent decanters were not required for the flow simulation, but were included to simulate the fluid environment. The polyhedral computational mesh of approximately one million cells is shown projected onto model surfaces.

Figure 2. SBR Tank Geometric Model and Computational Mesh.

Calibration of the CFD models

Modern CFD models can be used without calibration. The physics of CFD have been verified within the tolerance of most field measurements many times before. A possible exception is in the area of turbulence estimation. It is widely believed that the k-epsilon turbulence model is appropriate for the types of recirculating flows commonly seen in activated sludge

sedimentation tanks, but calibration is more important where the CFD is used as a base for solids transport or biokinetic models, since many of the empirical parameters used in these models are much less well established than the physical parameters applicable to fluid flow. Calibration techniques have included solids settling rate testing, solids profile matching, and clarifier sludge blanket matching during dynamic flows. See Griborio et al. (2008), Wicklein and Samstag (2009), Samstag and Griborio (2010), and Samstag et al. (2010). For this protocol we demonstrate the use of one of the most useful techniques, solids profile matching. The authors used Fluent Version 13 on a computing platform of 64-bit workstations with multiple CPU cores running a 64-bit Windows XP operating system.

Figure 3 presents contour plots of CFD simulations of dynamic solids profiles for the BFRWRF under conditions of normal operation with aeration on and with only the recirculation pumps on. The simulation of the aerated condition produced a good match to the fully mixed condition seen in the field tests. The solids profile match for simulation of pumped mixing after aeration had been turned off for 25 minutes confirmed the development of relatively clear water in the top of the tank that was seen in the field tests. See Samstag et al., 2012.

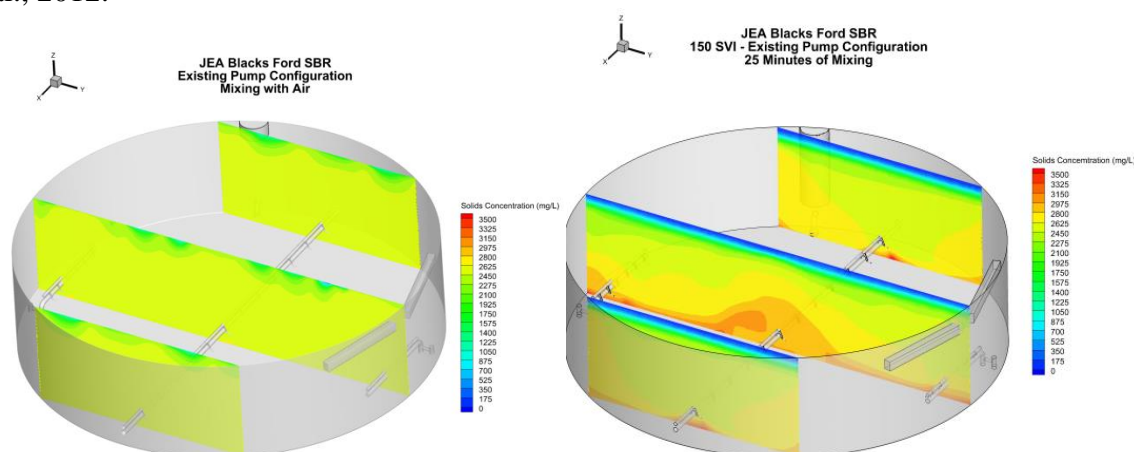

Figure 3. Solids profiles of CFD results with (left) and without (right) aeration.

These simulations were conducted using a user defined function (UDF) for solids settling and transport with coupling of the influence of solids gradients on the density profile and fluid flow. Hindered settling velocities were calculated based on a sludge volume index (SVI) of 150 mL/g, using the revised Daigger equation (Daigger, 1995). Further details are presented in Samstag et al. (2012).

The work did not include velocity profiling of the SBR tanks. This provides another opportunity for calibration. Calibration of velocity fields has been accomplished in sedimentation tanks. The early work of Larsen (1977) is compared to CFD in Wicklein and Samstag (2009) Samstag et al (2010) compares drogue velocity measurements to CFD model results.

Figure 4 presents the predicted velocity profile for the SBR tanks at the BFRWRF from the CFD model. With the aeration on, higher velocities penetrate to the upper reaches of the tank resulting in complete solids mixing. With aeration turned off very high velocities at the exit from the mixing jets dissipate rapidly in the tank leaving velocities less than 0.1 m/s in most of the tank.

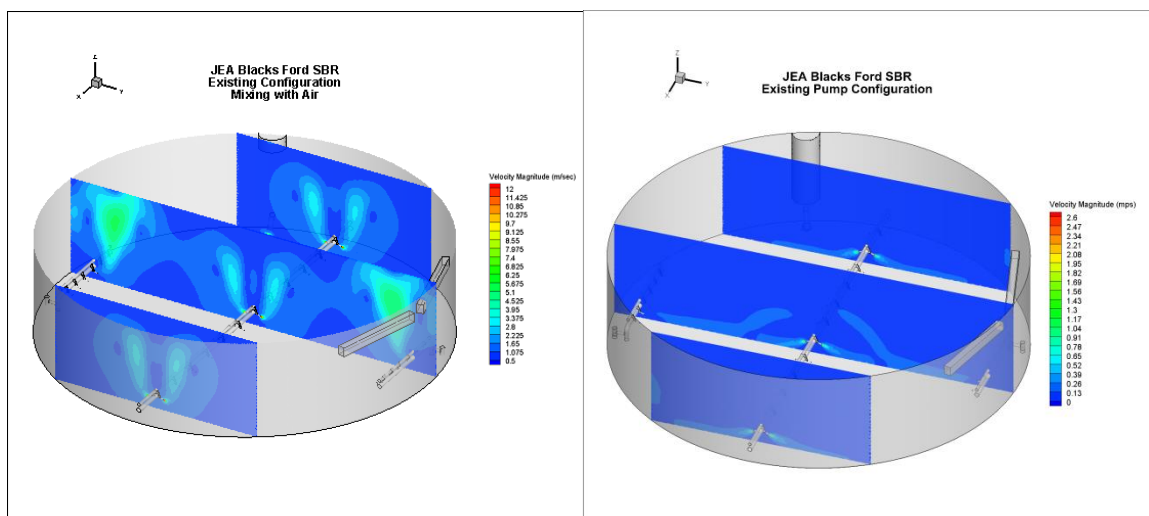

Figure 4. Velocity profiles for air mixing (left) and pumped mixing (right).

The importance of including density coupling in the CFD simulation is illustrated in Figure 5. The figure compares the results from simulation of 25 minutes of pumped mixing in the SBR tanks after turning off aeration with the density couple active (left side) to a neutral density simulation where the effect of concentration gradients on the density field was turned off (right side). Without including the density couple, the CFD simulation predicts relatively complete mixing for the pumped mix condition. This result is unrealistic based on the field tests. Since neutral density CFD simulation of mixing is common in the industry, this is a significant finding.

Figure 5. Comparison of solids profiles from density-coupled and neutral density models

CFD Model Alternatives

After calibration of the CFD model to conditions of operation in the field, the CFD model can be used to consider alternative configurations to improve operation. For the BFRWRF project, for example, a series of alternatives were considered in which the jet velocity was increased in an effort to improve solids mixing during the pumped mix cycle. CFD simulations were developed for four different jet velocities from 2.5 m/sec to 4.0 m/sec. The simulations indicated that increasing the velocity to 3.0 m/sec would reduce solids deposition in the tank after 25 minutes of pumped mixing after aeration is turned off, but that increasing the jet

velocity to 4.0 m/sec would be required to achieve a CoV for solids concentration less than 10 percent. Power requirements for this increase in mixing intensity would triple the installed power for this facility. These results showed that the original design was significantly inadequate to meet a specification of CoV less than 10 percent.

In another project Carollo investigated the efficiency of solids mixing in the plug flow racetrack tank. Two different mixers were investigated using an un-calibrated CFD model incorporating density-coupled solids settling and transport. This project also included a two-fluid model of the aerated zone in a side-sloped reactor.

Table 1 presents summary data for mixing efficiency derived from the field tests and calibrated and un-calibrated CFD simulations discussed above for:

- Pumped jet mixing
- Vertical hydrofoil mixers
- Vertical hyperboloid mixers
- Horizontal propeller mixers

The data indicate that the hydrofoil, hyperboloid, and horizontal propeller mixers have the potential for much greater power efficiency than pumped mixing. The equivalent power required for these mixers for a CoV of 10 percent varied in the range of 1.4 to 8.5 W/m³. These values are almost an order of magnitude greater than for pumped jet mixing.

CONCLUSIONS

A protocol has been developed for comparisons of the efficiency of activated sludge mixing systems using field-calibrated CFD models. A crucial difference in this protocol from previous work is to incorporate the effects of solids settling and transport on fluid motion. Elements of the protocol have been applied to jet aeration and mixing, vertical shaft hyperboloid mixers, horizontal propeller mixers, and diffused aeration. We propose this protocol as a comprehensive approach to optimizing activated sludge mixing and urge its adoption in future studies.

ACKNOWLEDGEMENTS

This work has been accomplished as part of Carollo Engineers' CFD modelling practice for the named clients. Support for this work by these clients and by Carollo Engineers is gratefully acknowledged. Field testing was assisted by staff from Carollo Engineers Orlando office, including Roderick Reardon, Sudhan Paranjape, and Erica Stone, whose help was greatly appreciated.

Abstract

The current state-of-the-art model for anaerobic digesters is Anaerobic Digestion Model No. 1 (ADM1). It is a bulk model with a framework that ignores spatial variations, leading to several inherent limitations. Anaerobic Digestion Model with Multi-Dimensional Architecture (ADM-MDA) is an extension to ADM1 that incorporates spatial discretization and computational fluid dynamics (CFD). A comparison between ADM1 and ADM-MDA shows that under some conditions, spatial variation alone can make the difference between a healthy digester and digester failure. These findings underscore the importance of CFD in digester simulations. This paper presents the results of this four-year numerical model development project.

Keywords

3D; ADM1; CFD; modelling; OpenFOAM; spatial resolution

INTRODUCTION

Anaerobic digestion modelling has traditionally been more focused on the biochemistry of digestion, and less focused on the fluid flow and reactor geometry. Anaerobic Digestion Model No. 1 (ADM1) (Batstone, Keller et al., 2002) is such a model, with a solid biochemical foundation, but little, if any, consideration of fluid flow. Intuitively this makes sense, as the biochemistry of anaerobic digesters is considerably more complicated than the fluid flow, particularly considering the fluid velocities can be near zero. However, fluid flow and thermal gradients may impact the model more significantly than this line of thinking suggests. There have been numerous experimental studies into fluid, such as Karim, Hoffmann et al. (2005a, 2005b), who studied the efficacy of various mixing strategies at different waste concentrations. Numerical studies into digester fluid flow also have been reported, although these generally ignore biochemistry, including Wu and Chen (2008), who performed a computational fluid dynamics (CFD) study into flow in lab-scale and pilot-scale digesters, focusing on the effect of using a non-Newtonian fluid model. Although sparse, a few studies exist that combine biochemistry and fluid flow, including Fleming (2002) who created a CFD model with biochemistry based on Hill's monod reaction model (1983a, 1983b). Other studies have accomplished some aspects of fluid flow and biochemistry, such as Batstone, Hernandez, et al. (2005), which used compartmental ADM1 simulations to establish spatial variation in a plug-flow reactor. To further address fluid flow and biochemistry, this project implements Anaerobic Digestion Model with Multi-Dimensional Architecture (ADM-MDA) (Gaden, 2013), a three-dimensional full implementation of ADM1 with an integrated CFD flow model.

