Albert, MD,^e Maria Grazia Roncarolo, MD,^{a,f} Luigi Naldini, MD, PhD,^{a,f} Alessandro Aiuti, MD, PhD,^{a,g} Anna Villa, MD,^{a,h} and Marita Bosticardo, PhD^a Milan, Cagliari, and Rome, Italy, Rotterdam, The Netherlands, and Munich, Germany

Background: Wiskott-Aldrich syndrome (WAS) is a severe X-linked immunodeficiency characterized by microthrombocytopenia, eczema, recurrent infections, and susceptibility to autoimmunity and lymphomas. Hematopoietic stem cell transplantation is the treatment of choice; however, administration of WAS gene-corrected autologous hematopoietic stem cells has been demonstrated as a feasible alternative therapeutic approach.

Objective: Because B-cell homeostasis is perturbed in patients with WAS and restoration of immune competence is one of the main therapeutic goals, we have evaluated reconstitution of the B-cell compartment in 4 patients who received autologous hematopoietic stem cells transduced with lentiviral vector after a reduced-intensity conditioning regimen combined with anti-CD20 administration.

Methods: We evaluated B-cell counts, B-cell subset distribution, B cell-activating factor and immunoglobulin levels, and autoantibody production before and after gene therapy (GT). WAS gene transfer in B cells was assessed by measuring vector copy numbers and expression of Wiskott-Aldrich syndrome protein. **Results:** After lentiviral vector-mediated GT, the number of transduced B cells progressively increased in the peripheral blood of all patients. Lentiviral vector-transduced progenitor cells were able to repopulate the B-cell compartment with a normal distribution of B-cell subsets both in bone marrow and the periphery, showing a WAS protein expression profile similar to that of healthy donors. In addition, after GT, we observed a normalized frequency of autoimmune-associated CD19⁺CD21⁻CD35⁻ and CD21^{low} B cells and a reduction in B cell-activating factor levels. Immunoglobulin serum levels and autoantibody production improved in all treated patients.

Conclusions: We provide evidence that lentiviral vector-mediated GT induces transgene expression in the B-cell compartment, resulting in ameliorated B-cell development and functionality and contributing to immunologic improvement in patients with WAS. (*J Allergy Clin Immunol* 2015;136:692-702.)

BAFF:	B cell-activating factor
BM:	Bone marrow
GT:	Gene therapy
HD:	Healthy donor
HSC:	Hematopoietic stem cell
IVIg:	Intravenous immunoglobulin
PB:	Peripheral blood
SDF-1 α :	Stromal cell-derived factor 1 α
VCN:	Vector copy number
WAS:	Wiskott-Aldrich syndrome
WASp:	Wiskott-Aldrich syndrome protein

In the last 15 years, extensive preclinical studies in human subjects and *Was*^{-/-} mice have evaluated the feasibility and efficacy of WAS gene therapy (GT) by means of both retroviral and lentiviral vectors, providing the basis for the clinical application of GT for WAS. The first clinical GT trial for WAS based on gammaretroviral vector-mediated gene transfer, showed sustained expression of WASp in HSCs, lymphoid cells, myeloid cells, and platelets after GT, resulting in a considerable clinical benefit to the patient.¹¹ However, the occurrence of leukemias in 7 of 10 treated patients¹² has raised concerns about the use of non-self-inactivating retroviral vectors.

We developed a GT approach based on a lentiviral vector encoding human WASp cDNA under the control of the human WAS endogenous promoter.¹³ The lentiviral GT protocol is characterized by a reduced-intensity conditioning coupled with depletion of B cells by anti-CD20 antibody administration before the infusion of transduced HSCs. Our initial results in 3 patients showed that lentiviral vector-mediated GT was feasible and led to successful correction of HSCs, resulting in reconstitution of WASp expression in all hematopoietic cell lineages.¹⁴

Because of the high risk of infections and autoimmune complications, correction of immune cell functions remains the main goal of WAS GT. Both GT trials have described an immunologic improvement about 2 years after treatment in terms of lymphocyte counts, *in vitro* T-cell functionality, use of T-cell receptor V β repertoire, natural killer cell immunologic synapse formation, and cytotoxic activity.^{11,14} Several studies on HSC transplantation outcomes demonstrated that successful immune reconstitution and protection from infections require development of humoral immune competence mediated by B lymphocytes.¹⁵ The B-cell compartment needs to be carefully investigated in the context of GT treatment. Indeed, WAS is characterized by impaired humoral immunity, with skewed immunoglobulin production and defects in polysaccharide antigen response,^{2,16} indicating intrinsic abnormalities of B-cell function. Very recently, B-cell perturbation has been described to contribute to immunodeficiency and autoimmunity in patients with WAS.^{17,18}

Thus we evaluated the effects of lentiviral vector-based GT on B-cell homeostasis and distribution, both in the BM and peripheral blood (PB) of patients with WAS until 36 months after treatment. To this end, we followed reconstitution of the B-cell compartment in terms of B-cell counts, B-cell subset distribution, plasma B cell-activating factor (BAFF) and immunoglobulin levels, and autoantibody production in 4 patients enrolled in the lentiviral vector-mediated GT clinical trial.

METHODS

Patients, treatment, and follow-up

Clinical classification and molecular analysis are described in Table E1 in this article's Online Repository at www.jacionline.org. The clinical protocol (ClinicalTrials.gov, no. NCT01515462) and criteria of eligibility for the study have been previously described.¹⁴ Human samples were obtained after obtaining informed consent according to the Helsinki Declaration with approval of local medical ethics committees (TIGET02). Some of the samples used as controls have been previously reported.¹⁸

Four male patients (age range, 1.1-5.9 years) affected by WAS were enrolled for the lentiviral vector-mediated GT and identified as Pt1, Pt2, Pt3, and Pt4. The clinical features of the first 3 patients have been previously described.¹⁴ Before the treatment, they showed severe clinical conditions, with a Zhu clinical score of 3 to 5 (see Table E1). At the time of treatment, Pt4 was 2.4 years old, with a clinical history of neonatal sepsis; chronic cytomegalovirus infection with frequent reactivations; lymphadenopathies; bleeding manifestations at the skin, gastrointestinal, and brain level; food polyallergy with anaphylaxis; and mild eczema. The patient was given a Zhu score of 5 because of severe refractory thrombocytopenia and the presence of circulating autoantibodies.¹⁹ All diagnoses were confirmed by genetic analysis and evaluation of WASp expression with flow cytometry (see Table E1). These patients, lacking an HLA-identical sibling donor and matched unrelated donor, underwent GT at a median age of 2.75 years and received a reduced-conditioning regimen protocol preceded by anti-CD20 mAb administration.¹⁴ CD34⁺ cells isolated from BM in all patients and also from mobilized PB in Pt1¹⁴ were transduced *ex vivo* with lentiviral w1.6W vector and reinfused into patients at a similar dose (see transduction efficiency and vector copy numbers [VCNs] in Table E1). Pt4, as well as other patients, did not experience mucositis or other chemotherapy-related toxicity. Autoimmune thrombocytopenia persisted in the early follow-up phase in Pt4, and this patient was treated with a high intravenous immunoglobulin (IVIg) dose, anti-CD20 mAb, steroids, and TPO agonists (romiplostim and eltrombopag). Autoantibody levels against platelets became negative 5.1 months after GT, and the patient reached platelet transfusion independence 9 months after GT, with absence of severe bleeding manifestations thereafter. A multilineage expression of WASp was observed in Pt4 after GT, persisting up to the latest time point analyzed (see Fig E1, A, in this article's Online Repository at www.jacionline.org).

Flow cytometric analysis of B-cell subsets and B-cell purification

The composition of the B-cell compartment was analyzed, as previously described.¹⁸ Briefly, the late stages of B-cell differentiation were analyzed by means of flow cytometric immunophenotyping with the following mAbs: CD34-phycoerythrin (8G12; BD, San Jose, Calif), CD19-PeCy7 (SJ25C1, BD), CD10-fluorescein isothiocyanate (MEM-78; Caltag, Burlingame, Calif), and CD20-phycoerythrin-Texas Red/energy coupled dye (B9E9; Immunotech, Glendale, Calif). B-cell subsets present in PB were characterized by using the following mAbs: CD19-PeCy7 (SJ25C1, BD), CD27-allophycocyanin (M-T271, BD) CD24-PB (SN3; Exbio, Praha, Czech Republic), CD21-allophycocyanin (B-ly4, BD), CD38-PerCP-Cy5.5 (HIT2, BD), and CD35-phycoerythrin (E11, BD). For intracytoplasmic detection of human WASp, cells were fixed and permeabilized with a Cytofix/Cytoperm kit (BD Pharmingen). The anti-WASp antibody 503 (a kind gift from Professors H. D. Ochs, Seattle, Wash, and L. D. Notarangelo, Boston, Mass) was used, followed by staining with secondary Alexa Fluor 488- or 647-conjugated goat anti-rabbit antibodies (Invitrogen, Carlsbad, Calif). Samples were acquired on a FACSCanto cytometer and analyzed with FlowJo Software (TreeStar, Ashland, Ore). CD19⁺ cells were purified from mononuclear cells derived from PB or BM by means of positive selection with immunomagnetic beads, according to the manufacturer's procedures (Miltenyi Biotec, Bergisch Gladbach, Germany).

Chemotaxis assay

The *in vitro* chemotaxis assay was performed with 5 μ m/L pore-size Transwell inserts (Costar Corporation, Corning, NY) in 24-well plates, as previously described.¹⁸ Briefly, CD20⁺ cells were purified from PBMCs of patients with

TABLE I. Absolute B-cell counts in the blood of patients with WAS before and after GT

	Pt1		Pt2		Pt3		Pt4	
	Before GT	+36 mo	Before GT	+30 mo	Before GT	+30 mo	Before GT	+24 mo
CD19 (10 ⁹ /L)	0.125* (0.2-1.6)	0.333 (0.2-1.6)	0.617* (0.6-3.1)	0.257 (0.2-2.1)	0.742* (0.6-2.7)	1.895 (0.2-2.1)	0.333 (0.2-2.1)	0.240 (0.2-2.1)

Absolute counts are shown before GT and at the last follow-up after GT for all patients. Reference values for the 5th and 95th percentiles of the respective age-matched HDs were reported by Comans-Bitter et al²⁶ and are indicated in parentheses. Values out of the normal range are shown in boldface.

*Values previously published.¹⁴

WAS and age-matched healthy donors (HDs) by using immunomagnetic beads (Miltenyi Biotec) and left overnight at 37°C in culture medium. Fifty thousand CD20⁺ cells were seeded in the upper chamber. In the bottom well we placed culture medium supplemented with 250 ng/mL recombinant human stromal cell-derived factor 1 α (SDF-1 α ; CXCL12; PeproTech, Rocky Hill, NJ) or medium alone and incubated at 37°C for 3 hours. Cells migrated into the lower chamber were counted for viable cells and stained with anti-CD19, anti-CD24, anti-CD38, and anti-CD27 antibodies (BD Biosciences) for phenotypic analysis by using fluorescence-activated cell sorting. Migration frequency was estimated as the percentage of migrated cells over the input cell number.

VCN

The number of lentiviral vector copies integrated per genome was evaluated by using quantitative PCR, as previously described.²⁰ Results of integrated vector copies were normalized for the number of evaluated genomes. All the reactions were performed according to the manufacturer's instructions and analyzed with an ABI PRISM 7900 sequence detection system (Applied Biosystems, Foster City, Calif).

ELISA

BAFF levels were measured in duplicate in plasma samples from patients with WAS and HDs by using a Quantikine Human BAFF/BLYS/TNFSF13B Immunoassay kit (R&D Systems, Minneapolis, Minn). The assay was performed according to the manufacturer's instructions, and OD values were evaluated at 450 nm.

Evaluation of immunoglobulin levels and presence of autoantibodies

Immunoglobulin levels and presence of autoantibodies were determined by Laboraf Diagnostics and Research (San Raffaele Hospital, Milan, Italy), according to internal standard procedures. Antibodies against platelets were detected by using a commercially available method, the solid phase red cell adherence test (SPRCA test, P-Capture Ready Screen; Immucor, Norcross, Ga), which was designed for laboratory detection of IgG anti-platelet antibodies.²¹⁻²³

Plasma samples isolated from all patients with WAS before and 2 years after GT were also screened for the presence of autoantibodies by using an autoantigen proteomic microarray comprising 123 different antigens. Autoantigen microarrays were manufactured, hybridized, and scanned by the Microarray Core Facility at the University of Texas Southwestern Medical Center (Dallas, Tex)²⁴ in a blind manner. A heat map was generated based on the normalized fluorescent intensity of autoantibodies and on a color scale range between +2 and -2 SDs. Values were mean centered, and antigens with a signal-to-noise ratio of less than 3 were considered undetectable and removed in both pre-GT and post-GT samples, thus reducing the number of antigens from 123 to 93. Differences related to each antigen between pre- and post-GT samples were evaluated by using the paired *t* test, and a global test *P* value was computed by using the global test R package to evaluate differences related to the whole antigen profile between pre- and post-GT samples.