MODEL DEVELOPMENT

Extending the governing equations of ADM1 from a bulk model to three dimensions is achieved by including spatial variables in the derivation. For instance, the mass balance for a species changes from:

$$\frac{dS_{var}}{dt} - \frac{V_l}{Q_l} (S_{var,in} - S_{var}) = r_{var},$$

to:

$$\frac{\partial S_{var}}{\partial t} + \nabla \bullet (\mathbf{U} S_{var}) - \nabla \bullet \Gamma_{var} \nabla S_{var} = r_{var}.$$

However, solving the new equation set is non-trivial as the introduction of spatial resolution changes a differential-algebraic equation set (DAE) to a partial differential algebraic equation set (PDAE), and few suitable solvers exist.

This project develops Coupled-Reaction-Advection-Flow Transient Solver (CRAFTS) to handle the new numerical framework. CRAFTS is a general reaction solver for single-phase, incompressible fluid flows. It allows users to define their own variables, reactions, inhibitions, coefficients and control logic without requiring any programming. CRAFTS also has a framework for User-Defined Functions (UDFs) that allows for custom algebraic algorithms, such as ADM1's Newton-Raphson ion model. CRAFTS is a novel PDAE solver that also employs a novel programmable logic controller (PLC) emulator. CRAFTS is built using OpenFOAM®, a free and open source CFD suite.

Gaden (2013) presents the full details of the model and its development.

CASE SETUP

To evaluate model performance, this study compares the performance of ADM1 against ADM-MDA on a case involving a 100 m³ rectangular digester. In this case, fluid injection events occur daily for two minutes at a velocity of 0.05 ms⁻¹, giving a hydraulic retention time of only 8.33 days. Fluid mixing events occur for ten minutes every hour.

RESULTS

Most variables show little differences between the two models, however, the continuum assumption of ADM1 leads to subtle differences in mass exchanged during each fluid injection event. These differences can amplify quickly with highly sensitive dynamic systems, such as ADM1. Figure 1a shows the two models have a significant disagreement with the total acetate concentration, S_{ac} . ADM1 suggests a stable digester, whereas ADM-MDA indicates an unhealthy digester. This disagreement can be explained by the fact that acetate degraders can be seen washing out only in ADM-MDA, Figure 1b.

Figure 1a. Total acetate concentration, S_{ac}

Figure 1b. Acetogenic biomass, X_{ac}

The spatial data that ADM-MDA provides can also be useful for design purposes. For instance, the model showed dissolved methane building up at the centre of the reactor, Figure 2. This suggests a change in mixing strategy might improve gas transfer rate. By way of contrast, ADM1 does not include spatial data.

Figure 2. ADM-MDA

Dissolved methane concentration, S_{ch4} , spatial distribution at $t = 56,651$ s (15h 44m 11s).

FUTURE DEVELOPMENT

This research project has produced a strong foundation for a spatially-resolved implementation of ADM1; however, the second-order accuracy inherent in CRAFTS' finite volume method can conflict with the numerical stiffness of ADM1. This may limit the practicality of the model, such as reduce the maximum mesh size. There are several promising areas for model improvement, including the gas model and the transport model. Source code from this research endeavour is being released as free and open source software to the ADM1 modelling community to facilitate further model developments, (Gaden, Bibeau, 2013).

Abstract

A mathematical model was developed to investigate hydraulic transport and bacterial selection during slow up-flow anaerobic feeding (0.9 m h^{-1}) of wastewater across the settled bed of granular sludge biofilms used in column-type sequencing-batch reactors to remove nutrients. A plug-flow regime with dispersion was identified from residence time distribution data ($\text{RMSE} < 0.010$, $R^2 = 0.999$). Metabolic formulations allowed assessing the effect of environmental conditions on the competition of polyphosphate- (PAO, *Accumulibacter*) and glycogen-accumulating organisms (GAO, *Competibacter*) for the uptake of acetate during anaerobic feeding. Since PAO and GAO metabolisms rely on distinct dynamics of intracellular storage polymers, the feeding phase length at nominal flowrate was shown to impact bacterial selection. In addition, acetate was preferentially consumed by PAO under alkaline conditions (pH 7.5-8.0) independently of temperature (10-30°C). GAO were only able to outcompete PAO under combined acidic (pH 6.0-6.5) and higher mesophilic (25-30°C) conditions. However, the difference in uptake rates was only half of the one obtained under conditions selecting for PAO. The model can support the assessment of spatial stratification of conversion processes across the bed and the design of operation and bed geometries towards optimal bacterial resource management in granular sludge.

Keywords

Biological nutrient removal; granular sludge biofilms; feeding phase; reactor regime; PAO/GAO

INTRODUCTION

Efficient biological nutrient removal (BNR) in intensified sequencing-batch reactors (SBR) using aerobic granular sludge (AGS) biofilms requires optimal management of the bacterial resource. Preferential selection of polyphosphate- (PAO, e.g. *Accumulibacter*) over glycogen-accumulating organisms (GAO, e.g. *Competibacter*) is required for enhanced biological phosphorus removal. PAO and GAO are selected under slow up-flow anaerobic feeding regime across the settled bed of AGS (de Kreuk and van Loosdrecht, 2004). Operation with selective purge of upper bed fractions can favor PAO over GAO (Winkler et al., 2011). Similarly to activated sludge systems (Oehmen et al., 2010), pH and temperature trigger PAO and GAO selection in AGS (Weissbrodt et al., 2013). Since the PAO/GAO competition relies on their ability to take up volatile fatty acids (VFA) under anaerobic conditions, a hydraulic-metabolic mathematical model was developed here to investigate the effect of combined feeding and environmental conditions on bacterial selection in AGS.

MATERIAL AND METHODS

Investigations were conducted in a lab-scale column-type reactor with a volume of $1.6 \cdot 10^{-3} \text{ m}^3$ and a height-to-diameter ratio of 9.66. The AGS bed of 0.33 m comprised 543 g of wet granular biomass with a biofilm density of 1120 kg m^{-3} and a homogeneous size distribution over the height ($1.7 \pm 1.2 \text{ mm}$). The influent was fed at a slow nominal flowrate of $1.2 \cdot 10^{-3} \text{ m}^3 \text{ h}^{-1}$ corresponding to superficial and interstitial velocities of 0.44 and 0.90 m h^{-1} , respectively.

A one-dimensional plug-flow hydraulic transport model with dispersion was implemented in Berkeley Madonna and calibrated based on residence time distributions (RTD) recorded at the bed and reactor outlets with on-line electrical conductivity after step-change of the inlet concentration of an inert NaBr tracer, according to Gujer (2008). Axial and radial dispersion coefficients were identified from the dimensionless variance of the normalized probability function of residence time. The calibrated hydraulic transport model was coupled to structured formulations of anaerobic metabolisms of *Accumulibacter* and *Competibacter* in function of pH (6.0-8.0) and temperature ($10\text{-}30^\circ\text{C}$) (Lopez-Vazquez *et al.*, 2009). Since VFA uptake by PAO and GAO rely on dynamics of intracellular storage polymers that are not transported with the flow, and cannot reach a steady-state, the feeding phase length (0.25-2.5 h) was studied as additional factor of bacterial selection.

RESULTS AND DISCUSSION

The structure of the calibrated hydraulic transport model comprised 50 mixed compartments in series and dispersion of 36% in volume and 7% in flowrate ($\text{RMSE} < 0.010$, $R^2 = 0.999$). The wastewater flow was related to laminar regime ($\text{Re}_{\text{bed}} = 0.25 < 1$). The dimensionless coefficient of axial dispersion in the z-direction of flow ($N_{Dz} = 0.047$), that corresponded to an absolute value (D_z) of $1.5 \cdot 10^{-2} \text{ m}^2 \text{ h}^{-1}$, was in the domain of large amount of dispersion (0.025-0.200) for packed bed bioreactors (Albuquerque and Santana, 2004). The radial dispersion transverse to the direction of flow ($N_{Dt} = 0.299$, $D_t = 9.6 \cdot 10^{-2} \text{ m}^2 \text{ h}^{-1}$) was even more higher in this AGS system with low Peclet numbers ($\text{Pe}_z = 21.3$ and $\text{Pe}_t = 3.4 < 100$). According to RTDs measured at bed and reactor outlets, no mixing occurs between the influent and the treated wastewater volume above the bed.

Under non-selective reference simulation conditions in a bed of 50 cm with 60 min feeding, 20°C , pH 7.0, $64 \text{ kg}_{\text{TSS}} \text{ m}_{\text{bed}}^{-3}$ with 67% $_{\text{VSS}}$ and 50% of active cells related to 25% PAO and 25% GAO, both populations removed acetate at equal volumetric rate ($1.25 \text{ kg}_{\text{COD}} \text{ h}^{-1} \text{ m}^{-3}$). Prolonged feeding of 120 and 150 min at nominal flowrate switched off GAO and PAO activities by full depletion of glycogen and polyphosphate, respectively. Simulations displayed preferential uptake of acetate by PAO under alkaline conditions (e.g. pH 8.0) independently from temperature ($10\text{-}30^\circ\text{C}$) (Figure 1). GAO were only able to outcompete PAO under combined acidic and higher mesophilic conditions (e.g. pH 6.0 and 30°C). However, the difference in acetate uptake rates in the bed was only half of the one obtained under conditions selecting for PAO. These results met with multifactorial experiments conducted in AGS-SBRs (Weissbrodt *et al.*, 2013). Contrary to pH, temperature significantly affected bed height requirements for full acetate uptake under anaerobic feeding.

CONCLUSIONS

Modelling hydraulic transport of wastewater during slow anaerobic feeding across AGS beds should integrate axial and radial dispersion components. For the application, the present approach highlighted that fill-and-draw phases can efficiently be implemented in column-type AGS-SBRs. The feeding phase length and indirectly the working volume impact bacterial

selection. Slightly alkaline conditions, e.g. by addition of lime in the influent, efficiently select for PAO. The amount of AGS should be adapted in function of temperature for full anaerobic VFA uptake during feeding.

Figure 1. Structure of the plug-flow hydraulic transport model with dispersion (A) and impact of pH and temperature on acetate uptake by PAO and GAO (B) under slow up-flow anaerobic feeding of wastewater across the bed of AGS.

Should activated sludge models consider influent seeding of nitrifiers? Field characterization of nitrifying bacteria

Shameem Jauffur, Siavash Isazadeh and Dominic Frigon

Department of Civil Engineering and Applied Mechanics, McGill University, 817 Sherbrooke St. West, Montreal, Quebec, H3A 0C3, Canada (Email of corresponding author: dominic.frigon@mcgill.ca).

Abstract

This study reveals the presence of nitrifying bacteria in influent municipal wastewaters reaching full-scale biological wastewater treatment plants (WWTPs). Respirometric assays showed that the influent nitrifiers could be activated following metabolic induction. We also show that there is a potential of the nitrifiers in the influent stream to actually seed activated sludge bioreactors. Influent-incurred nitrifier seeding affects model performance and influences ammonium (NH_4^+) removal. Simulation studies showed that the impact of nitrifier seeding by influent is more prominent at low temperatures. At 4 °C, a nitrifier seed of 5 mg-COD_{biomass}/L induces a 30% reduction in residual NH_4^+ level and a 17% gain in solids retention time (SRT) as compared to unseeded conditions. These findings support the need to fine-tune process modelling pertaining to NH_4^+ removal in wastewaters and provide a novel potential means of sustaining nitrification in cold temperature through seeding of influent with nitrifiers.