Statistical analysis

All results are expressed as means \pm SDs, if not stated otherwise. Statistical significance was assessed by using 2-tailed Mann-Whitney tests for comparisons between patients and HDs or paired *t* tests for comparisons before and after treatment. *P* values of less than .05 were considered significant.

RESULTS

Treatment and follow-up

After treatment with lentiviral vector-mediated GT, all patients showed a stable and multilineage engraftment of transduced HSCs, with expression of WASp progressively increasing and persisting in the different hematopoietic cell lineages. No adverse events related to the treatment were observed after GT, and all patients were alive and clinically well at the time of this study (Aiuti et al¹⁴ and unpublished results). Frequency and severity of infections and bleeding were reduced after the first year of follow-up. All patients became independent from platelet transfusions, with platelet counts progressively increasing over time, although not reaching normal levels. Eczema improved in all 4 patients, and no clinical manifestations of autoimmunity were observed after the first year of follow-up. All patients discontinued anti-infectious prophylaxis, and 2 of 4 (Pt1 and Pt3) stopped IVIg supplementation as well. After IVIg suspension, the 2 patients received regular vaccinations, and both showed a protective response to T cell-dependent antigens. Pt1 produced specific IgM after 2 doses of unconjugated vaccine (Pneumovax; Merck & Co, Whitehouse Station, NJ). Because protective antibody levels were not reached, the patient received 2 doses of conjugated pneumococcal vaccine (Pevnar 13; Wyeth, Dallas, Tex) and was able to mount a protective response.

Reconstitution and gene correction of B lymphocytes

We have previously demonstrated the efficacy of lentiviral w1.6W vector in restoring B-cell defects in a WAS mouse model.²⁵ On the basis of this evidence, we evaluated the effect of GT on the B-cell compartment in patients with WAS. To this end, we followed the reconstitution, transduction levels, and expression of WASp in B lymphocytes of 4 patients with WAS treated with GT. Before treatment, only Pt1 presented with few CD19⁺ B cells in PB, whereas B-cell counts were in the normal range in the remaining patients (Aiuti et al¹⁴ and Table I).^{14,26} During the first months after GT treatment, we observed a low number of B cells (unpublished results), as expected because of the combined effect of conditioning regimen and anti-CD20 mAb administration, which progressively increased, reaching the range of normality (Table I). All treated patients expressed WASp in CD19⁺ cells (Figs 1 and 2),¹⁴ demonstrating that newly generated B cells arising from transduced progenitor cells stably expressed the transgene. In PB the frequency of CD19⁺ cells expressing WASp was significantly increased 6 months after GT and remained stable over time at the last follow-up (Fig 1, A).

When feasible, we analyzed WASp expression in BM-isolated B cells in parallel to PB analysis (Fig 1, B). Higher frequencies of WASp-positive B cells were detected in PB compared with BM in all patients (Fig 1). Transduction levels were evaluated as VCNs in B cells isolated from PB and BM (see Fig E1, B and C).

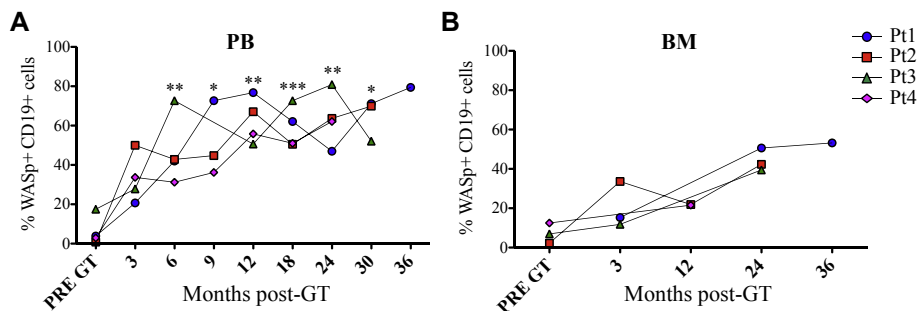

FIG 1. WASp expression in B cells after GT. WASp-expressing B cells in PB (A) and BM (B). Asterisks define the difference between pre-GT and post-GT samples. *** $P \leq .0005$, ** $P \leq .005$, and * $P < .05$.

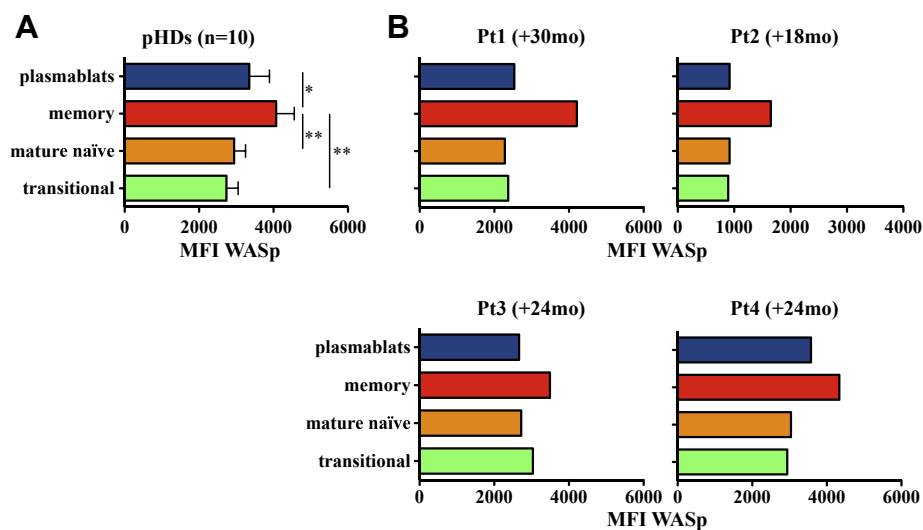

FIG 2. Expression of WASp among B-cell populations. A, WASp mean fluorescence intensity (MFI) in PB B-cell subsets of pediatric HDs (pHDs). Bars indicate means and SEMs. ** $P < .005$ and * $P < .05$. B, WASp MFI in B-cell subsets of treated patients is reported in individual graphs, with the time of the analysis indicated as months after GT between parentheses. All MFI values are normalized to the MFI of the negative control stained only with secondary antibody.

As previously shown,¹⁴ proportion of transduced B cells progressively increased in PB of all patients from the first months after GT. Furthermore, the higher WASp expression level in PB is in line with the higher VCN found in PB compared with BM, indicating a selective advantage of gene-corrected B cells in the periphery.

Kinetics of B-cell reconstitution in BM and PB after GT

We have previously demonstrated that WASp deficiency perturbs B-cell development, starting in the BM, where we described an altered distribution of B-cell precursor subsets.¹⁸ Thus we evaluated whether GT treatment could restore a normal distribution pattern in BM. As expected, patients showed a significantly high proportion of small pre-B-II cells ($CD34^-CD19^+CD10^{int}CD20^-$) and a low proportion of immature B cells ($CD34^-CD19^+CD10^{int}CD20^+$) before GT, which reverted to normal in all patients 1 year after treatment (Fig 3, A).

Next, we evaluated PB B-cell subpopulation distribution before and after treatment. Before GT, transitional B-cell frequencies

($CD19^+CD24^{high}CD38^{high}$) were higher in Pt2 and Pt3 when compared with HDs (Fig 3, B). Three months after treatment, transitional B cells represented the first subset detected at a high proportion in PB and then progressively decreased to proportions lower than pre-GT values (at 30 months after GT, $P = .049$), reaching normal values 24 months after GT ($P = .7566$; Fig 3, B). In parallel, the proportion of mature naive B cells ($CD19^+CD24^{dim}CD38^{dim}$) increased over time to reach values comparable with those observed in HDs ($P = .3489$; Fig 3, C). With regard to mature B-cell subsets, we observed that Pt1, Pt2, and Pt4 had normal percentages of memory B cells ($CD19^+CD27^+$) before and after GT (Fig 3, D). Pt3 displayed a severe reduction in memory B-cell frequency before GT (1.5% WAS before GT vs 4.7% to 19.2%, minimum and maximum values of HDs at <3 years, respectively), which increased up to values within the HD range 30 months after treatment (7.38% Pt3 vs 7.0% to 24.4%, minimum and maximum values of HDs at 3-12 years, respectively; Fig 3, D). Analysis of switched memory B cells in treated patients showed a trend similar to that of total memory B cells 2 years after GT (unpublished results). Plasmablasts ($CD19^+CD24^-CD38^{high}$) were in the normal range of values before and after GT, with

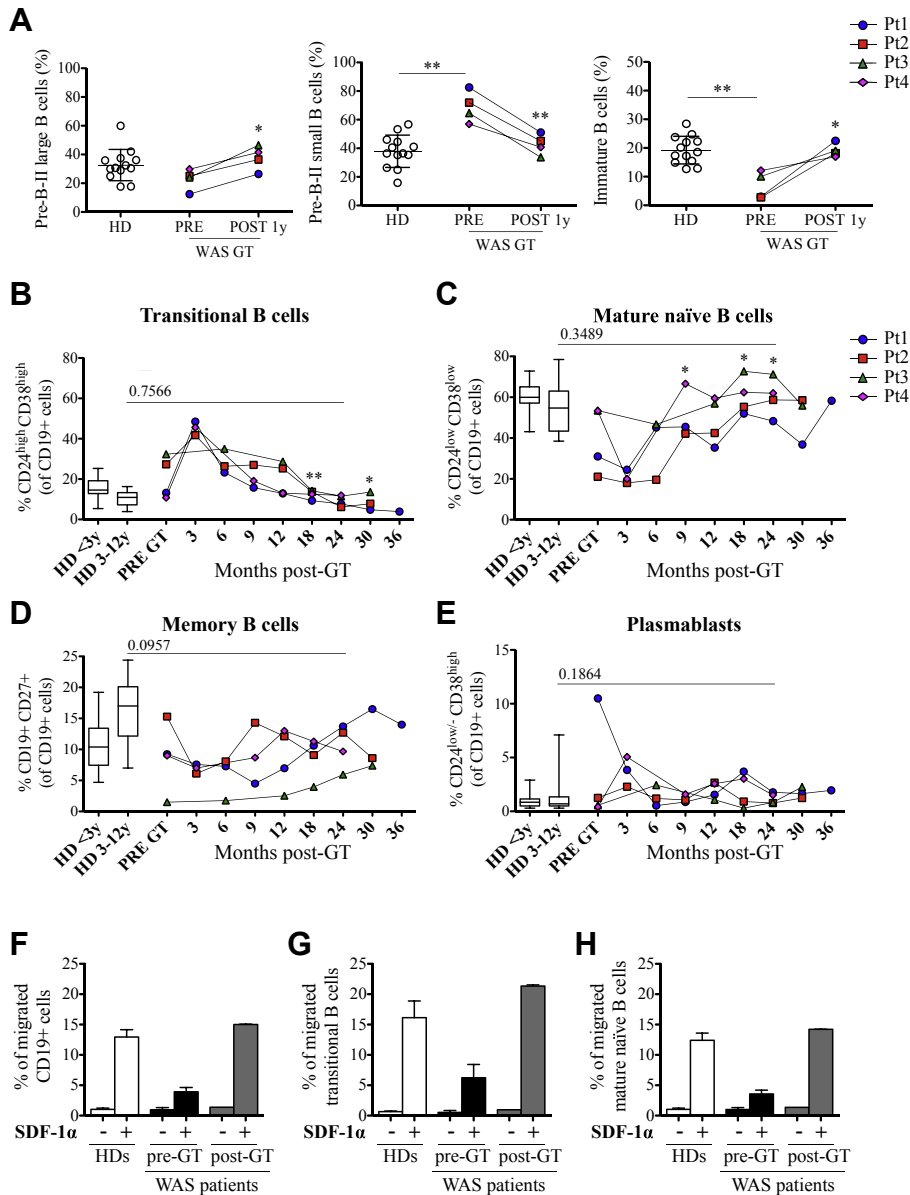

FIG 3. B-cell differentiation and *in vitro* migratory ability of B cells after GT. **A**, Proportion of pre-B-II large (CD10^{int}CD20^{int}), pre-B-II small (CD10^{int}CD20⁻), and immature B cells (CD10^{int}CD20⁺) determined on CD34⁻CD19⁺ cells and calculated on total BM precursor B cells, excluding recirculating mature B cells (CD10⁻CD20⁺). **B-E**, Proportion of B-cell subsets in PB (gated on CD19⁺; HD <3 years, n = 26; HD 3-12 years, n = 20). Box plots show medians, 25th and 75th percentiles, minimums, and maximums. Asterisks above horizontal lines indicate significant differences between patients with WAS and HDs. Asterisks without lines define differences between pre-GT and post-GT samples. **P ≤ .005 and *P < .05. **F-H**, *In vitro* migration of CD20⁺ cells isolated from age-matched HDs (white bars, n = 10) and patients with WAS before (black bars) and after (gray bars) GT (n = 2, Pt2 and Pt3) in the presence of SDF-1α (+) or medium alone (-). Percentages of migrated CD19⁺ cells (Fig 3, F), transitional cells (Fig 3, G), and mature naive B cells (Fig 3, H) were determined by using flow cytometric analysis.

the exception of Pt1, who presented with a higher plasmablast proportion before GT that normalized after therapy (Fig 3, E).