Keywords

Ammonia; influent; modelling, nitrification, nitrifying bacteria

INTRODUCTION

Ammonia (NH_3) represents a serious environmental hazard and a deadly threat to fish and aquatic life due to its toxicity (Campos *et al.* 2008). The most widely applied process worldwide for ammonia removal from municipal wastewater is nitrification: the aerobic biological conversion of NH_3 to nitrate (NO_3^-) via nitrite (NO_2^-) as a secreted intermediate (Mahvi *et al.* 2008). This microbial-induced catalyzed oxidation is a key process in wastewater treatment and effectively reduces the toxicity associated with NH_3 and the biochemical oxygen demand (BOD) of $\text{NH}_3/\text{NH}_4^+$. However, nitrification is a fragile temperature sensitive process (Van Dyke *et al.* 2003). It is, therefore, not surprising why many biological wastewater treatment systems carrying out nitrogen removal have encountered failures during winter season (Ilies and Mavinic 2001; Kim *et al.* 2006). Yet, since NH_3 is toxic to fish and other aquatic life during all seasons, stricter effluent standards are being implemented and enforced to protect aquatic environments like in the case of North American jurisdictions which have adopted year round regulations for the discharge of total ammonia nitrogen (Canada Fisheries Act 2012; U.S.A Federal Register 2013). Consequently, the conversion of NH_3 into NO_3^- is a requirement even during the winter season, which drives the increase of the design solids retention time (SRT) to prevent nitrifier washout (Rittmann and McCarty 2001). As a consequence, the footprints of these wastewater treatment plants (WWTPs) and the necessary capital investment are higher than for warmer climates.

Nitrifying microorganisms are clustered in few evolutionary lineages within the prokaryotic and archaeal domains. They are functionally classified as (1) Ammonia Oxidizing *Bacteria* (AOB) and Ammonia Oxidizing *Archea* (AOA), which oxidize NH_3 to NO_2^- , and (2) Nitrite Oxidizing *Bacteria* (NOB), which convert NO_2^- to NO_3^- (Schramm 2003). AOB and NOB share a close symbiotic relationship with each other forming densely packed microcolonies

and cell clusters in wastewater treatment systems, since the product of NH_3 oxidation by AOB is the substrate for NOB, and whose accumulation is inhibitory to AOB (Daims *et al.* 2006).

So far the possible seeding of nitrifiers in terms of AOB and NOB by influent wastewaters to activated sludge bioreactors has been overlooked. Even current best practices for biological wastewater treatment modelling, such as the International Water Association (IWA) consensus Activated Sludge Models (ASMs), assume no active biomass in municipal wastewater at the entrance of treatment facilities. If nitrifier seeding subsists in wastewater treatment systems, this may cause models to underestimate nitrification in extreme situations like cold temperature, and lead to over-sizing of aerated bioreactors. Evidencing the existence of significant influent nitrifier seeding may trigger important reviews of wastewater treatment system design practices for cold climate.

To our knowledge, no studies have been conducted so far to unravel the presence of nitrifiers in influent municipal wastewaters reaching full-scale biological wastewater treatment facilities. In this study, we provide answers to the following questions which we believe will promote our understanding of the ecophysiological implications and dynamics of nitrifiers across activated sludge wastewater treatment systems: Are autotrophic nitrifiers present and active in influents of full-scale municipal WWTPs? Are the influent nitrifying populations the same as those present in mixed liquors or in other words, is seeding possible and observed? And given the level of observed potential seeding, what type of gains in design SRT could be made if seeding is considered during modelling?

MATERIALS AND METHODS

Site description and sample collection

Influent and Mixed Liquor Suspended Solids (MLSS) samples were collected from 8 full-scale biological WWTPs located in the region of Montreal in Quebec, Canada. The treatment plants use the activated sludge type process and have different layouts and configurations (Table 1). 24-hour composite influent samples and grab MLSS samples were collected at a depth of 1 m during the Winter 2013. The biomass was spun by micro-centrifugation in 1.5 ml eppendorf tubes and periodically frozen at -20°C until time of analysis.

DNA extraction and PCR amplification of *amoA* and *nxB* genes

Genomic DNA was extracted from 0.25g of decanted samples (influent and mixed liquor) using the *MO BIO* UltraClean™ Fecal DNA Kit (Carlsbad, CA). The extracted DNA samples were diluted to 12 ng and used to determine the presence of nitrifiers by PCR amplifying specific genes using barcoded primers. Barcode multiplexing allows simultaneous sequencing and retrieving of samples based on the identification of sample specific Multiplex Identifier (MID) tag (Liu and Jansson 2010). Ammonia oxidizing *bacteria* (AOB) were analyzed by targeting the *amoA* functional gene using the forward primer *amoA-1F* GGG GTT TCT ACT GGT GGT and reverse primer *amoA-2R* CCC CTC TGC AAA GCC TTC TTC (Rotthauwe et al. 1997) while the nitrite oxidizing *bacteria* (NOB) population was studied by targeting the *nxB* gene using the forward primer *nxB-F169* TAC ATG TGG TGG AAC A and reverse primer *616R* CGG TTC TGG TCR ATC A (Maixner 2009). Each 50µl of PCR reaction mixture contained 2.5µl of 0.5M forward primer, 2.5µl of 0.5M reverse primer, 10µl of 1x PCR colorless buffer (Bioline), 2.75µl of 2.75mM MgCl₂, 0.5µl of 250µM dNTP mixture, 2µl of 12ng DNA template, 0.5µl of 2.5 units Taq DNA Polymerase (Bioline) and 29.25µl of UltraPure™ DNase/RNase-Free Distilled Water (Invitrogen). The PCR thermocycling conditions for *amoA* gene fragment amplification were as follows: 95 °C for 4 min, 35 cycles of 95 °C for 40 s, 56 °C for 30 s, 72 °C for 1 min followed by a final extended elongation at 72 °C for 10 min. The thermal profiles used for the amplification of *nxB* gene target sequence were as follows: 95 °C for 5 min, 35 cycles of 95 °C for 40 s, 62 °C for 40 s, 72 °C for 1 min followed by a final extended elongation at 72 °C for 10 min. The PCR amplicons were purified using the *MO BIO* UltraClean™ PCR Clean-UP Kit.

GX FLS Titanium 454-pyrosequencing

The amplicon concentration of each sample was determined using the Quant-iT™ PicoGreen kit and normalized to a concentration of 30 ng/µl. The PCR products were pooled and their quality assessed by the Bioanalyzer 2100 (Agilent Technologies). Purified amplicons were subjected to emulsion PCR (emPCR) based on Roche-454 Life Science Protocol and then pyrosequenced by the GS FLX Titanium Sequencing machine. The sequencing run was performed at the McGill University and Genome Quebec Innovation Centre (Montreal, QC) on 1/4th PicoTiter plate.

Sequence data analysis

The *amoA* and *nxB* gene sequences were trimmed and filtered using the QIIME Pipeline (Caporaso et al. 2010) to retain only good quality sequences devoid of primers and barcodes. Quality filtered sequences (minimum read length of 200 bp, quality score higher than 25 and without ambiguous bases and mismatches) were clustered at 97% sequence similarity and assigned to taxonomic operational taxonomic units (OTUs) using the RDP classifier (FunGene Pipeline and repository) (Wang et al. 2007). Bacterial diversity analyses (*alpha* and *beta*) were performed using the *BiodiversityR* package of the R-software, version 3.0.1, based on standardized OTU abundance data.

Respirometric-response assessment of influent nitrifying biomass

In order to assess the metabolic status of nitrifying biomass in the influent wastewater, approximately 8-10 L of influent were collected from the LaPrairie WWTP and the biosolids were concentrated to about 2500 mg/l. The concentrated biosolids were used to perform respirometric assays by batch respirometry using the Challenge Technology™ AER-208 Respirometer System to stimulate oxygen uptake rate (OUR) of AOB and NOB populations

through the addition of NH_4^+ and NO_2^- respectively as electron donors and measuring the resulting OUR profiles (Chandran and Smets 2005).

Steady-state modelling of NH_4^+ removal

Residual NH_4^+ (S_{NH}) concentration from nitrification was simulated to compare the impacts of temperature and SRT under nitrifier seeding and non-seeding conditions. The steady-state equations were derived using mass balances on the control volume (reactor and settling tank) (Rittmann and McCarty 2001). S_{NH} concentration resulting from treatment of a given bioreactor under non-seeding condition was computed using equation (1). The impact of nitrifier seeding on the

treatment system was expressed by reformulating Eq. (1) to Eq. (2) to incorporate a term defining nitrifying biomass in the influent stream (X_A^o) and mixed liquor (X_A). Default stoichiometric, kinetic and composition model parameters were adopted from ASM3 to perform the calculations (Henze *et al.* 2000).

$$S_{\text{NH}} = \frac{K_{\text{NH},A}}{\frac{\theta_x \hat{q} Y_A}{1 + b \theta_x} - 1} \quad (1)$$

$$S_{\text{NH}} = \frac{K_{\text{NH},A}}{\frac{\theta_x \hat{q} Y_A}{1 + b \theta_x - \frac{\theta_x}{\theta} \cdot \frac{X_A^o}{X_A}} - 1} \quad (2)$$

Where,

S_{NH}	Residual effluent NH_4^+
$K_{\text{NH},A}$	Saturation constant for NH_4^+
θ_x	Solids retention time
θ	Hydraulic retention time
b	Endogenous respiration rate
\hat{q}	Max. substrate uptake rate
Y_A	Nitrifier yield coefficient
X_A^o	Nitrifying biomass in influent
X_A	Nitrifying biomass in MLSS

RESULTS AND DISCUSSION

Presence of nitrifiers in influent

Nitrifiers (both AOB and NOB) were detected in all municipal influents collected from the 8 WWTPs. Scrutinizing the sequences at 97% sequence similarity resulted in an average of 360 distinct OTUs in the influent and 236 OTUs in the mixed liquor samples for the AOB sequences. An inferior number of OTUs was detected for the NOB sequences with an average of 96 OTUs in the influent and 76 OTUs in the mixed liquor samples. The significant ($P < 0.05$) lower diversity in the mixed liquor samples suggests that less OTUs dominate the mixed liquor samples than the number of OTUs entering the plants. Explicit comparison of the nitrifying AOB OTUs in the influent and mixed liquor samples by cluster analysis showed no clear distinction between these 2 types of sample, i.e., all influent and all mixed liquor samples did not cluster together (Figure 1a).

Yet, in general, influent and mixed liquor samples from the same plant also did not cluster together. However, since

the OTUs detected in the influents were also observed in the mixed liquors, seeding from the influent is possible. Comparison of the biotic similarity between the influent and mixed liquor AOB community assemblages of the same WWTP, using the Bray-Curtis and Kulczinski similarity indices based on standardized abundance datasets, showed that an average of 24% of AOB OTUs were shared between the two types of sample matrices with the shared OTU reaching as high as 68% in the case of Cowansville wastewater treatment facility. The most abundant AOB OTU in the influent also occurred as the most abundant AOB OTU in the mixed liquor for all the WWTPs.

Seeding was more apparent for the NOB populations with influent and mixed liquor NOB sequences clustering together for Vaudreuil, Cowansville, Granby, Pincourt and Farnham WWTPs (Figure 1b). Abundance-based similarity indices (Bray-Curtis and Kulczinski) showed an even higher sharing of NOB OTUs as compared to the AOB taxonomic units, averaging 61% with the highest degree of OTU sharing attaining as high as 86% in the case of Granby WWTP. Similar to the AOB abundance pattern, the most abundant NOB OTUs in the influent were also found to be most abundant ones in the mixed liquor.

Stochastic models describing bacterial community assemblies predict that random immigration of bacteria plays a crucial role in shaping bacterial communities (Ofiteru *et al.* 2010). The present study supports this prediction and allude the potential seeding of autotrophic nitrifying bacteria from influent streams to the activated sludge. The scale of bacterial immigration from the source community is likely to be dependent on the size of the source bacterial reservoir with the immigration rate being higher when the source community size is small (Curtis and Sloan 2006). Hence, seeding of nitrifiers in wastewater treatment systems may be more significant as compared to seeding of heterotrophic bacterial populations since nitrifiers are much less diverse than heterotrophs. According to Curtis *et al.* (2006), AOB have a low diversity in WWTPs with only 100-200 species growing in WWTPs in a global bacterial community of 10^{27} . This is line with our findings where we detected AOB populations comprising of 100-395 species and NOB constituting of even smaller populations with only 50-100 species, in the activated sludge samples.