To evaluate whether the normalization of B-cell subset distribution in the BM and PB in treated patients was associated with a qualitative improvement in B-cell function, we tested their *in vitro* chemotactic response to SDF-1α, which we previously described as defective in patients with WAS.¹⁸ We confirmed that WASp-deficient B cells isolated from 2 patients (Pt2 and

Pt3) before GT were less responsive to SDF-1α and observed that they had a normal migratory ability after GT (Fig 3, F-H). Indeed, the percentages of *in vitro*-migrated transitional (Fig 3, G) and mature naive (Fig 3, H) B cells after GT were higher than those before GT and comparable with those of HDs.

Because the absence of WASp perturbs B-cell subset distribution in human subjects^{17,18,27} and mice,^{28,29} we compared differential WASp expression during B-cell maturation in HDs

and patients with WAS after GT. When we evaluated the mean fluorescence intensity levels of WASp in different B-cell subsets in the blood of pediatric HDs, we detected a differential pattern of WASp expression among peripheral B-cell subsets. WASp is expressed at significantly higher levels in memory B cells compared with levels in transitional and mature naive B cells (Fig 2, A), suggesting that WASp expression is modulated in the different B-cell populations. In patients undergoing GT, we noticed the same pattern of WASp expression in different B-cell subpopulations, in particular in memory B cells (Fig 2, B). These data strongly suggest that the lentiviral vector-transduced CD34⁺ cells were able to repopulate the B-cell compartment with a normal distribution of B-cell subsets both in BM and the periphery, presenting a WASp expression profile similar to that of HDs.

Correction of immunophenotypic perturbation of B cells from patients with WAS after GT

To further characterize the composition of the peripheral B-cell compartment, we analyzed the expression of 2 complement receptors, CD35 and CD21, involved in maintenance of self-tolerance^{30,31} and less expressed by B cells from patients with WAS.^{18,27}

When we analyzed the expression of CD21 and CD35 before GT, we found a lower proportion of double-positive cells in all patients compared with HDs, with the exception of Pt3 (Fig 4, A and B). Three months after GT, an increase in the percentage of CD19⁺CD21⁺CD35⁺ B cells was already noticeable and reached statistical significance 1 year after GT compared with values before treatment (mean frequency of all patients 1 year after GT is 85.8% compared with 46.6% before GT). Moreover, the frequency of CD19⁺CD21⁺CD35⁺ B cells remained stable until the last follow-up, with levels similar to those of HDs (Fig 4, B). Interestingly, Pt3 showed complete absence of the CD21/CD35 double-negative population 2 years after treatment.

The B-cell compartment of patients with WAS is also characterized by the presence of an unusual population phenotypically identified as CD19⁺CD21⁻CD38⁻ (referred to as CD21^{low})¹⁸ that were enriched in autoreactive and unresponsive B cells that could be involved in the breakdown of B-cell tolerance.³²⁻³⁴ Before treatment, patients with WAS presented with an increased frequency of CD21^{low} B cells, which diminished 3 months after GT, becoming nearly absent starting at 18 months after treatment (Fig 4, C and D). We also assessed plasma BAFF levels, which are known to play a role in B-cell homeostasis and peripheral tolerance.^{35,36} Higher BAFF levels were found in all patients before GT compared with those of age-matched HDs ($P = .0018$; Fig 4, E). GT treatment led to a decrease in BAFF plasma levels in all treated patients, although they still remained statistically different from HDs (.0018 vs .015, P value of pre-GT patients and HDs vs P value of patients with WAS 30 months after GT and HDs).

In vivo B-cell function after GT

To evaluate B-cell functionality, we monitored production of immunoglobulins and autoantibodies before and after GT. Pt1¹⁴ and Pt3 have been taken off IVIg administration 10 and 20 months after treatment, respectively. Pt3 had IgG serum levels within the normal range at the last determination point, whereas in Pt1 IgG

serum levels were less than the normal range (Table II). The evaluation of IgG levels in Pt2¹⁴ and Pt4 was not informative because of IVIg administration. Of note, Pt2 and Pt4 experienced autoimmune thrombocytopenia in the first months after GT and received high doses of IVIg and anti-CD20 mAb, which might have slowed down the reconstitution of the B-cell compartment and delayed IVIg discontinuation. Before GT, patients showed variable levels of immunoglobulin classes. Pt1 had low IgM serum levels, which improved after treatment but remained less than normal levels. IgE levels improved in Pt2 after treatment, although IgM and IgA levels were still out of the range of normality. Pt3 showed higher IgA and IgE serum levels before treatment, which decreased after therapy. Pt4 showed lower IgM and higher IgE levels compared with HDs but improved after GT (Table II).

Patients with WAS have a higher risk of autoimmune manifestations,² even after HSC transplantation, when complete chimerism is not achieved.⁸ Thus we examined the production of autoantibodies in the sera of patients with WAS undergoing GT before and after GT (Table III). No positivity for anti-liver kidney microsomal antibodies, anti-smooth muscle antibodies, anti-mitochondrial antibodies, anti-DNA, perinuclear antineutrophil cytoplasmic antibodies, anti-neutrophil cytoplasmic antibodies, and direct and indirect Coombs tests was found before and after GT. Before GT, Pt3 showed anti-platelet antibodies, which were still present 2 years after GT, whereas anti-nuclear antibody levels normalized after GT. In Pt4 anti-platelet antibodies were present before treatment and disappeared at the last follow-up.

Furthermore, to extend the analysis to a broader panel of autoantigens, we used a high-throughput autoantigen microarray platform that contains 123 different autoantigens. We observed a trend toward global decreased reactivity to autoantigens in the plasma of patients with WAS 2 years after therapy versus before GT (global test $P = .0693$). Several antigens were significantly downregulated ($P < .05$, Fig 5).

DISCUSSION

In the present study we demonstrate that lentiviral vector-transduced hematopoietic progenitor cells can differentiate into WASp-expressing B cells, leading to normalization of B-cell development both in BM and PB. We show the correction of phenotypic perturbations of B cells from patients with WAS and a decrease in plasma BAFF concentrations toward levels in age-matched HDs. In addition, B-cell reconstitution led to discontinuation of IVIg infusions in 2 patients (Pt1 and Pt3).