Effects of nitrifier seeding on modelling approaches

The potential of biological activated sludge systems to perform nitrification is significantly limited at low temperatures, thereby requiring larger aeration tank sizes and longer aerobic SRTs. This is intimately linked to the slow growth rate of nitrifying bacterial biomass at low temperatures (Grady *et al.* 1999). Based on mass balance considerations, it had been estimated that supplementing a system with 0.1 g of nitrifiers per day per g of nitrifiers already present can effectively reduce the SRT up to 45% at 8 °C (Salem *et al.* 2003). The respirometric assays we performed showed that the influent AOB and NOB populations responded immediately to the addition of electron donors, and that they could attain full metabolic activity within 6.5 h and 4.5 h

Figure 2. OUR profile obtained from respirometric analysis. NO_2^- and NH_4^+ were added as substrate at 1.25h and 8.50h respectively. EP-Endogenous Phase.

respectively (Figure 2). This is indicative of active nitrifiers continuously entering WWTPs via the influent and hints towards potential seeding of activated sludge systems. Based on the activity test data, the level of nitrifiers in the influent of LaPrairie WWTP was estimated at 5 mg-COD_{biomass}/L, which corresponded to a seeding level at this site of 0.2-0.3 g of nitrifiers per day per gram of nitrifiers already present. The level of biomass observed in the influent of LaPrairie WWTP justifies further considering potential seeding for modelling and design purposes.

Modelling the NH_4^+ removal from wastewater under the level of nitrifier seeding observed at LaPrairie WWTP and non-seeding scenarios shows that influent nitrifier seeding does not seem to make a significant difference on S_{NH} concentrations at temperatures above 10 °C (Figure 3). However, as temperature decreases an accrued effect is observed on the S_{NH} concentrations when nitrifying biomass seeding is considered. At 4 °C, a seeding of 5 mg-COD_{biomass}/L of nitrifying biomass reduced the S_{NH} concentration by 30% as compared to unseeded condition. The same simulations showed that nitrifier seeding could allow a reduction of the SRT by approximately 17% to reach the same S_{NH} level as for the unseeded conditions. These findings demonstrate the kind of gains that can be made in design if seeding of nitrifiers is considered. This may be of interest to modellers and designers, especially at the design stage of wastewater treatment systems since determining the size of activated sludge reactors during design is done by considering the minimum SRT capable of sustaining high enough activity to provide satisfactory NH_4^+ removal. Considering nitrifier seeding from the influent stream may help reduce the size of aeration tanks at the design stage. In turn, alleviating over-sizing of reactors would translate in reductions in capital expenditure for the construction of wastewater treatment infrastructures. Potentially, this would also reduce the costs of operation because lower oxygen demands would follow as the oxygen demand by the plant is proportional to the SRT (Rittmann and McCarty 2001). However, although our study shows the existence of potential seeding from influent municipal wastewaters to activated sludge bioreactors, the extent of such seeding still needs to be assessed. Reproducing seeding scenarios in lab or pilot-scale bioreactors using actual influent nitrifiers from full-scale WWTPs may help to elucidate this aspect which will represent yet another step in understanding this phenomenon.

Figure 3. Simulation of NH_4^+ residual concentrations from nitrification in an activated sludge system under influent-nitrifier seeding (5 mg/L) and non-seeding conditions at different temperatures.

CONCLUSIONS

It is the first time that the presence of nitrifying bacteria (both AOB and NOB) has been revealed in influent municipal wastewaters reaching wastewater treatment facilities. Our findings advocate the existence of potential seeding of nitrifiers from influent streams to full-

scale activated sludge reactors that may be contributing to the nitrification process in these systems. Simulation of NH_4^+ removal showed that nitrification is enhanced at low temperature under seeding conditions as compared to unseeded scenarios. This may require fine-tuning of process modelling by incorporating seeding especially at low temperatures where the impact may be significant. Such aspect may prove useful in reactor design and improving operation optimality with the aim of sustaining nitrification all year-round including extreme winter seasons. It also paves the way for the implementation of a novel potential means to cope with nitrification in cold temperature by actually seeding influent wastewaters to increase the nitrifier fractions in sewer systems.

ACKNOWLEDGEMENT

The Funding for this work was provided by the Natural Sciences and Engineering Research Council (NSERC) of Canada and Air Liquide Canada. We extend our gratitude to operators of the WWTPs for granting us permission to collect samples and providing us with operational data.

Abstract: The success of many modelling studies strongly depends on the availability of sufficiently long influent time series - the main disturbance of a typical wastewater treatment plant (WWTP) - representing the inherent natural variability at the plant inlet as accurately as possible. This is an important point since most modelling projects suffer from a lack of realistic data representing the influent wastewater dynamics. The objective of this paper is to show the advantages of creating synthetic data when performing modelling studies for WWTPs. This study reviews the different principles that influent generators can be based on, in order to create realistic influent time series. In addition, the paper summarizes the variables that those models can describe: influent flow rate, temperature and traditional/emerging pollution compounds, weather conditions (dry/wet) as well as their temporal resolution (from minutes to years). The importance of calibration/validation is addressed and the authors critically analyse the pros and cons of manual versus automatic and frequentistic vs Bayesian methods. The presentation will focus on potential engineering applications of influent generators, illustrating the different model concepts with case studies. The authors have significant experience using these types of tools and have worked on interesting case studies that they will share with the audience. Discussion with experts at the WWTmod seminar shall facilitate identifying critical knowledge gaps in current WWTP influent disturbance models. Finally, the outcome of these discussions will be used to define specific tasks that should be tackled in the near future to achieve more general acceptance and use of WWTP influent generators.

Keywords: Disturbance generators, dynamics, flow, influents, pollution loads, uncertainty

INTRODUCTION

The use of activated sludge models (ASM) (Henze *et al.*, 2000) is constantly growing and both industry and academia are increasingly applying these tools when performing wastewater treatment plant (WWTP) engineering studies. The level of detail and the specific data required for a modelling exercise strongly depend on the project objectives. In general, the more specific the results of the simulation study, the more detailed the required set of data (Cierkens *et al.*, 2012). However, due to the high cost of measuring campaigns, many simulation studies of full-scale WWTPs suffer from a lack of sufficiently long and detailed time series for flow rates, temperature and nutrient/pollutant concentrations representing realistic wastewater influent dynamics. For this reason, model-based influent generators are an alternative that has recently gained considerable interest (Gernaey *et al.*, 2011).

METHODS

Literature offers a wide range of tools generating influent characteristics by means of mathematical models. The paper will analyse in detail:

- The shift in methods to generate influent dynamics from the simpler (black box) to the more complex (grey/white box) models including a more detailed description of the

phenomena taking place in the urban drainage system with more/less equations/model parameters (**Fig 1**). The type of approach will determine: 1) model parsimony (limiting the number of parameters); 2) model transparency (by using model parameters that have a physical meaning); and 3) model flexibility (easily extended to other applications) (Gernaey *et al.*, 2011).

- The data availability to create/re-create the different influents. Here, different relevant questions are to be answered: “Do I have measurements and can I therefore apply statistical analysis to obtain longer time series?” “Are measurements entirely missing and do I need a model that can provide realistic patterns without measurements?”

A more in depth analysis about methods will be complemented with the critical review carried out by **Martin and Vanrolleghem (2013)**.

Figure 1. Methods, characteristics, modelled compounds and engineering applications of influent generators.

COMPOUNDS AND TEMPORAL RESOLUTION

Another point of discussion will focus on what kind of compounds (and their temporal resolution) can be described with the current models. For example:

- Generation/frequency of (dry weather) flow rate, temperature, traditional components (COD, TSS, TN and TP) and emerging components (pharmaceuticals, illicit drugs);
- Generation/frequency of wet weather flow, temperature and traditional/emerging components.

Most of the models used to describe traditional compounds are based on intensive measuring campaigns carried out during the 90s (Butler *et al.*, 1995). In addition to the description of traditional pollutants some of these models can also describe emerging compounds. For example, De Keyser *et al.* (2010) developed a database summarizing different emission patterns for 26 priority pollutants (daily/weekly/seasonal /annual). Lindblom *et al.* (2006) and Snip *et al.* (2013) upgraded the phenomenological influent model presented by Gernaey *et al.* (2011) including the behaviour of bisphenol A, pyrene and some pharmaceuticals (antibiotics, painkillers, mood stabilizers). Ort *et al.* (2005) developed a conceptual stochastic model to characterise short-term variations of benzotriazole concentrations (a chemical contained in dishwasher detergents), which can be easily adapted to any down-the-drain household chemical. Additional model complexity is necessary to describe the behaviour of all these elements in wet-weather conditions (Gernaey *et al.*, 2011). Nevertheless some of the wet-weather generators are simplified and may not correctly represent the rainfall properties, the build-up/wash-off (pollution) and rainfall/run-off (water). Specifically, associated soil models currently do not include physico-chemical descriptions of moisture properties and some transport models are not capable to correctly describe the first-flush effect after a (heavy) storm event (Martin and Vanrolleghem, 2013). For these reasons the effect on flow rate, substances and temperature might be systematically under- or overestimated.

CALIBRATION AND VALIDATION

Another important point that will be discussed is related to several aspects that should be considered during calibration/validation of such influent generation models:

- In most black box models, parameter values are identified after processing long time series. However, these parameters are adjusted to fit the inputs and outputs and do not have any physical/biological/chemical meaning. On the other hand, grey and white box models are based on parameters that correspond to measurements or physical characteristics of the catchment.
- The traditional calibration procedure uses a trial and error process of parameter adjustments. Often, the goodness-of-fit of the calibrated model is basically a visual judgement comparing simulated and observed data. This process is subjective and can be quite long and tedious unless the process engineer has a good knowledge about the model behaviour (Flores-Alsina *et al.*, 2013). Automatic calibration has the advantage that it can (in some cases) accelerate the process and be objective as it is based on quantitative goodness-of-fit criteria.
- Frequentist analysis has demonstrated to work quite well in identifiable systems (Omlin and Reichert, 1999). Nevertheless, when the models present: 1) some apparent identifiability problems (Omlin and Reichert, 1999); or, 2) some structural uncertainty in the model formulation (Neumann and Gujer, 2008), this approach is no longer valid and other approaches based on Bayesian statistics are recommended. However, the calibration effort increases substantially when using more elaborate methods (Lindblom *et al.*, 2011; Rieckermann *et al.*, 2011; Talebizadeh *et al.*, 2013) (Fig 1).

ENGINEERING APPLICATIONS

The engineering applications of influent generators are various (Fig 1):

1. Increase data frequency: Sub-hour frequency of influent data is required when the model is used to test control strategies and wet-weather operation. Characterization of the influent implies a large effort and high costs when analysing samples for a series of pollutants. Recent developments in measurement technology have made sensors more reliable and cheap. Still, several standard lab analyses, such as COD, cannot be performed reliably in on-line mode in the influent of a WWTP (Olsson *et al.*, 2012). In these situations, influent generators can certainly increase the frequency of influent data and provide additional dynamics not revealed by measurements (Devisscher *et al.*, 2006; Gernaey *et al.*, 2011; Flores-Alsina *et al.*, 2013).

2. Design of sampling strategies: Grey / Black box influent generators can account for, amongst other factors, different types of dynamics, levels of occurrence and the effect of pumping strategies in the sewer when (mathematically) describing the occurrence of traditional/emerging pollutants. This feature can be extremely useful when designing sampling campaigns. Ort *et al.* (2010) demonstrated that errors of 50% or more are possible for 24-h composite samples when the compound is not sampled at a sufficiently high frequency.