We observed that GT normalized the proportions of early B-cell subsets, indicating that B-cell development occurs normally in the BM after GT. An increased proportion of immature B cells was observed in the BM of treated patients in association with a decrease in transitional B-cell numbers in the periphery in contrast to what has been described in untreated patients with WAS.¹⁸ We have previously demonstrated that the overrepresentation of transitional B cells in the PB of patients with WAS is, at least in part, due to an early export of immature B cells from the BM because of the inability of B cells from patients with WAS to sense retention signals mediated by CXCR4 and its ligand, SDF-1 α .¹⁸ Thus the restoration of proper retention signals mediated by WASp could contribute to the normalization of immature B cells in the BM and transitional B cells in the periphery.

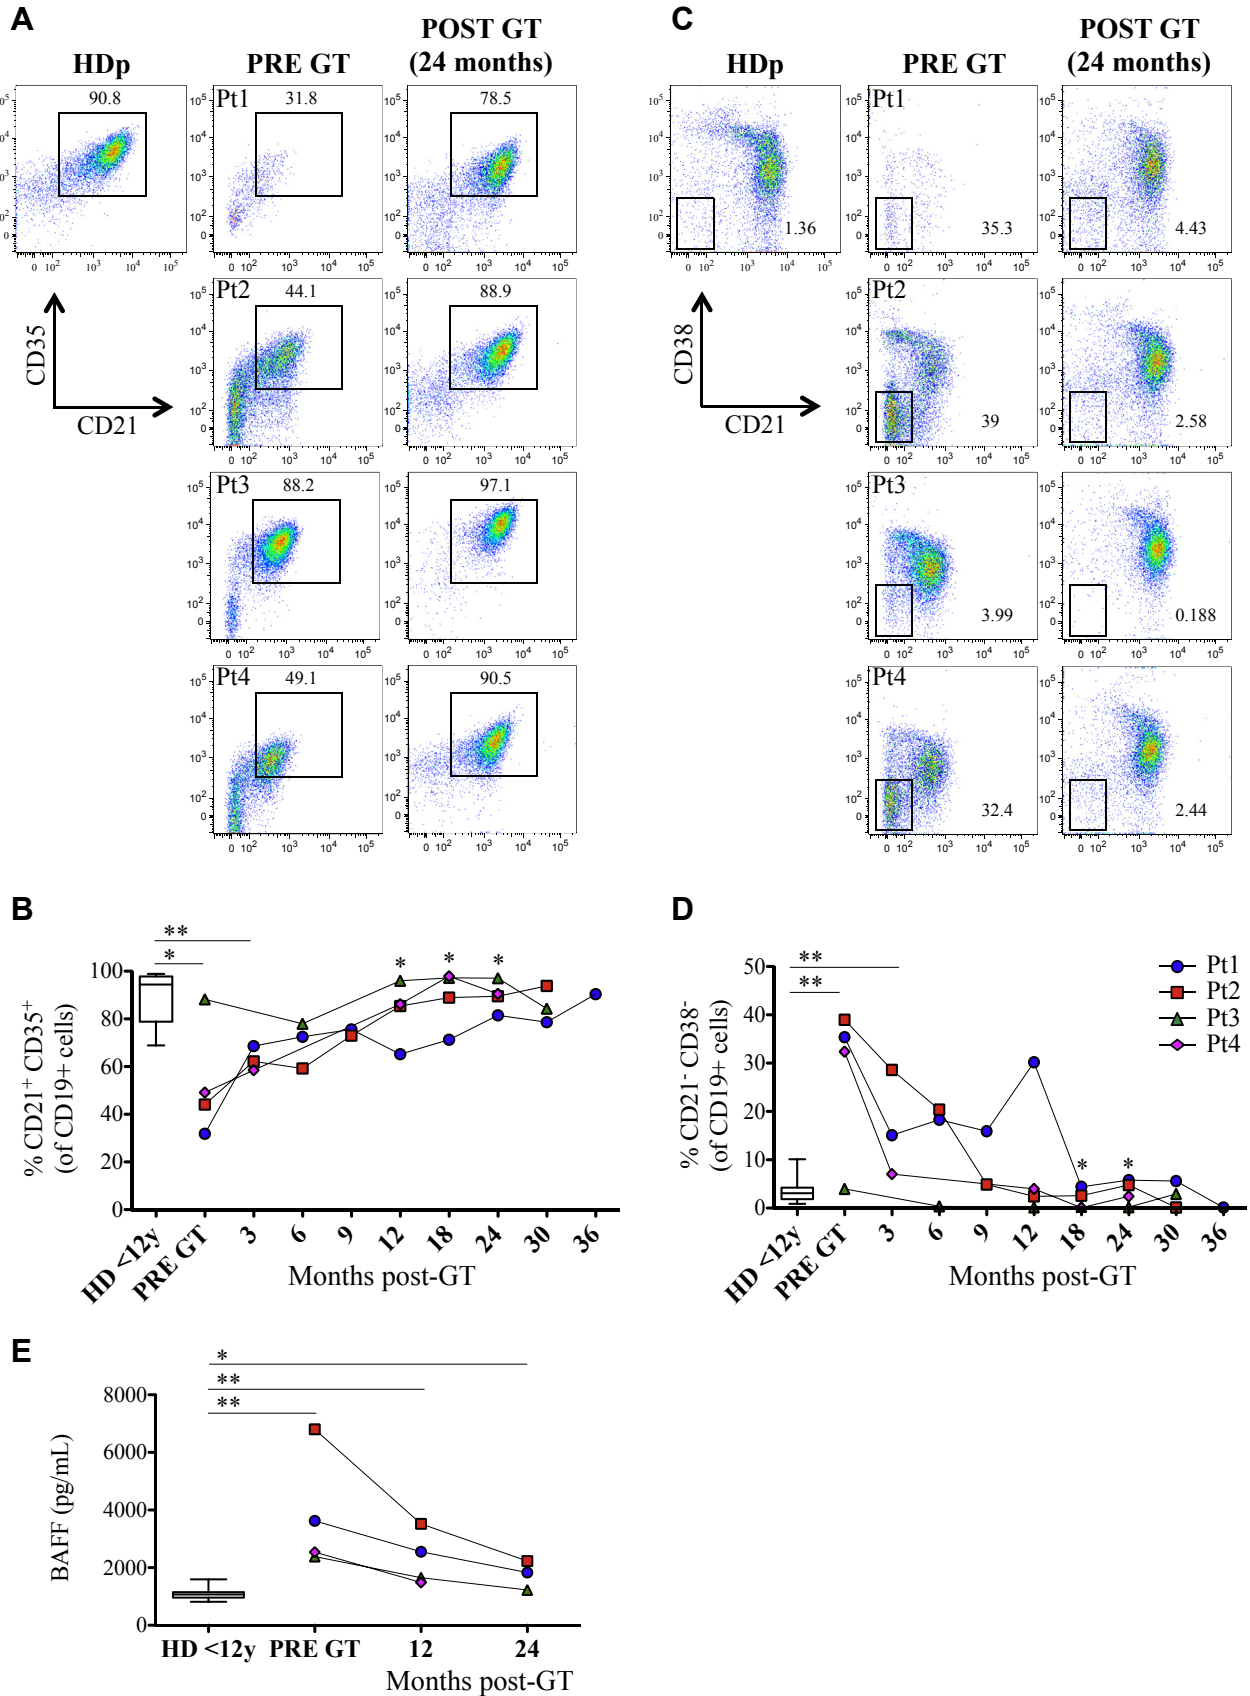

FIG 4. Normalization of phenotypic alterations of B cells from patients with WAS and BAFF levels after GT. **A** and **B**, CD21 and CD35 expression on CD19⁺ cells in patients with WAS before and after GT and in HDs (n = 16). **C** and **D**, CD21⁻ B cells in patients with WAS before and after GT and in HDs (n = 45). **E**, BAFF levels before and after GT and in HDs (n = 24). -, Negativity to antigens; +, positivity to antigens together with autoantibody titers; AMA, anti-mitochondrial antibodies; ANA, anti-nuclear antibodies; anti-plt, anti-platelet antibodies; ASMA, anti-smooth muscle antibodies; c-ANCA, cytoplasmic anti-neutrophil cytoplasmic antibodies; ENA, anti-extractable nuclear antibodies; LKM, anti-liver kidney microsomal antibodies; ND, not done; p-ANCA, perinuclear anti-neutrophil cytoplasmic antibodies.

*Patient receiving IVIg therapy.

Several studies in WAS murine models have shown that WASp is crucial for peripheral B-cell homeostasis but could be dispensable during early murine hematopoiesis.^{25,28,29,37} Our analysis of WASp expression in B cells from patients undergoing GT confirms the selective advantage of WASp-expressing cells in the periphery with respect to the BM compartment. In particular, at the peripheral level WASp is highly expressed in mature B cells, such as memory cells and plasmablasts. These data are in agreement with findings reporting a selective advantage of WASp-positive mature B cells in competitive transplant settings and heterozygous mice^{28,29} and further confirm the preclinical data of lentiviral vector-mediated GT in *Was*^{-/-} mice.²⁵ However, similar to the retroviral vector-mediated GT trial,¹¹ WASp-negative cells are still present in the B-cell compartment in our patients. This is in line with results obtained from preclinical studies conducted in sublethally irradiated *Was*^{-/-} mice treated with *Was*^{-/-} cells transduced with the w1.6W lentiviral vector (the same vector used in our trial). However, even in the presence of mixed chimerism of WASp-positive and WASp-negative B cells, GT led to an improvement in B-cell function in terms of response to T cell-independent antigens and autoantibody titers.²⁵ In our cohort of patients with WAS, 2 of 4 treated patients discontinued immunoglobulin treatment, and 1 is decreasing the frequency of infusions, suggesting that *in vivo* B-cell function is being restored.

Importantly, the reduced-intensity conditioning regimen (low doses of busulfan and fludarabine) and administration of

anti-CD20 mAb, which is chosen in patients undergoing GT to avoid conditioning-related toxicity, might affect the kinetics of B-cell reconstitution. Indeed, observations obtained from the outcome of HSC transplantation in a cohort of pediatric patients with WAS indicate a better disease-free survival in patients receiving a fully myeloablative conditioning regimen,³⁸ similar to observations previously reported for B-cell reconstitution in patients with severe combined immunodeficiencies.³⁹ To this end, data from ongoing GT clinical trials performed in different centers using the same clinical vector in patients with WAS but different conditioning regimens will be instrumental to understand the relevance of conditioning in the kinetics of immune reconstitution in autologous BM transplantation.

During B-cell development, the maintenance of the primary B-cell pool and the fate of self-reactive B cells are largely coordinated by B-cell receptor, BAFF, and its receptor.^{35,40} Before GT, increased BAFF plasma levels, which might decrease the threshold for the survival of autoreactive B-cell clones,³⁵ were found in patients with WAS similar to those reported in patients with other immunodeficiencies⁴¹ and autoimmune diseases.⁴²⁻⁴⁵ Thus we hypothesize that the reduced BAFF plasma levels found in GT-treated patients, reflecting the improvement in B-cell lymphopenia and B-cell subset distribution,⁴¹ could ultimately result in a less favorable environment for survival of autoreactive B cells. Consistently, we observed a significant decrease in CD21^{low} B-cell frequencies, which were described to be enriched