3. Fractionation: Influent fractionators can easily be plugged in to the time series created by influent generators. The main idea is to correlate the model state variables used in the ASM models (Henze *et al.*, 2000) with their analytical measurements. For example, Grau *et al.* (2007) and Gernaey *et al.* (2011) proposed two alternatives based on different principles. The first approach is based on an optimizer that finds suitable fractionation parameters according to the available data. The second approach uses (fixed) parameter values in order to convert for example COD_{sol} into non-biodegradable (S_I) and biodegradable (S_S) soluble substrates using the ASM1 (Henze *et al.*, 2000).

4. Uncertainty/Sensitivity analysis of influent profiles: The use of probability distribution functions in some of the influent generator models combined with Monte Carlo simulations might help to quantify the range and/or uncertainty of simulated data (wastewater properties). These simulation outputs can be used to better design WWTPs using probabilistic concepts rather than safety factors (Rousseau *et al.*, 2001; Belia *et al.*, 2009; Flores-Alsina *et al.*, 2012; Talebizadeh *et al.*, 2013) or to test the robustness of control strategies (Benedetti *et al.*, 2006; Flores-Alsina *et al.*, 2008;).

5. Generation of scenarios: Dynamics and complexity of factors influencing wastewater systems make reliable predictions very difficult, i.e. the characteristics of the catchment area can change substantially over the years. For this reason, it is necessary to improve the planning and design of wastewater treatment infrastructures through methodologies that systematically account for uncertain futures (Dominguez and Gujer, 2006). The use of the presented tools can be very beneficial to answer “what-if” questions (Gernaey *et al.*, 2011; Flores-Alsina *et al.*, 2013; Martin and Vanrolleghem, 2013).

PURPOSE OF THE PAPER

The main objective of this presentation/paper is to demonstrate the advantages of influent generators (reduce the cost of measuring campaigns, fill data gaps, create additional scenarios) with several illustrative case studies. The second purpose is to identify critical knowledge gaps related to model development, calibration procedures and increasing the number of (wastewater) engineering applications. Comments received at the conference will be included in subsequent influent generator model upgrades (the authors are actively working on model development), thus addressing modellers’ needs. This will finally achieve a more general acceptance and – equally important – common standards on model building and calibration of influent generators.

Abstract

Model-based analysis and optimization of wastewater treatment plants usually consists of numerous simulations and large data sets generated. Finding specific information in these data sets is not always a trivial task especially when this information is hidden in temporary algebraic variables that are not easily accessible or not defined as such. An extremely simple yet effective colour-based evaluation method is proposed for system analysis, e.g. for bottleneck identification. The tool proved very useful in evaluating large amounts of data and in taking certain decisions. Including the tool in simulation platforms could facilitate ASM model analysis and provide transparency for both experienced and inexperienced modellers.

Keywords

Post-processing; bottleneck identification; data evaluation; ASM analysis

INTRODUCTION

Present-day wastewater treatment plant (WWTP) optimization is largely based on model-based analysis. However this analysis usually results in the execution of a large number of simulations and the generation of large data sets. Trying to find explanations why one scenario (unexpectedly) performs better than the other or even trying to determine which scenario is the better one requires “number crunching”. Visual inspection of time series contains the risk of overlooking things, whereas summarizing time series into single numbers (average, minimum, maximum, etc.) results in significant loss of information. Simple colour-based evaluation methods might be a third approach to facilitate the data evaluation. In addition, the description of process rates or kinetics has become increasingly complex and typically multiple switching functions are joined to yield the overall process rate. Although of profound importance, these switching functions are somewhat “hidden” and often not explicitly available as output variable, meaning that intermediate calculation results are not directly accessible for the modeller. Detailed analysis of these switching functions can provide useful insight. The goal of this paper is to demonstrate the proposed system analysis tool based on an illustrative example.

MATERIALS AND METHODS

A method is proposed for the analysis of kinetic expressions that consist of a product of switching functions. These switching functions, e.g. Monod functions (Monod, 1942), are used to describe the effect of a limiting factor on a particular biological process or to (de)activate a process when a factor is exceeding a threshold. Typically, several switching functions are joined together and finally result in having a process run in the range between its maximal rate and zero. However, when a rate drops, it is not always obvious from the simulation which switching function is actually the limiting factor due to their joined nature and the fact that they are not separately calculated as algebraic states or output variables. Hence, these switching functions contain valuable “hidden” information on the activity of the process. Using colour coding for all distinctive switching functions allows for a fast inspection of the impact of all switching functions on the overall process rate and to detect

which factor is limiting. The method was applied using the WWTP model of Eindhoven (Amerlinck *et al.*, 2013) to evaluate the evolution of enhanced biological phosphorus removal (EBPR), nitrification and denitrification activity in scenarios with reduced phosphate concentration in the inlet (induced by the application of dissolved air flotation (DAF)). As an illustrative example, the process rate limitation of autotrophic growth is shown here. In the ASM2d model (Henze *et al.*, 2000) the growth rate of autotrophs (Equation 1) contains switching functions for oxygen (S_O), ammonium (S_{NH}), phosphate (S_{PO}) and alkalinity (S_{ALK}).

$$P_{AUT} = \mu_{AUT} \cdot \frac{C(S_O)}{C(S_O) + K_{O,AUT}} \cdot \frac{C(S_{NH})}{C(S_{NH}) + K_{NH,AUT}} \cdot \frac{C(S_{PO})}{C(S_{PO}) + K_P} \cdot \frac{C(S_{ALK})}{C(S_{ALK}) + K_{ALK,AUT}} \cdot C(X_O) \quad \text{Equation 13}$$

RESULTS AND DISCUSSION

Dynamic simulation of a scenario with reduced phosphate concentration in the inlet of the biological treatment (Figure), resulting from the application of a DAF, showed an unexpected but significant increase in ammonium concentration while oxygen levels and the amount of nitrifiers seemed sufficiently high.

Figure 1. The circular modified UCT configuration of the activated sludge tanks at the WWTP of Eindhoven and the mapping of tanks in series used in the model.

At some points in time phosphate was rather low but it could not be deduced directly from the dynamic simulation results that this was causing the decrease in nitrification activity. In contrast, the proposed method gave a clear view on this aspect. Table shows the individual effect of the distinct Monod switching functions (row 1-4) and the overall autotrophic growth rate as a fraction of the maximum growth rate (row 5, being the product of rows 1-4), for the different reaction zones, averaged over the entire simulation period. Colours evolve from

green, indicating a high value (no limitation) over orange to red, indicating a low value (severe limitation).

From Table it can be clearly seen that phosphate is not limiting in the anaerobic (AN01 through AN04) and anoxic zones (DT01 and DT02). The limiting factor in these zones is obviously the lack of oxygen. However, in the aerobic zones (BT01 through BT06) a relation can be seen between the limitation in the autotrophic growth rate and the Monod switching function for phosphate. I.e. while the Monod switching functions for alkalinity, ammonium and oxygen are high (and thus not limiting), the Monod switching function for phosphate and as a consequence also the overall autotrophic growth rate is low.

Table 1. Oxygen limitation (in the anaerobic and anoxic zones) and phosphate limitation (in the aerobic zones) of the overall autotrophic growth visualized through the impact of the different Monod terms for the different sections of the activated sludge tank, averaged over the entire simulation period, using a colour-based system analysis tool.

AVERAGE	AN01	AN02	AN03	AN04	DT01	DT02	BT01	BT02	BT03	BT04	BT05	BT06
Monod S_{ALK}	0.93	0.93	0.92	0.92	0.93	0.93	0.93	0.93	0.93	0.93	0.93	0.93
Monod S_{NH}	1.00	1.00	1.00	1.00	1.00	1.00	0.99	0.99	0.99	0.99	0.98	0.98
Monod S_O	0.06	0.00	0.00	0.00	0.02	0.06	0.77	0.75	0.70	0.88	0.88	0.85
Monod S_{PO}	0.98	0.99	0.99	0.99	0.80	0.76	0.36	0.29	0.28	0.29	0.29	0.29
Overall	0.05	0.00	0.00	0.00	0.01	0.01	0.21	0.13	0.10	0.21	0.20	0.19

Table 10 shows the dynamic behaviour of the same autotrophic growth rate (as a fraction of the maximum growth rate; similar as row 5 of Table but dynamic instead of averaged). Table on the other hand shows only the Monod term for phosphate as nutrient for growth (similar as row 4 of Table but dynamic). Also from Table 10 and Table this relation, between the autotrophic growth rate and the Monod switching function for phosphate, can be deduced. I.e. when the Monod term for phosphate reaches higher percentages (green colour) the growth of autotrophs increases (yellow to green colours). The switching functions for oxygen (S_O), ammonium (S_{NH}) and alkalinity (S_{ALK}) remain high and do not show the same trend (results not shown), although they lower the activity of the nitrification process slightly.

Table 10. Recovery over time of the growth rate of autotrophs for the different sections of the activated sludge tank shown using a colour-based evaluation method.

CONCLUSION

A simple yet effective colour-based system analysis tool for ASM was illustrated for supporting model analysis. The tool allowed expert modellers to make a fast system analysis given the large amount of simulation outputs. The tool also facilitated discussion with and reporting for the non-expert modellers and proved to be a valuable tool in the decision-making process.

ACKNOWLEDGEMENT

The authors would like to thank Waterboard the Dommel for the financial support and the many in-depth discussions.

Abstract

Research on nitrous oxide (N₂O) formation in engineered wastewater systems has experienced an exponential development in the recent years due to the important environmental impact of this greenhouse gas. These efforts have crystalized in a large number of publications that aim to identify the importance of the main microbial processes responsible for its production and consumption. The conceptualization of these pathways in mathematical models has the potential to become a key tool to increase our understanding on the complex interrelationships within these ecosystems and develop strategies to minimize the carbon footprint of wastewater treatment plants. The present contribution aims to summarize the recent developments in this field and makes use of standard identifiability measures to show how the choice of experimental protocols and model structures can potentially impact their calibration.

Modelling; nitrous oxide; wastewater, calibration, uncertainty

INTRODUCTION

Process modelling can be a valuable tool to predict and minimize the environmental footprint of nitrogen removal processes in wastewater treatment plants. Consequently, several models have been proposed to date in order to describe the production and dynamics of nitrous oxide (N₂O) both from aerobic ammonium oxidizing bacteria (AOB, e.g. Ni et al., 2011) and heterotrophic bacteria (HB, e.g. Hiatt and Grady Jr., 2008). Recent studies have identified AOB as the main driver for N₂O emissions during biological nitrogen removal operations (Wunderlin et al., 2013).

While some of these models make use of parametric correlations obtained from the fitting of experimental data (Houweling et al., 2011), most of the documented modelling approaches are pseudo-mechanistic, meaning that the proposed biochemical processes producing or consuming N₂O are mathematically outlined with traditional biokinetic formulations (Ni et al., 2011; Mampaey et al., 2013; Ni et al., 2013a). A recent study has attempted to examine the ability of different model structures to predict the N₂O production mechanisms by AOB (Ni et al., 2013b). However, the methodology used was biased by an ambiguous selection of calibrated model parameters. Furthermore, the wide range of model structures used result in comparably low number of parameter values published in this field, which in turn does not allow for a consensus-based set.

The present contribution makes an in-depth and robust assessment of the predictive capabilities of existing model structures by using standard metrics for parameter identifiability under well-defined experimental conditions.