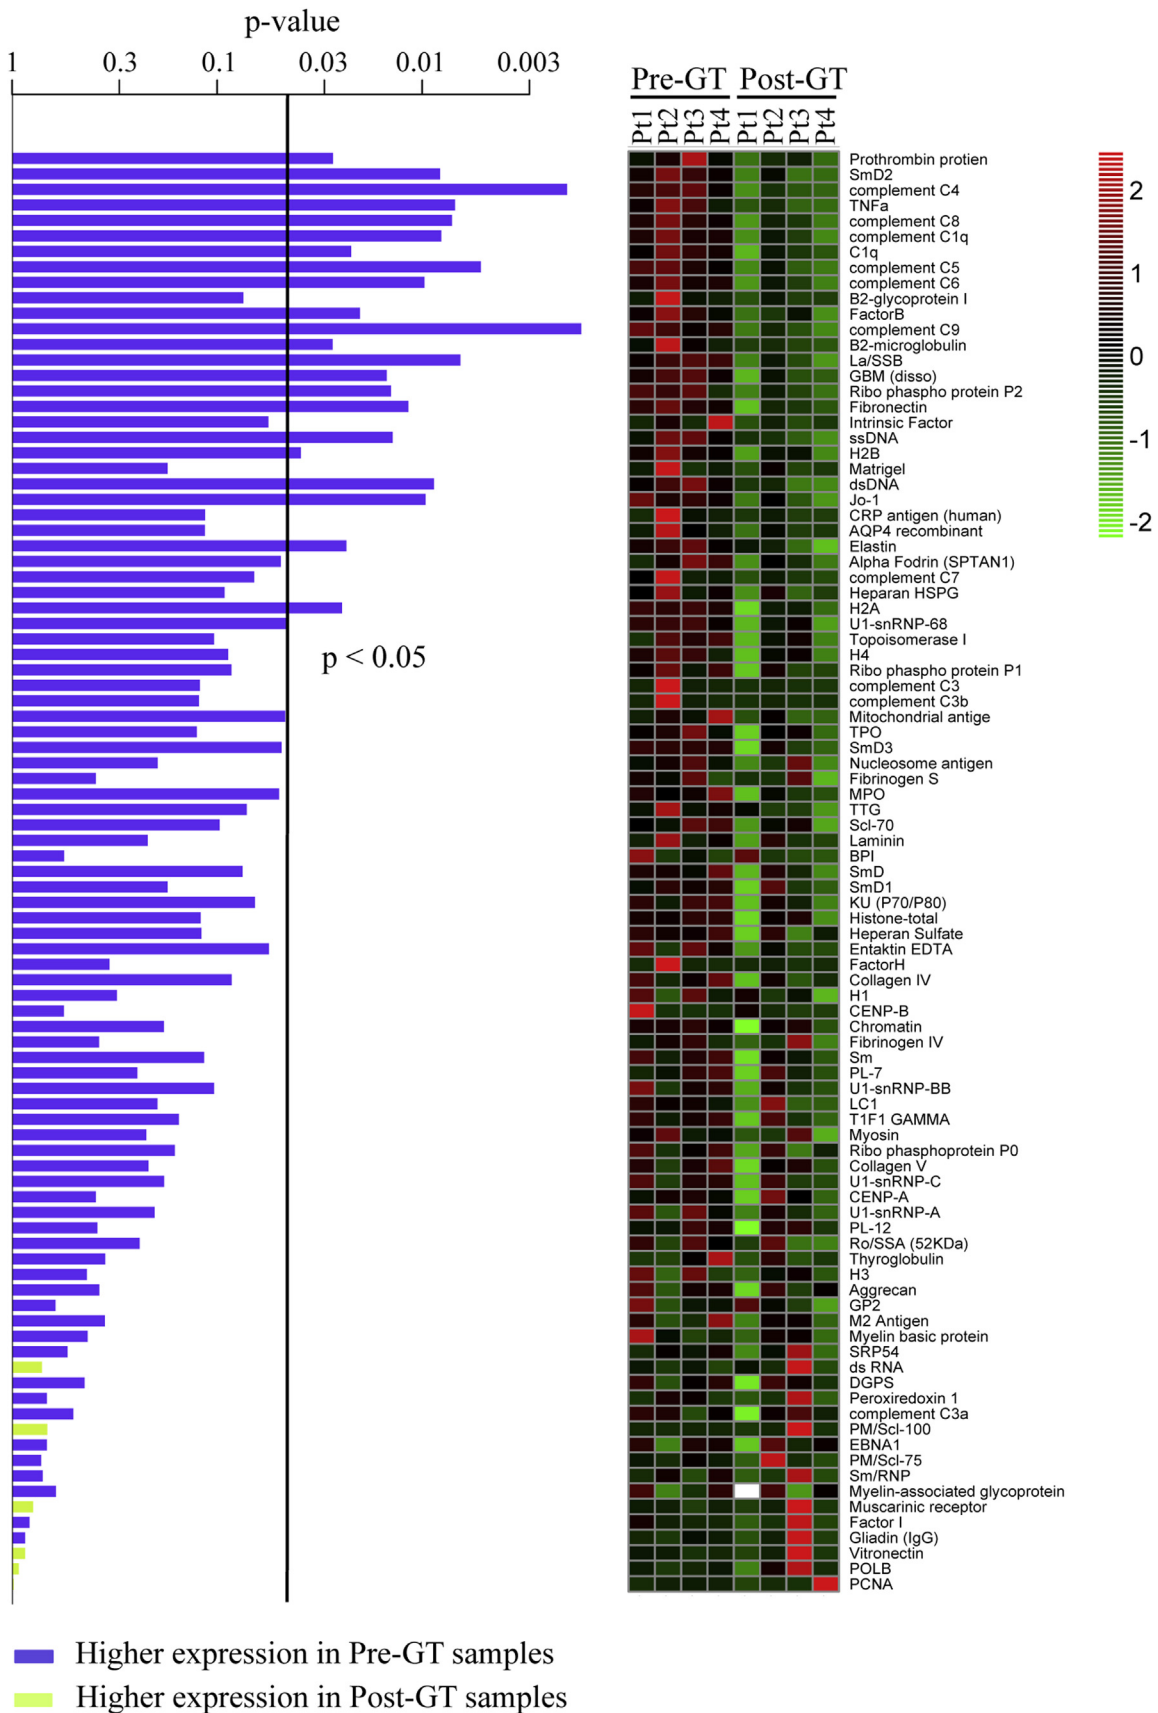

FIG 5. Decreased autoantibody production in patients with WAS after GT. IgG reactivities against 123 antigens were tested by using an autoantigen array. P values resulting from paired t tests of differential expression between pre-GT and matched post-GT samples are shown in the left panel. Blue and green bars refer to autoantibodies with higher expression in pre-GT and post-GT samples, respectively. The vertical line indicates a P value of less than .05. Data are represented as a heat map (right panel), with values mean centered and colors scaled from -2 to +2 SD. The legend shows z scores.

in anergic autoreactive clones³² and expanded in patients with autoimmune diseases.^{32,34,46} CD21^{low} B cells, which were probably removed by anti-CD20 administration, might not find favorable conditions to expand after GT treatment. However, patients have not yet normalized BAFF levels 2 years after GT, suggesting that full recovery of the B-cell compartment might require more time. Of note, the slow kinetics of BAFF level reduction were also observed in adenosine deaminase-deficient patients after GT⁴⁷ and might be associated with the use of a reduced-intensity conditioning.⁴⁸ Finally, upon GT treatment, we observed a correction of the expression of the complement receptors CD21 and CD35, which are involved in the capture and presentation of opsonized antigens⁴⁹ and in negative selection of self-reactive B lymphocytes³⁰ and represent a common trait in patients with WAS.^{18,27}

In conclusion, although longer follow-up is required to evaluate full B-cell restoration, our data indicate that the lentiviral vector-mediated GT treatment for WAS is efficacious in inducing WASp expression in B cells, leading to a correction of phenotypic perturbation and resulting in a robust and stable B-cell reconstitution.

We thank all the medical staff of the HSR-TIGET Pediatric Clinical Research Unit, Pediatric Immunohematology, and Bone Marrow Transplant Unit. We thank the patients and their families for their commitment and cooperation. We thank H. D. Ochs and L. D. Notarangelo for the anti-WASp antibody. We thank Alessandro Nonis and Clelia di Serio (University Center for Statistics in the Biomedical Sciences, Università Vita-Salute San Raffaele, Milan, Italy) for help with statistical analyses.

Clinical implications: Lentiviral vector-mediated GT treatment for WAS restores WASp expression in B cells and corrects phenotypic perturbations.