MATERIALS AND METHODS

Three models describing N_2O production by AOB (Ni *et al.*, 2011; Mampaey *et al.*, 2013; Ni *et al.*, 2013a) were implemented in Aquasim 2.1 (Reichert, 1994). The parameter sets used in each model were the ones suggested in each study. The following reactor was modelled in all three cases: it had a volume of 3L, it was considered completely mixed, and it contained a population of AOB which corresponded to about 10% of the active VSS fraction in the assayed sludge (2500 mg-VSS/L, values derived from Ekama and Wentzel, 2008, and Saunders *et al.*, 2013). Four experimental scenarios were further considered for each model, all of them had a total duration of 12.5 hours:

- **Case A:** A batch test where three NH_4^+ pulses of 6 mg N/L were added at times 0, 3.3, and 7.2 hours in the presence of a controlled dissolved oxygen (DO) concentration of 2 mg/L.
- **Case B:** A batch test where three NH_4^+ pulses of 6 mg N/L were added under uncontrolled DO conditions at the same times as previously indicated.
- **Case C:** A chemostat test at an NH_4^+ load of 0.1 g N/day where the aeration is turned off 3.3 hours after the beginning of the experiment and turned back on 3.3 hours after the disturbance.
- **Case D:** A chemostat test at an NH_4^+ load of 0.1 g N/day and constant aeration rate where the NH_4^+ load is increased 20 fold after 3.3 hours of operation and is brought to the initial value 3.3 hours after the disturbance.

The metrics described by Brun *et al.* (2001), i.e. the mean square sensitivity measure (δ^{msqr}) and the collinearity index (γ), were adapted for the assessment of the structural identifiability of the considered model. Both identifiability parameters were coded as scripts in MATLAB (Sin and Vanrolleghem, 2007). The numerical data required to drive those functions was generated with a batch version of Aquasim run in parallel by using the implemented model files.

RESULTS AND DISCUSSION

The study of the local sensitivity functions for the considered models is summarized in Figure 1 (only for Case B). Ideally, higher values for the mean sensitivity measurement (δ^{msqr}) are preferred, as they reflect a higher impact of the model parameters on the model output and hence a higher probability of describing experimental data. This measurement should agree with a low collinearity index (below 5), which forms a measure of the higher identifiability of the feasible parameter subsets that can describe of N_2O dynamics. Here, even though there is a higher percentage of identifiable parameter subsets for the model proposed by Mampaey *et al.* (i.e. % of all subsets with an identifiability index below 5), they have on average a lower sensitivity (reflected by an average mean squared sensitivity measure computed for all the considered model parameters), which may complicate model calibration.

Figure 1. Average model sensitivities and percentage of identifiable parameter subsets wrt N_2O dynamics in selected model structures.

In contrast, there is a smaller fraction of identifiable parameter subsets in both models by Ni *et al.* However, their sensitivity is clearly larger, suggesting that a careful selection of parameter subsets (so that they are identifiable) can make the calibration of these models easier in comparison to the model suggested by Mampaey *et al.* This higher degree of sensitivity could derive from a higher degree of simplification in the processes involved in N_2O production and consumption in both models by Ni *et al.* (4 processes are involved versus 5 in Mampaey *et al.*).

Using the model by Ni *et al.* (2011) as an example (Figure 2), it can be seen how the experimental conditions can impact the sensitivity of the parameters involved in N_2O production. Those experimental protocols with higher associated oxygen dynamics (i.e., cases B and C) result in modelling scenarios that yield parameters with higher average sensitivity on the N_2O concentration, which should ease the calibration of the considered model. Similar trends were obtained for the other two models studied.

Figure 2. Average model sensitivities and percentage of identifiable parameter subsets wrt N_2O dynamics in Ni *et al.* 2011 under the modelled experimental cases. *Case A*: Batch, cnt DO; *Case B*: Batch, uncontrolled DO; *Case C*: Chemostat, negative pulse in aeration; *Case D*: Chemostat, NH_4^+ load pulse.

CONCLUSIONS

It is possible to conclude that the selection of a model structure and an experimental protocol both have a direct impact on the calibration procedure of process models describing N_2O production by AOB. Further work should facilitate the preparation of experimental protocols for calibration of existing process models for N_2O dynamics.

ABSTRACT

A mathematical model was applied to evaluate the influence of microbial kinetics of the process operation on the coexistence of nitrite dependent anaerobic methane oxidizing bacteria (N-DAMO) and anaerobic ammonium oxidizing bacteria (Anammox) in a single granule. Only if the influent contained the exact stoichiometric ratios at which both bacteria got enough nitrite, complete ammonium and methane removal could be realized. At high nitrogen biomass loadings N-DAMO lost the competition against Anammox bacteria. In addition, was the influence of granular size evaluated showing that a granules size of up to 0.75mm enabled a simultaneous ammonium and methane removal efficiency above 85%.

INTRODUCTION

During anaerobic digestion methane is formed which can be used for energy generation through cogeneration. However, some of the methane remains in a dissolved state in the effluent of the anaerobic digestion (reject water) and may escape into the atmosphere during downstream processing. Given the large global warming potential of methane, being about 25 CO₂ equivalents over a 100 year time horizon, even small quantities of methane emissions can largely affect the carbon footprint of a wastewater treatment plant (WWTP). Since reject water typically contains high ammonium concentrations and little or no organic carbon, Anammox-based system are often applied to remove nitrogen in an autotrophic way. To prevent greenhouse gas emissions, it would clearly be beneficial if dissolved methane could be biologically removed from the reject water at the same time as nitrogen. Recently a new bacterium (*Candidatus Methyloirabilis oxyfera*) was discovered capable of oxidizing methane with nitrite as electron and converting it to nitrogen gas and carbon dioxide (Ettwig *et al.*, 2010). A combination of biological anaerobic methane oxidation (N-DAMO) and anaerobic ammonium oxidation (Anammox) could hence solve the methane emissions caused from reject water. Some early experiments have already been done, demonstrating the possible coexistence of both bacteria performing simultaneous removal of methane and ammonium (Leusken *et al.*, 2011). Since both bacteria have a doubling time of more than ten days proper biomass retention is needed to handle large volumetric flows and loading capacities such as encountered in a WWTP (Ettwig *et al.*, 2010; Strous *et al.*, 1998). Granular sludge reactors are a type of biofilm reactors in which biomass is grown in the form of dense, fast-settling granules, resulting in compact systems which allows a high loading rate due to a large biofilm surface area in the reactor. Therefore, granules offer a good option for simultaneous growth of both N-DAMO and Anammox bacteria combine both slow growing bacteria in one granule. Due to the slow growth rates of the involved bacteria, experimental work aiming at process optimization can be very time consuming. Mathematical models have been shown earlier to be useful to optimize the performance of granular sludge reactors (Batstone *et al.*, 2004; De Kreuk *et al.*, 2007). In this study, a mathematical model is applied to evaluate the influence of process operation on the coexistence of anaerobic methane and ammonium oxidizing bacteria in a single granule.

GRANULAR SLUDGE REACTOR MODEL

A one-dimensional biofilm model was set up to describe growth and decay of anaerobic methane oxidizers (N-DAMO) and anaerobic ammonium oxidizers (Anammox) in a granular sludge reactor. The model was implemented in the Aquasim software. The reactor volume was considered to be fixed at 400 m³. Spherical biomass particles (granules) are grown from an initial radius of 0.01 mm to a

predefined steady state granule radius such that the reactor eventually contains 100 m^3 of particulate material, comprising both active biomass as well as inerts generated during endogenous respiration. The reactor behaviour has been simulated at a flow rate of $2500 \text{ m}^3 \cdot \text{d}^{-1}$ at a total nitrogen concentration of $1000 \text{ g N} \cdot \text{m}^{-3}$ and $200 \text{ g COD} \cdot \text{m}^{-3}$ of methane, respectively. These values are based on typical values as measured in reject water (Bandara *et al.*, 2011). Furthermore, it was assumed that the total nitrogen concentration fed into the system consisted of $430 \text{ g N} \cdot \text{m}^{-3}$ of ammonium and $570 \text{ g N} \cdot \text{m}^{-3}$ of nitrite, corresponding to stoichiometric-optimal nitrite:methane and nitrite:ammonium ratios for conversion with methane and ammonium, by N-DAMO and Anammox, respectively.

RESULTS AND DISCUSSION- Competition for nitrite and ammonium

N-DAMO bacteria mainly grew in inner part of the granules, which can be explained by their slower growth rate, whereas Anammox mainly grew in the outer part of the granule. The inner part of the granules was consisting of inerts (Figure 1). In the model different $\text{NO}_2^-/\text{total N}$ ratios (total N $1000 \text{ mg N} \cdot \text{m}^{-3}$) were tested at a fixed COD concentration ($200 \text{ g COD} \cdot \text{m}^{-3}$) to study at which influent composition both bacteria could coexist. At lower ratios (ammonium in excess) N-DAMO bacteria were out competed by Anammox bacteria. However, at ratios close to the stoichiometric equilibrium (NO_2^- , NH_4^+ , CH_4) needed to completely remove methane and ammonium, N-DAMO bacteria could retain in the system. At high ratios Anammox bacteria got restricted by ammonium leading to an accumulation of nitrite in the bulk (Figure 2).

Figure 2. Reactor performance in terms of (●) ammonium, (x) methane, (▲) nitrate, (♦) nitrite, and (–) N_2 at different nitrite over nitrogen ratios.

Influence of volumetric biomass loading rate and granular size

For granule radius in a range of $0.1\text{--}0.75 \text{ mm}$ both types of bacteria coexisted in approximately equal amounts leading to a simultaneous methane and ammonium removal above 85% . At higher granule sizes inerts increase due to substrate depletion in the inner core of the granule hence restricting microbial growth. In addition, N-DAMO bacteria decrease at higher granules radius due the lower diffusion coefficient of methane compared to ammonium. Bigger granules favoured Anammox bacteria whereas smaller granules enabled the coexistence of both bacteria in one granule (Figure 3). The effect of changing the total biomass volume on the bulk liquid concentrations as well as on the biomass fractions of both bacteria was evaluated based on media containing the stoichiometric ratios needed for a complete ammonium and methane removal (Figure 3). When only little biomass was in the reactor (biomass volume lower than 50 m^3) Anammox dominated the system (Figure 4 phase I). At a biomass volume from 50 m^3 until 100 m^3 both bacteria started to compete for substrate and space (no inerts). During this transition period (50 m^3 until 100 m^3) the removal efficiencies, which could be explained by ammonium and nitrite affinity constants (data not shown). From 100 m^3 on N-DAMO bacteria dominated the granule and the oscillation in bulk liquid concentrations stopped. When N-DAMO dominated the system ($>100 \text{ m}^3$) simultaneous ammonium and methane removal could be realized (Figure 4 phase II). The results showed that the volumetric biomass loading rate needs to be sufficiently low to allow simultaneous methane and ammonium removal.

Figure 4. (A) Reactor performance of (◆) biomass loading, (+) biomass activity, (x) nitrogen removal efficiency, and (-) methane removal efficiency as well as (B) biomass profiles of (▲) Anammox bacteria, (●) N-DAMO bacteria, and (■) interts at different biomass volume fractions in the reactor. The total volume of the reactor was considered to be 400 m^3 . In phase I (A) no methane was removed and (B) no N-DAMO were present. In phase II (A) methane was removed (B) and N-DAMO grew in the system. (C) only in this period oscillations occurred.

CONCLUSIONS

- Simultaneous anaerobic methane and ammonium removal, through N-DAMO and Anammox bacteria respectively, was described for the first time through a mathematical model, which was subsequently applied to simulate these reactions in a granule sludge reactor.
- Bigger granules favoured Anammox bacteria whereas smaller granules enabled the coexistence of both bacteria in one granule
- The volumetric biomass loading rate needs to be sufficiently low to allow simultaneous methane and ammonium removal. At high loading rates, N-DAMO are outcompeted by Anammox bacteria.
- The stability of simultaneous anaerobic methane and ammonium removal is severely affected by the ammonium and nitrite affinity constants of N-DAMO and Anammox bacteria.

Abstract

A knowledge-based risk assessment modelling approach is proposed to provide a qualitative means of benchmarking WWTP design and control strategies in terms of risk of N₂O production. The approach makes use of ASM model output variables corresponding to conditions that have been specifically linked to the risk of WWTP N₂O production in the literature, and applies a fuzzy logic rule-based system to qualitatively assign risk of N₂O production, as opposed to predicting actual emission. To demonstrate the proof of concept, the qualitative N₂O risk model was used to interpret mathematical simulation data and distinguish risk of N₂O production resulting from two different aeration control strategies (DO set points of 2 mg·L⁻¹ and 1.3 mg·L⁻¹). The approach demonstrated its potential in assessing risk of N₂O production on a plant-wide level, as well as the reactor level, which allowed diagnosing specific risks and identifying opportunities for mitigation. Results also demonstrated how the N₂O risk model tool can be helpful in selecting appropriate mechanistic N₂O production models through its risk diagnosis. The N₂O risk assessment model can also serve as a practical decision support tool for qualitatively assessing multi-criteria control strategies as seen in the N₂O risk, effluent quality, and operational cost benchmarking results. The tool is flexible and can be used not only with mathematical model output data, but also online, or SCADA data for examining risk of N₂O production for current and historical plant operations.

Keywords

Activated Sludge Model (ASM), nitrous oxide, qualitative modelling, risk assessment modelling

INTRODUCTION

A considerable amount of focus has been placed on modelling full-scale wastewater treatment plant (WWTP) nitrous oxide (N₂O) emissions in recent years given their high global warming potential. As a result, several promising mechanistic models have been developed (Yu et al., 2010; Ni et al., 2011; Houweling et al., 2011; Law et al., 2012; Ni et al., 2012; Guo and Vanrolleghem, 2013; Mampaey et al., 2013; Ni et al., 2013). However, there is not yet a rigorously validated and consensus-based model. This is largely due to the complex and interactive nature of the processes leading to N₂O emissions from activated sludge systems, including ammonia-oxidizing bacteria (AOB) cell metabolism and gene expressions (Yu et al., 2010; Chandran et al., 2011), AOB and nitrite-oxidizing bacteria (NOB) kinetic rates (Foley et al., 2010), mass transfer processes, and the dynamic operational and environmental conditions that impact the propensity of full-scale microbial populations for producing N₂O during both nitrification and denitrification (Kampschreur et al., 2009; Foley et al., 2010,

Chandran *et al.*, 2011). As researchers continue to make strides in reaching a consensus on N₂O dominant pathways, model validation, and implementing and calibrating multiple N₂O pathway models, a knowledge-based risk assessment modelling approach is proposed to complement the progression of the mechanistic description of N₂O production, and provide a qualitative means of benchmarking WWTP design and control strategies. A similar knowledge-based risk assessment modelling approach (AS risk model) has been successfully developed and implemented by Comas *et al.* (2008) for diagnosing the risk of microbiology related solids separation problems, such as filamentous bulking, foaming, and rising sludge, resulting from various activated sludge control strategies. Parallels between modelling activated sludge solids separation problems and N₂O production, such as the lack of validated mechanistic models and interest in more holistic benchmarking of control strategies, thus motivated the extension of this risk assessment modelling concept for heuristically diagnosing WWTP N₂O production.

METHODS

The methodology for developing the N₂O risk model is generally consistent with that of the AS risk model development (Comas *et al.*, 2008). The proposed integrated mathematical / knowledge-based risk assessment modelling approach makes use of ASM state variables corresponding to conditions that have been specifically linked to the risk of WWTP N₂O production in the literature (Kampschreur *et al.*, 2009; Foley *et al.*, 2010; Ahn *et al.*, 2010; GWRC, 2011), but not yet formalized in a modelling platform through which N₂O risk can be assessed with other criteria in various WWTP simulation scenarios. Therefore, a knowledge base of the operational conditions/parameters associated with risk of N₂O production via heterotrophic denitrification and AOB nitrification/denitrification pathways was compiled and then classified in terms of low, medium, and high risk according to values found in the literature correlating to low, medium, and high N₂O production in either full-scale or lab-scale studies. This knowledge was then represented in a fuzzy logic, IF / THEN rule-based system implemented in both Matlab and Excel, through which a qualitative risk score can be dynamically assigned for each variable representing the operational risk condition. The risk score is based on scale from 0 to 1, with 1 representing the highest risk.

To demonstrate the proof of concept of N₂O risk assessment modelling, the risk model was implemented for only three of the several risk parameters defined in the knowledge base: high nitrite (NO₂⁻) for nitrification and denitrification reactors, and low dissolved oxygen (DO) and ammonia oxidation rate (AOR) via DO for nitrification reactors (**Table 1**). This portion of the N₂O risk model was applied to the Benchmark Simulation Model No. 2 (BSM2), a five reactor (two anoxic and three aerobic) MLE configuration. Two different control scenarios were compared: Scenario 1 - DO set point of Activated Sludge Unit (ASU) No. 4 (ASU4) is **2 mg·L⁻¹**, and Scenario 2 – DO setpoint of ASU4 is **1.3 mg·L⁻¹**, with k_La set proportionally as 1.5k_La, k_La, and 0.5k_La for the aerobic reactors ASU3, ASU4, and ASU5, respectively. The model implemented in Porro *et al.* (2011), which includes two-step nitrification and four-step denitrification, was used since the NO₂⁻ state variable could be used for implementing the N₂O risk model for the high NO₂⁻ condition, whereas the original BSM2 platform implementing ASM1 only includes single-step nitrification and, hence, no NO₂⁻ variable. Although the model used in Porro *et al.* (2011) also includes the implementation of mechanistic models for N₂O production, the N₂O variables are ignored since the purpose of the paper is demonstrating a qualitative approach to assessing control strategies for N₂O production risk as opposed to a quantitative approach (i.e. mechanistically predicting N₂O concentrations). The ASM model output data was then input into the Excel version of the risk

model to plot dynamic N_2O risk based upon the corresponding BSM2 model output state variables. Similarly to Corominas *et al.* (2012) and Guo *et al.* (2012), Operational Cost Index (OCI), which includes energy costs, and Effluent Quality Index (EQI) per Nopens *et al.* (2010) were also compared for the two scenarios along with overall N_2O risk to demonstrate the N_2O risk assessment model's potential in multi-criteria decision support.

RESULTS AND DISCUSSION

Table 2 summarizes N_2O risk model results in each of the reactors by average overall risk, from taking the maximum risk of the three individual risk parameters results for each time step, and by percent of time under high risk, with high risk being a risk score of greater than or equal to 0.8, as defined by Comas *et al.* (2008). Also summarized in **Table 2** is the average overall risk score for all of the reactors, as well as the percent of time under high risk accounting for all reactors, or the percent of the total simulation time in which at least one reactor was under high risk. As anticipated, the two different DO control set points resulted in different conditions in each of the reactors, and hence, noticeable differences in average overall risk scores and time under high risk between the two scenarios. Obviously the largest differences are seen in the aerobic reactors, since the only change between the scenarios was the DO set point. These differences in risk results in the aerobic reactors are due to the DO concentration itself, as low DO implicates the potential for N_2O production via AOB denitrification (Kampschreur *et al.*, 2009; Tallec *et al.*, 2008), and higher DO implicates N_2O production via the hydroxylamine oxidation pathway (Law *et al.*, 2012), as well as the NO_2^- concentrations, which implicate AOB denitrification (Kampschreur *et al.*, 2009). Inspecting the N_2O production risk results in each of the reactors, ASU5 reactor stands out for Scenario 2, with an average overall risk score of 0.95 and 96 percent of the time under high risk.

To give a sense of the N_2O risk model tool's capabilities, **Figure 1** is provided to illustrate further inspection of the risk results, comparing plots of both the individual and overall risk in ASU5 for both scenarios. As the DO set point is lower in Scenario 2, and ASU5 has a k_{La} that is half that of ASU4 where the DO set point is controlled, it can be understood why the DO levels are significantly lower and hence the N_2O production risk, due to low DO, significantly higher. To add to the risk of ASU5, the lower DO concentrations also lead to higher NO_2^- concentrations compared to Scenario 1 due to the difference in oxygen half-saturation constants between AOB and NOB (Hanaki *et al.*, 1990; Mota *et al.*, 2005), and therefore, higher risk due to high NO_2^- concentrations. As the ASU5 DO concentrations in both scenarios are less than the low risk threshold ($<1.8 \text{ mg}\cdot\text{L}^{-1}$) for AOR risk, N_2O production risk due to AOR (hydroxylamine oxidation pathway) is always zero in both scenarios for ASU5. As the two remaining risk parameters with high risk values account for AOB denitrification, one could surmise that the particular conditions for ASU5 lend to N_2O production via the AOB denitrification pathway. This highlights the capability of the tool in helping to hypothesize pathways, and therefore, also to select mechanistic models of N_2O production. As the specific risks can be diagnosed, the N_2O risk model tool also demonstrates its potential in identifying opportunities for mitigating N_2O production risk. In this case, it is clear that better control of the DO in ASU5, or better distribution of the air between ASU3 and ASU5 could help to minimize the risk in ASU5, and hence the overall risk for Scenario 2 since ASU5 was under high risk 96 percent of the simulation time. The opportunity to better distribute air among reactors was also noted by Guo *et al.* (2012) for minimizing greenhouse gas mass transfer and emissions into the air as it is related to the k_{La} . However, in this case, the N_2O risk model assesses only the effect of DO on risk of production and not mass transfer and emissions. It is also clear from these results that looking at only average overall risk

alone, may not fully diagnose the potential N₂O production risk as the average overall risk score for each scenario only differed by 0.07. Since different reactors can be under high risk at different times, it is helpful to also consider the amount of time in which at least one reactor is under high risk.

Table 3 summarizes the N₂O risk, EQI, and OCI results for both scenarios. As anticipated the lower DO control resulted in some cost savings based upon the OCI; however, the EQI decreased slightly, and the average overall N₂O risk score increased slightly. However, the time under high risk for all five reactors increased significantly, by 1.5 times to almost 100 percent of the simulation time. Depending upon objectives, this information could be helpful in determining whether the five percent savings in the OCI is worth increasing the time under high N₂O production risk to almost 100 percent of the time. This information could also help in decision making by prompting further investigation into the conditions in ASU5. For example, if better control or distribution of the air among ASU3 and ASU5 is feasible, as suggested previously, then risk could potentially be mitigated, while still realizing the same cost savings since essentially the same amount of air would be added, just distributed differently.

CONCLUSIONS AND PERSPECTIVES

The integrated mathematical / knowledge-based risk assessment modelling concept by Comas *et al.* (2008) has been adapted for assessing the risk of N₂O production in WWTPs. The qualitative N₂O risk model approach was used to interpret mathematical simulation data and distinguish risk of N₂O production resulting from two different aeration control strategies. The approach demonstrated potential for assessing risk of N₂O production on a plant-wide level, as well as the reactor level, which allowed diagnosing specific risks and identifying opportunities for mitigation. Results also demonstrated how the N₂O risk model tool can complement the application of mechanistic models of N₂O production through the implication of specific N₂O production pathways in the risk diagnosis, which can then be used in hypothesizing underlying mechanisms and selecting appropriate mechanistic N₂O production models. The N₂O risk assessment model can also serve as a practical decision support tool for qualitatively assessing multi-criteria control strategies as seen in the results. As the Excel version of the risk assessment model was used in this study, the results not only demonstrate the potential application of the tool with mathematical model output data, but also with online, or SCADA data for operators interested in making use of the available knowledge and examining risk of N₂O production for current and historical plant operations. Work is ongoing confirming AOR values/risk and to test the entire knowledge base with full-scale data from various measurement campaigns.

Abstract

This paper offers a modeling approach for estimation of greenhouse gas emissions based on apparent differential AOB-NOB rates estimation and NirK kinetics as the main key parameters. This simplified greenhouse gas model was calibrated with data obtained from a full-scale experiment on the mainstream deammonification stage at the Strass WWTP showing increased N₂O emissions at higher DO set-points. The latter was directly correlated with the increased AOB-NOB differential at higher DO set-points resulting in increased nitrite accumulation.

INTRODUCTION

The formation of N₂O and NO is considered complex and difficult to predict due to the interplay of many possible factors, contributors and mechanisms within the contributors. As aerobic ammonium oxidizing bacteria (AOB) are believed to be the main contributors to the N₂O and NO emissions in wastewater treatment plants (Chandran et al. 2011, Ni et al. 2013), the main focus in research, measuring campaigns and modeling studies goes to understanding the AOB mechanisms of NO/N₂O production in detail. Two main routes are distinguished in those studies and referred to as the forward (through NH₂OH) and reverse (through nitrite) route. The forward route is mainly linked to peaks in ammonium loading, while the reverse route is mainly dependent on nitrite accumulation as shown in pure or enriched AOB cultures (Chandran et al. 2011).

Simulation of N₂O emissions based on the different routes studied in these detailed AOB studies becomes quite complex especially as the relative contributions of both routes and its kinetics are not known and calibration could be difficult as measurements of all possible intermediates and gene expressions in real systems is scarce and difficult to accomplish. In this study we propose a simplified approach based on apparent rate differential estimation between AOB and nitrite oxidizers (NOB) considering nitrite as the main precursor for N₂O emission. Model calibration was done based on greenhouse emission data obtained from the full-scale plant in Strass. In this system mainstream deammonification was applied and greenhouse gas emissions were deliberately increased by increasing the dissolved oxygen (DO) set-point and nitrogen loading (addition of filtrate) resulting in higher nitrite accumulation.

EXPERIMENT

Greenhouse gas emissions were measured on the B-stage of the Strass WWTP (Austria) in which a full-scale mainstream deammonification trial was taking place at that moment (Wett et al. 2012). During normal operations the B-stage was operated with a fully anoxic predenitrification stage followed by a nitrification stage (carrousel) at a DO set-point at the end of the aeration zones of 2 mg O₂/L (reactors Naer3b and Naer4b in schematic Figure 4). The plant was fed with 6000 kg COD/d and 560 kg N/d (raw sewage). To test the relation between the operational conditions and the greenhouse gas emissions, the DO set-point in the

nitrification zone was changed for 2.5h to 1, 3 and 2 mg O₂/L subsequently. At DO set-points of 3 and 2 mg O₂/L the nitrogen load was increased with 10% by addition of filtrate to the mainstream reactor. The latter allowed for continuous aeration during the testing (NH₄-based control). Oxygen profiles within the nitrification carrousel are given in Table 1.

Table 1: Observed DO profiles in the nitrification carrousel at different DO set-points

DO set-point	Observed DO concentration (mg O ₂ /L)							
	Nanox3a	Nanox3b	Naer3a	Naer3b	Nanox4a	Nanox4b	Naer4a	Naer4b
1	0.7	0.1	0.4	1	0.7	0.1	0.4	1
2	0.8	0.15	0.7	2	0.8	0.15	0.7	2
3	2	1.2	2	3	2	1.2	2	3

RESULTS AND DISCUSSION

Why is the apparent differential AOB-NOB rate the key parameter?

Forward N₂O route

High ammonium peak loadings are described as triggers for N₂O production and believed to happen through the forward pathway. However, ammonium peak loadings will also result in a dynamic nitrite accumulation due to a larger differential between AOB and NOB rates at high ammonium residual levels (Figure 1). Therefore, the reverse N₂O pathway starting from this accumulated nitrite could play a more important role than described right now, especially as hydroxylamine accumulation remains very minor. No hydroxylamine could be detected in the B-stage of the WWTP in Strass (Austria) under different loading conditions and ammonium residual concentrations (data not shown).

Reverse N₂O route

The reverse pathway is described to be mainly dependent on oxygen conditions (Chandran et al 2011). Measurements of NO and N₂O emissions in the mainstream B-stage of the wastewater treatment plant in Strass (Austria) showed increased emissions when operating at higher dissolved oxygen (DO) concentrations, while you would expect the opposite based on Chandran et al. (2011) (Figure 2). This effect could be explained by a higher nitrite accumulation at higher DO compared to lower DO operation (0.5 compared to 4 mg NO₂-N/L at 1 and 3 mg O₂/L, respectively) as the apparent oxygen affinity coefficient for AOB was higher than for NOB and the differential in rates happens mainly at high DO (Figure 2).

Figure 1: Simulation of Monod kinetics of AOB and NOB explains the nitrite accumulation at higher ammonium residual concentration (Downing et al 1964) which represents ammonium peak loading conditions (based on WEFTEC presentation of Dold P., 2012)

Figure 2: left: Increased levels of N₂O emission going from low (1 mg O₂/L) to high DO (3 mg O₂/L) operation in the B-stage of the WWTP in Strass (Austria), right: Simulation of AOB and NOB kinetics measured at that time in the full-scale reactor showing increased differential rate between AOB and NOB at high DO.

Nitrite/NirK kinetics as the basis of N₂O/NO formation

The key genes in the N₂O pathway starting from nitrite (reverse route) are nitrite reductase (NirK) and nitric oxide reductase (Nor). Expression of NirK is dependent on nitrite levels, ammonium presence and oxygen levels (Yu et al. 2010). The nitrite concentration dependency, which is the results of the differential AOB-NOB rates, was determined in a batch experiment. The nitrite affinity coefficient for NO and N₂O production was observed to be 1 mg NO₂-N/L in the presence of ammonium and transient anoxia operation (Figure 3). Besides nitrite levels, implementation of an oxygen switch for NirK expression simulating the first order decay of nirK during aerobic conditions is often needed to explain the decrease in N₂O/NO emission after the transition from anoxic to aerobic (Yu et al 2010, Wett 2012) and was therefore incorporated in the model.

Figure 3: Left: Monod model fit for NO and N₂O specific production rate of B-stage sludge from Blue Plains advanced WWTP (Washington DC) depending on the nitrite concentration in the system during transient anoxia (10/10 minutes) and in the presence of excess ammonium (10 mg N/L).

GHG Model

The Strass plant (Austria) was modelled using the same 4-step nitrification/denitrification and GHG model (Sumo-N in the Sumo simulator) as described in the GHG workshop at WWTMod 2012. The model contains the Hyatt and Grady (2008) heterotrophic denitrification model and the autotrophic denitrification concept (Mampaey et al. 2013), extended by the nirK enzyme indicator (Table 2). The latter concept was originally based on the observation that during transition periods from anoxic to aerobic conditions GHG-emissions first tend to increase and then at continued aeration concentrations decrease. Enzyme measurements (Yu et al. 2010) indicated during periods of nitrite availability a corresponding accumulation specifically of NirK known to catalyse NO-formation and and a

more pronounced depletion of this enzyme at increasing DO concentrations. The enzyme-activity growth- and decay-approach is considered as a method to describe the dynamics of NO-formation depending on preceding process conditions. The calibration consisted of setting up the plant configuration with the proper loading and DO values, and adjusting half saturation values in order to obtain the right N₂O release proportions (Table 3).

Table 2: Rate expressions used in the model to describe the kinetics for NO and N₂O production by AOB

Processes by AOB	Rate expression
NO ₂ → NO	$\mu_{AOB} * X_{AOB} * Msat(S_{O_2}; k_{O_2, AOB}) * Msat(S_{NH_4}; k_{NH_4, nut}) * \eta_{NO_2, AOB} * X_{ENZ, AOB} * Msat(S_{NO_2}; k_{NO_2, AOB})$
NO → N ₂ O	$\mu_{AOB} * X_{AOB} * Msat(S_{O_2}; k_{O_2, AOB}) * Msat(S_{NH_4}; k_{NH_4, nut}) * \eta_{NO, AOB} * Msat(S_{NO}; k_{NO, AOB})$
Enzyme activation	$\mu_{ENZ, AOB} * X_{AOB} * Msat(S_{NO_2}; k_{NO_2, AOBENZ}) * Max(0; (1 - X_{ENZ, AOB}) / ((1 - X_{ENZ, AOB}) + k_{scaling})) * (k_{scaling} + 1)$
Enzyme decay	$b_{ENZ, AOB} * Msat(X_{ENZ, AOB}; k_{ENZ, AOB}) * Msat(S_{O_2}; k_{O_2, AOBENZ})$

$Msat(var; k) = var / (k + var)$;

Table 3: Parameters used in the GHG model for the Strass case study.

Parameter	Symbol	Value	Unit
O ₂ half saturation coefficient for AOB	$k_{O_2, AOB}$	0.4	mg O ₂ /L
O ₂ half saturation coefficient for NOB	$k_{O_2, NOB}$	0.4	mg O ₂ /L
O ₂ inhibition coefficient OHO	$k_{O_2, OHO}$	0.05	mg O ₂ /L
NO ₂ half saturation coefficient for AOB	$k_{NO_2, AOB}$	0.2	mg NO ₂ -N/L
NO ₂ half saturation coefficient for NOB	$k_{NO_2, NOB}$	0.2	mg NO ₂ -N/L
NO ₂ half saturation coefficient for OHO	$k_{NO_2, OHO}$	1	mg NO ₂ -N/L
NO half saturation coefficient for AOB	$k_{NO, AOB}$	0.001	mg NO-N/L
NO half saturation coefficient for OHO	$k_{NO, OHO}$	0.001	mg NO-N/L
N ₂ O half saturation coefficient for OHO	$k_{N_2O, OHO}$	0.1	mg N ₂ O-N/L
NO ₂ nirK enzyme half saturation for AOB	$k_{NO_2, AOBENZ}$	0.1	mg NO ₂ -N/L
O ₂ half saturation for enzyme decay in AOB	$k_{O_2, AOBENZ}$	0.1	mg O ₂ /L
Maximum enzyme activation rate	$\mu_{ENZ, AOB}$	1	d ⁻¹
Correction factor for NO production by AOB	$\eta_{NO_2, AOB}$	1	-
Correction factor for N ₂ O production by AOB	$\eta_{NO, AOB}$	1	-
Maximum growth rates for AOB	μ_{AOB}	0.9	d ⁻¹
Maximum growth rates for NOB	μ_{NOB}	0.7	d ⁻¹
Maximum growth rates for OHO	μ_{OHO}	6	d ⁻¹

Figure 4: Sumo configuration of the Strass Mainstream Deammonification process

Oxygen profiles were calibrated by adjusting the kLa_{O_2} to 240, 280 and 350 d⁻¹ for DO set-points 1, 2 and 3 mg O₂/L. Due to the fact that this experiment was done at full scale (less defined boundaries) and due to the complexity of NOB out-selection during mainstream

deammonification (Al-Omari *et al.* 2014) modeled nitrite accumulation values were slightly lower than the observed values. Nitrite concentrations of 0.3, 1.3 and 1.7 mg NO₂-N/L were obtained by the model at 1, 2 and 3 mg O₂/L, respectively, while an increase of 0.5 to 4 mg NO₂-N/L was observed during the experiment. Although absolute nitrite levels were lower, the model showed the stepwise increase in N₂O emission with increasing DO set-point and thus increasing AOB-NOB differential (Figure 5).

It should be noted that the N₂O emissions obtained in this experiment were very high (3, 9 and 15% of N load at 1, 2 and 3 mg O₂/L) and were enhanced on purpose during this experiment. It was not the attempt of this experiment to minimize emission but rather test potential conditions which would increase the emissions. Moreover, no adaptation of the system towards the transient condition applied in this experiment (oxygen and loading) was allowed which further maximized the potential effect. The emission observed in this experiment are therefore not expected during long term mainstream deammonification operation as optimal balances between NOB out-selection and anoxic nitrite removal by anammox or denitrification will decrease nitrite accumulation especially at the transition between anoxic to aerobic conditions. Moreover, adaptation can occur which will further decrease the emissions (Yu *et al.* 2010).

Figure 5: Modeled vs observed N₂O emission at increasing DO set-points and subsequently higher nitrite accumulation

CONCLUSION

This study that with a simplified GHG model only focused on the reverse N₂O pathways, increased N₂O at higher DO concentrations and thus higher AOB-NOB differential could be predicted.
